where R is the radius of the jet, z is the distance along the jet axis and h_∞ is the specific enthalpy of the gaseous phase evaluated at atmospheric temperature T_∞. Equation 15.21.44 is valid at the end of the entrainment zone; it should not be used to determine conditions part way through the zone.

The authors discuss the thermal effects within the entrainment zone, particularly the formation of vapour from evaporating liquid droplets and the condensation of vapour onto droplets, and refer to the work of Weimer, Faeth and Olson (1973) on the latter. They conclude that it is reasonable to proceed on the assumption that the liquid and vapour phases are at the normal boiling point. Then, for a release that is all liquid and is from a vessel at ambient temperature, the specific enthalpies may be taken as

$$h = h_g(T_{bp}) \qquad [15.21.45]$$

$$h_o = h_f(T_\infty) \qquad [15.21.46]$$

$$h_\infty = h_g(T_\infty) \qquad [15.21.47]$$

where the subscript bp denotes boiling point.

Then, rearranging Equation 15.21.44 gives the following equations for the end of the entrainment zone

$$\frac{u_{tp}}{u_a} = \left[1 + 2E_o\left(\frac{\rho_\infty}{\rho_a}\right)^{1/2}\frac{z_{tp}}{R_a}\right]^{-1} \qquad [15.21.48]$$

$$\frac{R_{tp}}{R_a} = \left(\frac{\rho_a}{\rho_\infty}\right)^{1/2}\left[1 + 2E_o\left(\frac{\rho_\infty}{\rho_a}\right)^{1/2}\frac{z_{tp}}{R_a}\right] \qquad [15.21.49]$$

$$\frac{z_{tp}}{R_a} = \frac{1}{2E_o}\left(\frac{\rho_a}{\rho_\infty}\right)^{1/2}\left[\frac{h_o - h_\infty}{h_g(T_{bp}) - h_\infty} - 1\right] \qquad [15.21.50]$$

where the subscript tp denotes two-phase.

Utilizing Equations 15.21.45–15.21.47, the last factor in Equation 15.21.50 is modified to give

$$\frac{z_{tp}}{R_a} = \frac{1}{2E_o}\left(\frac{\rho_a}{\rho_\infty}\right)^{1/2}\frac{(1 - x_a)h_{fg}}{c_{pg}(T_\infty - T_{bp})} \qquad [15.21.51]$$

where c_{pg} is the specific heat of the gaseous phase.

As an illustration, consider the example given by the authors of an ammonia jet in one of the Desert Tortoise ammonia release trials, described by Goldwire (1986) and considered in more detail in Section 15.3. This example is summarized in Table 15.41.

15.22 Dense Gas Dispersion

The account given so far of gas dispersion has been confined to the dispersion of gases of neutral buoyancy, or passive dispersion. A large proportion of industrially important gases exhibit negative buoyancy. It is these gases particularly which are prominent in hazard assessment.

An account of the dispersion of dense, or heavy, gases is given in this and following sections. Section 15.23 deals with source terms; Section 15.24 with models and modelling; Section 15.25 with modified conventional models; Sections 15.26–15.28 with some principal box models; Sections 15.29–15.33 with some if-theory and other three-dimensional models; Section 15.34 with the *Workbook*; Section 15.35 with the DRIFT three-dimensional model; Section 15.36 with some other models; Sections 15.37 and 15.38 with field trials; Section 15.39 with physical modelling; Section 15.40 with terrain, obstructions and buildings; Section 15.41 with validation and comparison; Section 15.42 with particular gases; and Sections 15.43 and 15.44 with elevated plumes and an elevated plume model. Further aspects of dense gas dispersion are treated in Section 15.45 on concentration and concentration fluctuations; Sections 15.46 and 15.47 on flammable and toxic gas clouds; Section 15.48 on dispersion over short ranges; Section 15.49 on hazard ranges for dispersion; and Sections 15.53 and 15.54 on vapour cloud mitigation. Selected references on dense gas dispersion are given in Table 15.42.

15.22.1 Dense gas

Many of the more hazardous gases such as hydrocarbons, chlorine, ammonia and hydrogen fluoride, and oxygen, are capable of giving a gas cloud that is denser than air.

Table 15.41 *Illustrative calculation for a two-phase flashing jet of liquefied ammonia from pressure storage (after Fauske and Epstein, 1988) (Courtesy of Butterworth-Heinemann)*

A Scenario

Atmospheric pressure $P_\infty = 1.01 \times 10^5$ Pa
Density of ambient air $\rho_\infty = 1.1$ kg/m^3
Orifice diameter $d_b = 0.0945$ m
Storage temperature $T_o = 297$ K (24°C)
Storage pressure $P_o = 1.4 \times 10^6$ Pa
Discharge velocity $u_f = 22.7$ m/s
Pressure of jet at discharge conditions $P_b = 0.968 \times 10^6$ Pa
Density of jet at discharge conditions $\rho_b = 603$ kg/m^3
Density of gaseous ammonia at discharge conditions (boilingpoint, atmospheric pressure) $\rho_g = 0.89$ kg/m^3
Specific heat of liquid ammonia $c_{pf} = 4.46 \times 10^3$ J/kg K
Specific heat of gaseous ammonia $c_{pg} = 10^3$ J/kg K
Latent heat of vaporization of ammonia $h_{fg} = 1.37 \times 10^6$ J/kg
Normal boiling point of ammonia $T_{bp} = 240$ K (−33°C)
Entrainment coefficient $E_o = 0.116$

B Jet[a]

Quality at end of depressurization zone:

$$x_a = c_{pf}(T_o - T_{bp})/h_{fg} = 4.46 \times 10^6(297 - 240)/1.37 \times 10^6 = 0.19$$

Density of jet at end of depressurization zone:

$$\rho_a \approx \rho_g/x_a = 0.89/0.19 = 4.68 \text{ kg/m}^3$$

Velocity of the jet at end of depressurization zone:

$$u_a = u_b + (P_b - P_a)/u_b\rho_b = 22.7 + (0.968 \times 10^6 - 0.101 \times 10^6)/(22.7 \times 603) = 86 \text{ m/s}$$

Radius of jet at end of depressurization zone:

$$R_a = R_b\left(\frac{u_b\rho_b}{u_a\rho_a}\right)^{1/2} = \frac{0.0945}{2}\left(\frac{22.7 \times 603}{86 \times 4.68}\right)^{1/2} = 0.275 \text{ m}$$

Distance to end of two-phase jet zone:

$$z_{tp} = R_a \frac{1}{2E_o}\left(\frac{\rho_a}{\rho}\right)^{1/2} \frac{h_{fg}(1 - x_a)}{c_{pg}(T_\infty - T_{bp})} = 0.275 \frac{1}{2 \times 0.116}\left(\frac{4.68}{1.1}\right)^{1/2} \frac{1.37 \times 10^6(1 - 0.19)}{10^3(306 - 240)} = 39.1 \text{ m}$$

Velocity at end of two-phase jet zone:

$$u_{tp} = u_a\left[1 + 2E_o\left(\frac{\rho_\infty}{\rho_a}\right)^{1/2}\frac{z_{tp}}{R_a}\right]^{-1} = 86\left[1 + 2 \times 0.116\left(\frac{1.1}{4.68}\right)^{1/2}\frac{39.1}{0.275}\right]^{-1} = 5.06 \text{ m/s}$$

Radius at end of two-phase jet zone:

$$R_{tp} = R_a\left(\frac{\rho_a}{\rho_\infty}\right)^{1/2}\left[1 + 2E_o\left(\frac{\rho_\infty}{\rho_a}\right)^{1/2}\frac{z_{tp}}{R_a}\right] = 0.275\left(\frac{4.68}{1.1}\right)^{1/2}\left[1 + 2 \times 0.116\left(\frac{1.1}{4.68}\right)^{1/2}\frac{39.1}{0.275}\right] = 9.6 \text{ m}$$

---

[a] The numerical values in this example have been revised after consultation with one of the authors (HKF).

Whether or not a particular gas release forms a gas cloud that is denser than air depends on a number of factors. These are:

(1) the molecular weight of the gas;
(2) the temperature of the gas;
(3) the presence of liquid spray;
(4) the temperature and humidity of the air.

A gas cloud may be dense by virtue of the molecular weight of the gas released. However, even if the molecular weight of the gas is less than that of air, the gas cloud may be rendered dense by other factors. If the boiling point of the gas is low so that the gas cloud is cold, this may be sufficient to make the cloud dense.

The presence of liquid spray is another factor that can render the cloud dense. The effect of vaporization of the droplets of liquid is to remove heat from the gas and so cool it.

The density of the cloud is also affected by the humidity of the ambient air. The effect of the condensation of the droplets of water is to add heat to the gas. In general, the cloud will tend to have a higher density when mixed with dry air than with wet air.

The effect of molecular weight and temperature may be illustrated by considering the densities of gas clouds from releases of chlorine, methane and ammonia into dry air. The molecular weight of chlorine (71) is much greater than that of air (28.9) and thus gives a cloud heavier than air at ambient temperature. The cloud given by chlorine at its boiling point (−34°C) is even heavier.

Methane (mol. wt. 16) is much lighter than air at ambient temperature. But the cloud given by methane at its boiling point (−161°C) is heavier than air. Ammonia (mol. wt. 17) is much lighter than air at ambient temperature. The cloud given by ammonia at its boiling point (−33°C) is also lighter than air. But ammonia clouds tend to be denser than air due to presence of liquid spray.

There is now ample evidence, both from experiments and incidents, that releases of liquefied gas such as propane, LNG, ammonia, chlorine and hydrogen fluoride give rise to dense gas clouds.

As the gas cloud is diluted, the concentration, and the relative density, decrease and the mode of dispersion changes from dense gas dispersion to passive dispersion of a neutrally buoyant gas.

15.22.2 van Ulden's experiment

Experimental work on the dispersion of a heavy gas has been described by van Ulden (1974). Some results from this work are shown in Figure 15.76. Figures 15.76(a) and (b) show, respectively, the growth of the height and radius of the dense gas cloud from an instantaneous release at ground level. The first part of the curve in the former figure shows the initial sharp decrease in cloud height due to gravity slumping, followed by a gradual increase in height. The height is much less and the radius much greater than that predicted by the Gaussian model, which overestimates the height and underestimates the radius by factors of 5 and 2.5, respectively.

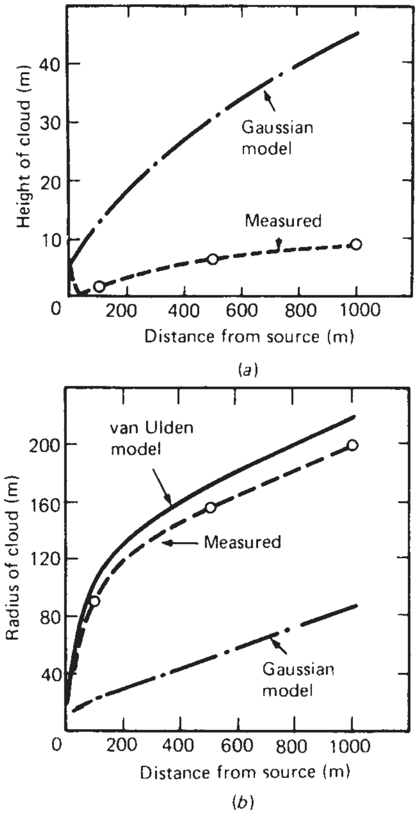

Figure 15.76 Dutch Freon 12 trial on dense gas dispersion (van Ulden, 1974): (a) growth of height; (b) growth of radius (Courtesy of Elsevier Publishing Company)

Van Ulden formulated a model for dense gas dispersion which was influential in the development of the topic. This is described in Section 15.26.

15.22.3 Experimental work

Experimental work bearing on dense gas dispersion includes not only field trials but also physical modelling in wind tunnels and water flumes, the latter being often on the laboratory scale. The work on field trials is described in Sections 15.37 and 15.38 and the physical modelling in Section 15.3(2). The laboratory experiments are referred to in discussion of the particular aspects to which they relate.

15.22.4 Dense gas behaviour

The behaviour of a dense gas may be described by considering the development of the gas cloud from the bursting of a vessel. The source term for this is usually modelled by assuming that air is entrained in a ratio of some 10–20:1 and that a cloud of unit aspect ratio is formed.

The behaviour of the cloud is influenced by gravity. Three stages may be distinguished:

(1) gravity slumping;
(2) gravity spreading;
(3) passive dispersion.

The flow is gravity driven in both the first two stages. The first stage is normally described as gravity slumping. The second stage is gravity-driven flow with stable stratification. The term 'gravity spreading' is applied sometimes to both the first two stages and sometimes only to the second stage; it is used here in the latter sense. The third stage is one of passive dispersion.

Gravity-driven flow is illustrated in Figure 15.77, which shows shadowgraphs taken in a water tunnel, these illustrate the intrusion of a more dense fluid into a less dense one on surfaces of different slopes. Features are the 'head' at the leading edge of the denser fluid and the mixing at the horizontal interface between the two fluids.

The density difference between the cloud and the atmosphere, or density excess, has four main effects. First, it imparts a strong horizontal velocity to the cloud. Second, it creates velocity shear. Third, it inhibits vertical mixing by atmospheric turbulence through the top of the cloud. Fourth, it affects the inertia of the cloud.

The inhibition of vertical mixing by atmospheric turbulence through the top of the cloud means that the mixing is less sensitive to the stability conditions. Vertical mixing still occurs, however, due to other forms of turbulence in the cloud. Moreover, the inhibition of mixing by atmospheric turbulence is counteracted by the creation of a large top surface area on the cloud due to gravity spreading.

If the ratio of the density difference to the density of the atmosphere, or reduced density, is small, an important approximation may be made. This is to neglect the effect of the density difference on the inertia. This is the Boussinescq approximation and it is widely used in dense gas dispersion modelling.

15.22.5 LNG spill study

Another piece of work which was influential in the development of the topic was the study for the US Coast Guard by Havens (1978) of the hazard range from a spill of 25,000 m^3 of LNG onto water. The work was a comparative study of the predictions of the distance to the lower flammability limit given by seven gas dispersion models. These predictions ranged from 0.75 up to 50 km. Reference to this study was made in Chapter 9 as an illustration of uncertainty in modelling. It is considered again in Section 15.41 in the context of validation of models.

15.23 Dispersion of Dense Gas: Source Terms

The source term can be critical for the modelling of the subsequent dispersion of a dense gas. It is therefore important that the source model should be realistic and complete. If the model for the source term is poor, the results of the whole dense gas dispersion estimate may be seriously in error.

15.23.1 Release scenarios

The modelling of release scenarios is assisted by an appropriate classification. Such classifications have been given by a number of workers, including Fryer and Kaiser (1979 SRD R152), Griffiths and Kaiser (1979 SRD R154) and Kaiser (1989).

The main concern is the modelling of the source term for a release of liquefied gas. The classification given for liquefied gases is

(1) Pressurized release
  (a) small hole in vapour space,
  (b) large hole in vapour space – catastrophic failure,
  (c) intermediate-sized hole in vapour space,
  (d) hole in liquid space;
(2) Refrigerated release
  (a) spill onto land,
  (b) spill onto water;
(3) Jet release.

These cases are considered in turn for a dense gas.

15.23.2 Release from pressurized containment

For a pressurized liquefied gas, a release from a small hole in the vapour space (Case 1(a)) gives rise to a vapour jet which loses momentum and turns into a dense gas plume. This is considered further in Section 15.43.

A catastrophic failure of the vessel (Case 1(b)) results in the flash-off of a vapour fraction with the liquid falling to its normal boiling point. The vapour fraction is obtained by heat balance. A proportion of the residual liquid is also ejected as liquid droplets, or spray. The evidence is that in fact substantially all the residual liquid becomes airborne. Such a release generates considerable turbulence and results in the entrainment of large amounts of air. The liquid droplets in the cloud undergo partial evaporation with a further drop in their temperature. Thereafter the heat required for their further evaporation is taken from the gas cloud, which results in cooling of the cloud.

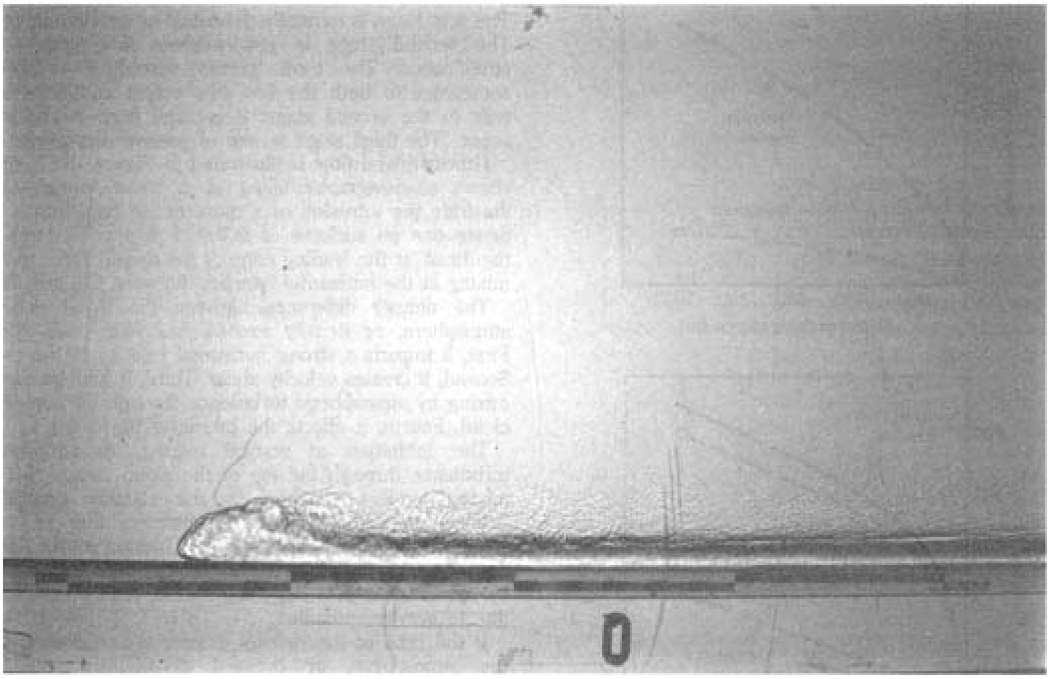
A release from a hole of intermediate size (Case 1(c)) may be presumed to give as spray a liquid fraction intermediate between the above two cases. Work bearing on this is described in Section 15.10. Some simple experiments by A.R. Edwards (1978) suggest that the liquid fraction which becomes airborne is a function of the ratio of the hole size to the vessel area. When this ratio reached about 0.01 the liquid fraction ejected became appreciable, whilst above a ratio of about 0.1 virtually all the liquid become airborne as spray. More detailed work is described in Section 15.10.

A hole in the liquid space (Case 1(d)) gives a two-phase flashing jet, as considered below.

15.23.3 Release from refrigerated containment

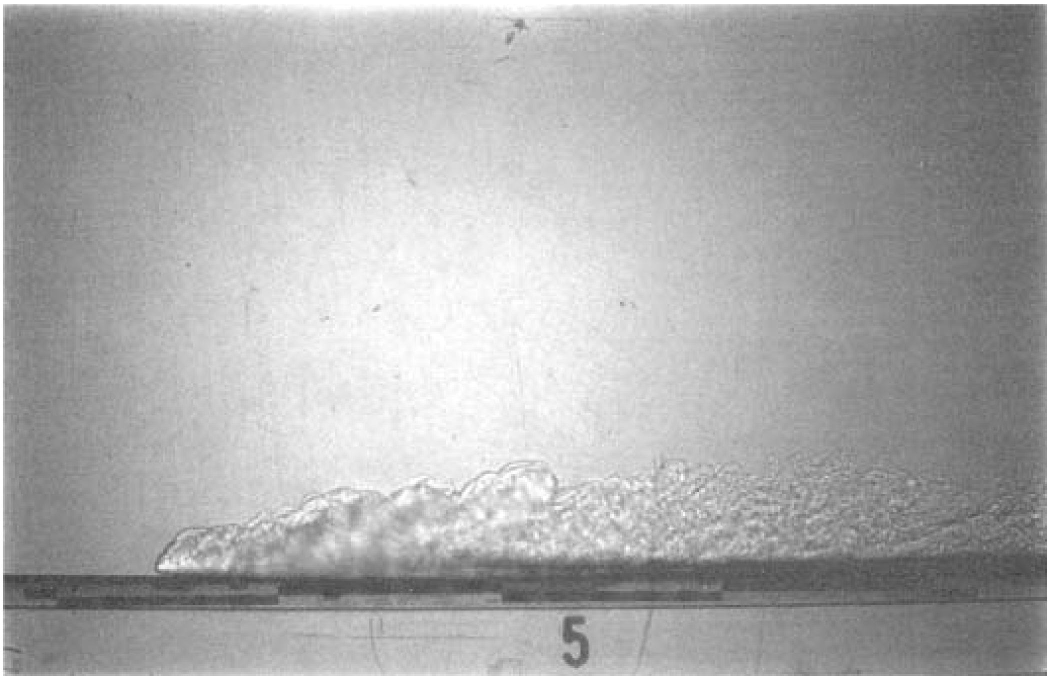
For a fully refrigerated liquefied gas, a spill onto land (Case 2(a)) results in a spreading, vaporizing pool. If the spill is into a bund, the size of the pool is constrained by the bund. Otherwise, the pool spreads until the liquid depth is so small that spreading ceases and break-up occurs. If the release is violent, there is a possibility that the wave created will spill over the edge of the bund.

The vaporization from the pool is a function of the area of the pool and of the rate of vaporization per unit area. The vaporization process is governed by the heat transfer from the surface to the liquid, which is initially high but rapidly falls off as the surface chills.

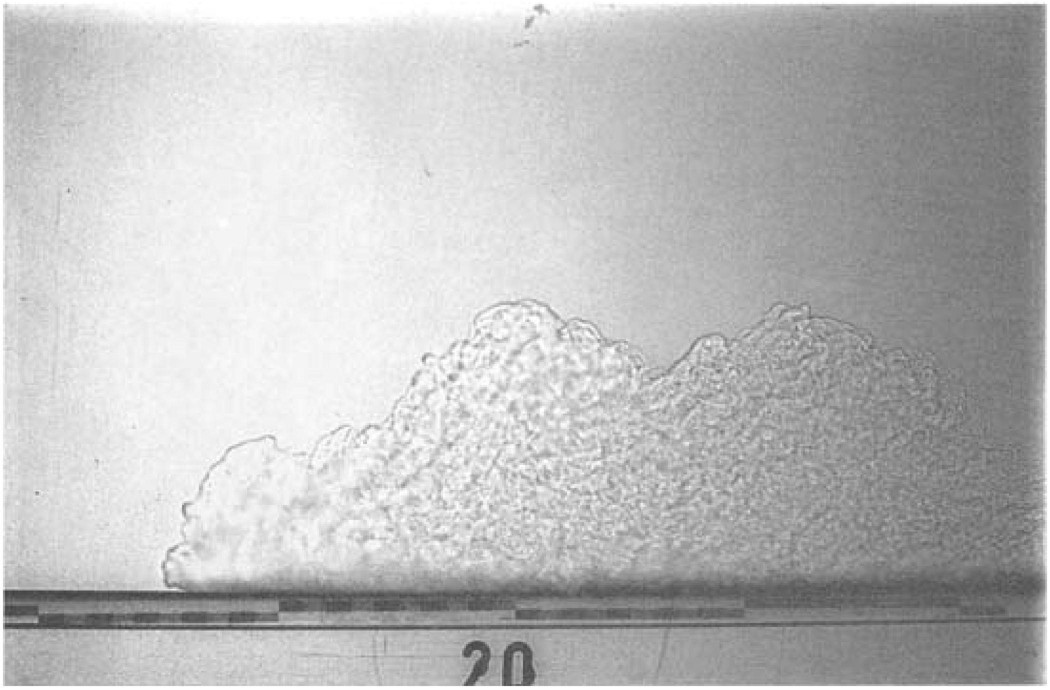


(a)

Figure 15.77 *Continued*



(b)



(c)

Figure 15.77 *Water tunnel modelling of the intrusion of a more dense fluid into a less dense one on flat and on sloping surface (Britter and Linden, 1980: (a) slope 0°; (b) slope 5°; (c) slope 20°. The entrainment increases with slope both into the head and into the flow behind it (Courtesy of Cambridge University Press)*

For a pool of fixed size filled rapidly, the pattern is one of very high vapour flow for a short initial period, lasting perhaps a minute, followed by rapid and then more gradual decline. For a spreading pool the vapour flow tends to pass through a maximum.

A spill onto water (Case 2(b)) again results in a pool spreading until the liquid depth becomes small and break-up occurs. The vaporization from the pool is a function of the area of pool and of the specific rate of vaporization. In this case, however, renewal of the water surface occurs and the heat transfer rate is constant and high. The vapour flow starts high and increases as the pool spreads, then falls off quite sharply as the pool evaporates.

Another possible scenario is an elevated jet release. In this case the liquid may well vaporize completely before it reaches the surface. Since the heat of vaporization is obtained from the entrained air rather than the surface, the resultant gas cloud is much colder.

15.23.4 Release from semi-refrigerated containment

For a semi-refrigerated liquefied gas, the scenarios are basically similar to those for the fully pressurized case.

The liquid is, however, at a lower pressure and a lower temperature. This may be expected to affect the proportion of the residual liquid which becomes airborne and the extent of rainout. The evidence is limited, but suggests that a semi-refrigerated release behaves broadly like a full refrigerated one. The main difference is that some, limited, degree of rainout may occur.

15.23.5 Two-phase jets

For a pressurized liquefied gas, a hole in the liquid space of a vessel or in a pipe gives a two-phase flashing jet. Accounts of such jets include those by Mudan (1984a), Wheatley (1987 SRD R410), Fauske and Epstein (1988), Webber and Kukkonen (1990) and Webber (1991).

The development of such a jet proceeds through three zones. The first is the depressurization, or flashing, zone in which the vapour and liquid droplets form. This extends several hole diameters and increases rapidly in diameter. The second zone is that of the two-phase momentum jet at atmospheric pressure into which air is entrained. The third zone starts where the jet loses momentum and other dispersion mechanisms take over.

The jet disintegrates into a spray of liquid droplets. These tend to remain airborne until they evaporate rather than to rain out.

Two-phase jets are considered in more detail in Section 15.21.

15.23.6 Initial density

The density of the gas cloud formed from the release depends on a number of factors. These include the density of the contaminant gas, the normal boiling point, the fraction of liquid present as droplets and the humidity of the ambient air. Typically, the density and temperature of the gas cloud is given as a function of the concentration of contaminant gas with the liquid fraction and humidity as parameters. The factors affecting the density of the gas cloud are discussed in general in Section 15.22 and, for particular gases, in Section 15.42.

15.23.7 Air entrainment

The mass of air entrained into the gas cloud is a crucial feature of the source model. There are available some estimates of the extent of entrainment for some of the scenarios just described.

For vaporization from a pool on land, the vapour is generally taken as pure vapour and the entrainment of air is modelled within the dense gas dispersion model.

For vaporization from a pool on water, the same approach appears often to be used. However, the turbulence generated by the boiling will cause some entrainment of air. Kaiser (1980) has estimated this as an entrainment within 5s of enough air to dilute the contaminant gas by a factor of 10.

For catastrophic failure of a pressurized containment vessel, estimates have been made by Fryer and Kaiser (1979 SRD R152) of the aspect ratio and of the mass of air entrained for ammonia. The gas cloud is assumed to form a cylinder. From field trials and incidents they suggest that the radius and height of this cloud be taken as equal and the mass ratio of air to contaminant gas as some 2 : 1 This applies to the failure of a vessel at a quite high pressure, with a correspondingly high degree of induced turbulence; the degree of entrainment may be expected to be rather less if the vessel pressure is lower.

The *Second Canvey Report* takes for the initial cylindrical gas cloud a value of the aspect ratio, or ratio of diameter to height, of unity and this value is adopted in the Workbook by Britter and McQuaid (1988).

Further discussion of such empirical estimates for catastrophic failure is given in Section 15.8, which also gives models of vessel failure from which alternative estimates of the quantity of air entrained may be made.

For two-phase flashing jets and for elevated jets the entraiment of air is part of the model for the jet. An account of these models is given in Section 15.21.

15.23.8 Liquid droplets

Another important aspect of the source term is the initial liquid fraction present in the gas cloud as spray, together with the extent to which this rains out and, if so, evaporates again. The methods of estimating the liquid fraction have been described briefly above and are dealt with in more detail in Section 15.10.

The liquid droplets tend not to rain out but rather to evaporate. The behaviour of liquid droplets in the gas cloud is considered in Section 15.2. If rainout does occur, the liquid in the resulting pool will evaporate and the contribution to the source term of this re-evaporation may be significant.

15.23.9 Matching to dispersion model

For the determination of the dispersion of the material released, the source model has to be matched to the dispersion model. The cases for which such matching is required include:

(1) vaporization from a liquid pool;
(2) catastrophic failure of a vessel;
(3) two-phase flashing jet;
(4) elevated jet.

Vaporization from a liquid pool appears at first sight to constitute a relatively simple source. However, both the area of and the rate of heat transfer to the pool are variable. Therefore either the vapour flow has to be treated as an idealized instantaneous or continuous release or the dense gas dispersion model has to be able to handle a time-varying release. In addition, a gas blanket may form above the pool. A separate submodel of this gas blanket may be included in the dense gas dispersion model.

Catastrophic failure of a vessel is generally modelled by taking as the source term a cylindrical cloud of defined aspect ratio and containing a specified quantity of entrained air. It may then be treated by the dense gas dispersion model as an instantaneous release. A similar approach may be used for a release from an intermediate sized hole.

A two-phase flashing jet model may or may not be readily conformable with the dispersion model. Models of such jets are described in Section 15.21, including some which are designed explicitly to give a smooth transition to a dense gas dispersion model.

For an elevated jet, models have been developed that conform with dense gas dispersion models, but the two-phase aspect of such jets is not well developed. The models for an elevated jet give two main types of output. One type consists simply of the touchdown distance and the concentration at touchdown. The other gives the full profile of the touchdown plume, including dimensions, velocity and concentration. It is this latter type which gives the better match to a dense gas dispersion model. Both types of model for an elevated jet are described in Section 15.4. A jet would generally be expected to constitute a continuous release, unless the time is so short that this is not appropriate.

The matching of emission and vaporization models to dispersion models is treated in the CCPS *Workbook of Test Cases for Vapour Cloud Source Dispersion Models* (1989/8). This is described in Section 15.52.

15.23.10 LNG

Treatments of the source terms for specific gases are also available. Source terms for LNG have been discussed by Kaiser (1980) and Puttock (1987c, 1988a, 1989).

As stated above, for LNG spilled onto water evidence for field trials involving Refrigerant 12 suggests that the violent boiling results within about 5 s in the entrainment of some 10 times as much air. It is not known how this effect scales up.

LNG is not normally stored under pressure, but if it were the extent of air entrainment following catastrophic failure would be sufficient to dilute it close to its lower flammability limit.

An elevated jet release of LNG might well disintegrate and evaporate before it reached the surface.

15.23.11 Ammonia

Source terms for ammonia have been discussed by Kaiser and Walker (1978), Fryer and Kaiser (1979 SRD RR152), Griffiths and Kaiser (1979 SRD R154) and Kaiser (1980, 1989). They consider in particular the field trials with Refrigerant 12 and the ammonia release incidents at Potchefstroom in 1973 (Case History A65), Houston in 1976 (Case History A84), and Pensacola in 1977, and deduce for catastrophic failure of a vessel rules of thumb for aspect ratio and air entrainment, as mentioned above and described more fully in Section 15.8. The work of Wheatley (1986) on two-phase flashing jets is concerned specifically with ammonia.

15.24 Dispersion of Dense Gas: Models and Modelling

The mathematical modelling of dense gas dispersion is a complex subject with a large literature.

15.24.1 Types of model

There are three broad classes of model of dense gas dispersion:

(1) modified conventional models;
(2) box and slab models;
(3) K-theory and other three-dimensional models.

15.24.2 Modified conventional models

Once it was realized that some materials exhibit a degree of dense gas behaviour, the initial response was to attempt to modify existing models such as the Sutton and Pasquill–Gifford models, usually by making empirical adjustments to the diffusion parameter C or the dispersion coefficient u. This approach is described in Section 15.25. It was soon appreciated, however, that the behaviour of a dense gas is radically different from that of a neutrally buoyant gas and that a totally different approach is necessary.

15.24.3 Box models

A new generation of models, usually known as box models, was created. In the simple box model the gas cloud is assumed to be a pancake-shaped cloud with properties uniform in the crosswind and vertical directions. The model contains relations which describe the growth of the radius and height of an instantaneous release, or the crosswind width and height of a continuous release, and the entrainment of air at the top and edges of the cloud. The concentration in the cloud is obtained by mass balance. For an instantaneous release it is uniform in all three directions. For a continuous release it is uniform in the crosswind and vertical directions, but varies in the downwind direction.

The characteristic features of a typical box model are as follows. The cloud shape is determined by gravity-driven flow. Mixing inside the cloud is sufficiently rapid that the cloud has uniform concentration. Air entrainment velocities are specified as a function of cloud advection velocity, density difference and turbulence levels.

Although simple in concept, the box model actually places considerable demands on the modeller to specify correctly the various features just mentioned, such as cloud advection velocity and entrainment rates. In this respect it contrasts with the three-dimensional models described below, which largely take care of these aspects. In this sense, the apparent simplicity of the box model is deceptive. A box model contains a small number of adjustable parameters. These may be determined individually by experiment and confirmed by field trials.

The features of the box model for the investigation of dense gas dispersion have been described by McQuaid (1984a). A box model utilizes a top-hat concentration profile. McQuaid cites a number of other problems in fluid mechanics in which a similar 'black box' approach has been used, including the analysis of the boundary layer by Clauser (1954) and of plumes and of wakes by B.R. Morton, Taylor and Turner (1956) and B.R. Morton (1962).

A box model is based on the principle of similarity. For dense gas dispersion the conditions necessary for similarity are given by McQuaid as that the gas cloud is not so large as to alter the ambient atmosphere and that it is not subject to rapid change of depth.

McQuaid discusses the applicability of box models for the assessment of releases of flammable or toxic materials. He concludes that for toxic releases a box model gives concentrations which are generally sufficiently accurate, given the relatively high uncertainty in relations for toxic injury, but may be insufficiently accurate for some problems which arise in relation to flammability.

Box models are relatively simple, but have a number of drawbacks. One is that they are essentially limited to flat, unobstructed terrain and are not designed to handle terrain with slopes, obstructions, buildings or other special features. Another defect is the assumption of uniform concentration which may be inadequate for assessment of flammability and toxicity. A box model is sometimes termed a bulk property (BP) model.

Box models have been the dominant type of model used for dense gas dispersion and several such models are described below.

15.24.4 Advanced similarity models

Box models are simple similarity models which are based on assumptions about the shape of the gas cloud. A development from these is the advanced similarity models, which incorporate also assumptions about the concentration profile. The HEGADAS model, described below, is an advanced similarity model.

15.24.5 *K*-theory models

The limitations of box models have led to increasing use of the more fundamental if-theory models. An if-theory model consists of a set of equations for the conservation of mass, energy, momentum, and so on, together with boundary conditions. The model determines the variation of properties, velocity and concentration along the flow streamlines.

When the basic equations are averaged with respect to time certain second-order terms appear. The number of equations is less than the number of unknowns. It is therefore necessary to specify some of the unknowns in terms of the others. This is known as 'turbulence closure' and much work has been done on methods of effecting it. In an if-theory model the closure is a low order one. It is effected by making the gradient transfer assumption.

The model utilizes empirical relationships for the eddy diffusivities and eddy viscosities as a function of space, and sometimes also of stability category or Richardson number. Higher order closures are those in which additional equations are derived for the Reynolds stresses (e.g. $\bar{u}\bar{w}$) and therefore also for the velocity concentration correlations (e.g. $\bar{w}\bar{c}$). The new equations include third-order terms which in turn have to be modelled.

For undisturbed ambient flows if-theory models are reasonably satisfactory. But the presence of dense gas or obstructions renders them less so. In such cases the relations used for the eddy diffusivity K become inadequate, because they take insufficient account of local variations. In particular, the Reynolds analogy for the equivalence of mass, heat and momentum eddy diffusivities is not valid when the flow has stable density stratification.

The development of if-theory models was influenced by the need to obtain analytical solutions. This requirement meant that K had to be specified in a way compatible with this aim. The advent of computers has removed this constraint.

In some areas of work on turbulent diffusion the use of eddy diffusivities is regarded as out-dated and use is made of higher order closure models, if-theory models were in use before the recognition of the need for models specific to dense gas dispersion and a if-theory model, SIGMET, was in fact one of the first models applied to this problem. An if-theory model is sometimes termed a turbulence scheme model.

K-theory models are full three-dimensional models, but they may also be used in the two-dimensional mode, and in fact it is often sufficient to use them in this way.

Several of the models described below are if-theory models.

15.24.6 $\kappa-\epsilon$ Models

As just mentioned, the presence of a dense gas or of obstructions tends to render inadequate the relations normally used for the eddy diffusivity in a *K*-theory model.

The eddy diffusivity K is related to the turbulence energy (and the energy dissipation rate ϵ as follows:

$$K \propto \frac{\kappa^2}{\epsilon} \qquad [15.24.1]$$

The value of the eddy diffusivity is subject to local variations which are much more significant in the presence of dense gas or obstructions. A region of high density gradient tends to give low values of κ and thus, from Equation 15.24.1, very low values of K.

One way of overcoming this difficulty is to determine local values for κ and ϵ and then use them to obtain local values for K. This may be done by formulating the transport equations for κ and ϵ. This creates a two-equation $\kappa-\epsilon$ model. The parameters required for this $\kappa-\epsilon$ model are available and apply over a wide range of flows. This approach retains eddy diffusivity but allows it to vary locally.

$\kappa-\epsilon$ models are used extensively for the study of flows in regions of recirculation. One of the models described below, HEAVYGAS, is a $\kappa-\epsilon$ model.

15.24.7 Algebraic stress models

The $\kappa-\epsilon$ models just described still utilize the gradient transport relationship in regions where the diffusivities are very low and difficult to specify. They still retain the assumption that the eddy diffusivity is isotropic. It is known, however, that stability affects the different components of the Reynolds stresses in different ways.

A development that addresses this problem is the algebraic stress model. This replaces the gradient transport relation with equations which relate the various fluxes and stresses to the velocity and density gradients. This type of model is not, however, developed for dense gas dispersion.

15.24.8 Density difference

The treatment described below makes use of certain common relations and, before describing the principal models, it is convenient to give some of these relations. For the density intrusion represented by a dense gas spreading in ambient air

$$\Delta\rho = \rho - \rho_{\mathrm{a}} \qquad [15.24.2]$$

$$\Delta = \frac{\Delta\rho}{\rho_{\mathrm{a}}} \qquad [15.24.3]$$

$$g' = g\frac{\rho - \rho_a}{\rho_a} \qquad [15.24.4a]$$

$$= g\Delta \qquad [15.24.4b]$$

where $\Delta\rho$ and Δ are the absolute and reduced density differences between the gas cloud and the ambient air, g and g' are the absolute and reduced accelerations due to gravity, ρ is the density of the cloud and ρ_a is the density of the ambient air. The variable g' is generally referred to simply as the 'reduced gravity'.

An alternative reduced density difference is also used defined as

$$\Delta' = \frac{\Delta\rho}{\rho} \qquad [15.24.5]$$

where Δ' is an alternative reduced density difference.

15.24.9 Wind velocity

The vertical wind velocity profile is frequently obtained from the empirical expression

$$u = u_r\left(\frac{z}{z_r}\right)^p \qquad [15.24.6]$$

where u is the wind velocity, u_r is the wind velocity at the reference height z_r, z is the height, z_o is the roughness length and p is an index.

Use is made of the logarithmic vertical wind velocity profile:

$$u = \frac{u_*}{k}\ln\left(\frac{z}{z_r}\right) \qquad [15.24.7]$$

where u is the friction velocity, z_o is the roughness length and k is the von Karman constant.

The logarithmic vertical wind velocity profile is also used in the modified form:

$$u = \frac{u_*}{k}\left[\ln\left(\frac{z + z_o}{z_o}\right) - \psi\left(\frac{z}{L}\right)\right] \qquad [15.24.8]$$

where L is the Monin–Obukhov length and ψ is a profile function.

15.24.10 Heat transfer

Heat transfer from the ground to the cloud will, in general, have contributions from both natural and forced convection. For natural convection use is frequently made of the relation given by McAdams (1954) for heat transfer from an upwards-facing heated plate:

$$\mathrm{Nu} = 0.14(\mathrm{G}r\,\mathrm{Pr})^{1/3} \qquad [15.24.9]$$

with

$$\mathrm{Nu} = \frac{hL}{k_f} \qquad [15.24.10]$$

$$\mathrm{Gr} = \frac{L^3\rho_f\beta_f g\Delta T}{\mu_f} \qquad [15.24.11]$$

$$\mathrm{Pr} = \frac{c_{pf}\mu_f}{k_f} \qquad [15.24.12]$$

$$\beta_f = 1/T \qquad [15.24.13]$$

where c_p is the specific heat, Gr is the Grashof number, h is the heat transfer coefficient, k is the thermal conductivity, L is a characteristic linear dimension, Nu is the Nusselt number, Pr is the Prandtl number, T is the absolute temperature, ΔT is the temperature difference for heat transfer, β is the coefficient of thermal expansion, μ is the viscosity, ρ is the density and the subscript f denotes film conditions. Then from Equation 15.24.9

$$h_{gr} = 0.14\left(\frac{\rho_f^2 k_f^3 g}{\mu_f^2}\frac{c_{pf}\mu_f}{k_f}\frac{\Delta T}{T}\right)^{1/3} \qquad [15.24.14]$$

where the subscript gr denotes between the ground and the cloud.

For heat transfer by forced convection use is made of the relation given by Treybal (1955) for heat transfer from an upwards-facing heated plate:

$$j_H = \mathrm{St_H}\mathrm{Pr}^{2/3} = \frac{C_f}{2} \qquad [15.24.15]$$

with

$$\mathrm{St_H} = \frac{k}{c_p G} \qquad [15.24.16]$$

$$C_f = 2\left(\frac{u_*}{u}\right)^2 \qquad [15.24.17]$$

where C_f is a friction factor, G is the mass velocity, j_H is the j factor for heat transfer, $\mathrm{St_H}$ is the Stanton number for heat transfer and u is the velocity of the cloud. Equation 15.24.15 can be rearranged to give, for the case considered,

$$h_{gr} = \left[\left(\frac{c_p\mu}{k}\right)^{-2/3}\left(\frac{u_*}{u}\right)^2\right]u\rho c_p \qquad [15.24.18]$$

15.24.11 Density intrusion models

A dense fluid within a less dense fluid, such as a dense gas cloud in the atmosphere, represents a density intrusion which flows as a gravity current. The modelling of density intrusions and of the associated gravity-driven flow is a distinct area of work with applications in a number of fields. Reviews of gravity currents have been given by Benjamin (1968) and Simpson (1982). Gravity currents occur in many natural situations in the atmosphere and the ocean and they are relevant to industrial accidents such as oil spills and dense gas releases.

Work on gravity-driven flow includes the investigation of: the different phases of the flow (e.g. Huppert and Simpson, 1980); of the flow on a flat surface, and in particular the 'head' which develops at the leading edge (e.g. Benjamin, 1968) and the mixing which occurs (e.g. Britter and Simpson, 1978); of flow on slopes (e.g. Ellison and Turner, 1959; Britter and Linden, 1980; Beghin, Hopfinger and Britter, 1981); and of flow over and around obstacles (e.g. Rottman *et al.*, 1985).

The driving force of the gravity current is the buoyancy force. This is opposed by the inertial force, which is dominant initially, and the viscous force, which becomes dominant later. There is therefore an inertia-buoyancy phase and a viscous-buoyancy phase.

A model of gravity-driven flow which is increasingly utilized is the 'shallow water equations'. These are described in *Water Waves* (Stoker, 1957), Stratified Flows (Yih, 1980) and *Introduction to Water Waves* (Crapper, 1984). A derivation of the shallow water equations has been given by Penney and Thornhill (1952).

The non-linear shallow water equations are:

$$\frac{\partial h}{\partial t}+\frac{\partial (uh)}{\partial x}+n\frac{uh}{x}=0 \qquad [15.24.19]$$

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+g'\frac{\partial h}{\partial x}=0 \qquad [15.24.20]$$

where g' is the reduced gravity, h is the height of the dense fluid, u is the velocity of the dense fluid, x is the distance and n is a symmetry index. For planar flow $n = 0$, and for axisymmetric flow $n = 1$.

From Bernouilli's equation, the velocity of the gravity-driven wave is

$$c=(g'h)^{1/2} \qquad [15.24.21]$$

where c is the velocity of the wave. Then, from Equations 15.24.19–15.24.21, for $n = 0$

$$\frac{\partial c}{\partial t}+\frac{c}{2}\frac{\partial u}{\partial x}+u\frac{\partial c}{\partial x}=0 \qquad [15.24.22]$$

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+2c\frac{\partial c}{\partial x}=0 \qquad [15.24.23]$$

15.24.12 Basic box model relations

The basic equations of the typical box model are:

$$\frac{\mathrm{d}R}{\mathrm{d}t}=c_{\mathrm{E}}(g'H)^{1/2} \qquad [15.24.24]$$

$$\frac{\mathrm{d}V}{\mathrm{d}t}=\pi R^2 u_{\mathrm{e}}+2\pi RHw_{\mathrm{e}} \qquad [15.24.25]$$

where g' is the reduced gravity, H is the height of the cloud, R is the radius of the cloud, u_{e} is the top entrainment velocity, V is the volume of the cloud, w_{e} is the edge entrainment velocity and c_{E} is the damping coefficient.

Equation 15.24.24 may also be formulated in terms of the negative buoyancy B:

$$B=g'V \qquad [15.24.26a]$$

$$=g'(\pi R^2 H) \qquad [15.24.26b]$$

Thus, from Equation 15.24.24 and 15.24.26b

$$\frac{\mathrm{d}R}{\mathrm{d}t}=c_{\mathrm{E}}\left(\frac{B}{\pi}\right)^{1/2}\frac{1}{R} \qquad [15.24.27]$$

15.24.13 Model development

Since the work on dense gas dispersion in the Netherlands in the early 1970s, notably the work of van Ulden, there has been a high level of interest and work on the subject, including mathematical modelling, physical modelling and field trials. Some early workers, such as the Bureau of Mines and Clancey, attempted to adapt passive dispersion models to dense gas dispersion, as described in Section 15.25. However, in view of the fundamentally different physical phenomena involved, this attempt came to be regarded as inappropriate, although the newer models often incorporate features of, and make transition to, passive dispersion models.

The next generation of models were box models. Of these, the models of van Ulden, of Cox and Roe (developed as the BG/C&W model) and the SRD models (DENZ and CRUNCH) are described in Sections 15.26–15.28, respectively. Even at this stage the box models did not have the field entirely to themselves. An early and influential if-theory model was SIGMET, which has already been referred to in connection with LNG spill study and which is described further in Section 15.29.

The more modern systems of models include: SLAB and FEM3; HEGADAS and HGSYSTEM; DEGADIS; and SLUMP and HEAVYGAS. These are described in Sections 15.30–15.33, respectively. Both advanced box models and three-dimensional models are represented here. A different type of modern model is the similarity model given in the Workbook and described in Section 15.34. In Section 15.35 an account is given of DRIFT, a model which develops but transcends the box model approach. Some other models are described in Section 15.36.

15.25 Dispersion of Dense Gas: Modified Conventional Models

15.25.1 Bureau of Mines model

Attempts were made in early work to modify the parameters in passive gas dispersion models to take into account heavy gas behaviour. An account is given, although the approach has now been largely superseded by other methods.

Thus, for example, for a neutral gas the vertical dispersion coefficient σ_z in the Pasquill–Gifford equations tends to be about half the value of the horizontal dispersion coefficient, but work at the Bureau of Mines (Burgess and Zabetakis, 1973 BM RI 7752) indicated that for a heavy gas

$$\sigma_z=0.2\sigma_y \qquad [15.25.1]$$

where σ_y and σ_z are the dispersion coefficients in the crosswind and vertical (y and z) directions, respectively. Equation 15.25.1 has been used by Burgess and Zabetakis to take into account the density effect in the gas cloud formed in the Port'Hudson explosion in 1970 (Case History A52).

15.25.2 Clancey model

V.J. Clancey (1976a) suggested that in Equation 15.16.25 the generalized diffusion parameter in the vertical direction C_z should be taken as

$$C_z=\tfrac{1}{2}C_x=\tfrac{1}{2}C_y \qquad [15.25.2]$$

where C_x, C_y and C_z are the generalized diffusion parameters in the downwind, crosswind and vertical (x, y and z) directions, respectively.

15.25.3 Germeles and Drake model

A modified Gaussian model was presented by Germeles and Drake (1975) to describe the dispersion of LNG vapour clouds. This model has also been described by Ermak, Chan *et al.* (1982).

The Germeles and Drake model for a continuous release contains elements both of a dense gas box model and a passive dispersion model. The source is assumed to be a cylindrical cloud with an initial radius R_{i} that of the pool and initial height H_{i} given by

$$H_{\mathrm{i}} = 2R_{\mathrm{i}}W_{\mathrm{v}}/u \qquad [15.25.3]$$

The mass and heat content of the source are

$$m = \pi\rho R^2 H \qquad [15.25.4]$$

$$E = mc_{\mathrm{p}}T \qquad [15.25.5]$$

where c_{p} is the specific heat of the gas in the source cloud, E is the heat in the source cloud, m is the mass of gas in the source cloud, T is the absolute temperature, u is the wind speed, W_{v} is the velocity of the vapour source, and ρ is the density. The value of W_{v} is some 250 times the liquid regression rate.

The development of the source cloud is as follows. For the rate of change of the radius use is made of Equation 15.24.24 and for that of the mass and heat content

$$\frac{\mathrm{d}m}{\mathrm{d}t} = \pi\rho_{\mathrm{a}}R^2u_{\mathrm{e}} \qquad [15.25.6]$$

$$\frac{\mathrm{d}E}{\mathrm{d}t} = \pi\rho_{\mathrm{a}}R^2c_{\mathrm{pa}}T_{\mathrm{a}}u_{\mathrm{e}} + \epsilon_{\mathrm{v}} + \epsilon_{\mathrm{w}} \qquad [15.25.7]$$

where u_{e} is the top entrainment velocity, ϵ_{v} is the heat released by the condensation and by freezing of the water vapour, ϵ_{w} is the surface heat flux and subscript a denotes air.

It is assumed that the release is from a finite line source of width L located at a virtual source a distance x_{v} upwind of the true source. Use is then made of a model of the Pasquill–Gifford type to model the dispersion. This gives for the concentration

$$c(x,y,z) = \frac{\dot{V}}{(2\pi)^{1/2}uL\sigma_z}\exp\left(-\frac{z^2}{2\sigma_z^2}\right) \times \left\{\mathrm{erf}\left[\frac{(L/2)-y}{2^{1/2}\sigma_{\mathrm{v}}}\right] + \mathrm{erf}\left[\frac{(L/2)+y}{2^{1/2}\sigma_{\mathrm{v}}}\right]\right\} \qquad [15.25.8]$$

where c is the volumetric concentration, L is the width of the source, $\dot{V}$ is the volumetric rate of release, and σ_y and σ_z are the dispersion coefficients in the crosswind and vertical directions, respectively. The values used for σ_y and σ_z are the regular Pasquill–Gifford values.

The source model is run until the radial velocity of the cloud is equal to the wind speed. The source length L is then set equal to the diameter $2R$ of the cloud and the virtual source distance x_{v} is found from the values of $\sigma_y(x_{\mathrm{v}})$ and $\sigma_z(x_{\mathrm{v}})$ required to make the concentration at the source centre, as given by Equation 15.25.8, equal to that in the source cloud. Equation 15.25.8 is then used with these parameters to determine the concentrations downwind.

Ermak, Chan *et al.* (1982) have compared the performance of the Germeles and Drake model with that of other models in relation to the Burro trials.

15.26 Dispersion of Dense Gas: Van Ulden Model

15.26.1 Van Ulden model

The experimental work of van Ulden (1974) which demonstrated the marked difference in behaviour between a neutrally buoyant gas and a dense gas has already been described. At the same time van Ulden also presented a theoretical model. The main model was for the dispersion of an instantaneous release of dense gas in still air, but a model for a continuous release with finite wind velocity was also outlined. Van Ulden has subsequently extended his model (van Ulden 1979, 1984, 1987, 1988; van Ulden and de Haan, 1983).

In van Ulden's original work the behaviour of the cloud is modelled as a two-stage process, in which spreading occurs in the first stage by gravity slumping and in the second by Gaussian dispersion. In the first stage the dispersion is treated as a dense fluid flow process but with air entrainment at the edge of the cloud.

The starting point of the model is the following equation for the movement of a front of dense fluid such as that resulting from a dam burst:

$$u_{\mathrm{f}} = c_{\mathrm{E}}(\Delta \cdot gH_{\mathrm{f}})^{1/2} \qquad [15.26.1]$$

with

$$\Delta = (\rho_1 - \rho_2)/\rho_1 \qquad [15.26.2]$$

where H_{f} is the height of the front, u_{f} is the velocity of the front, Δ is the reduced density difference, ρ_1 is the density of the fluid behind the wavefront, ρ_2 is the density of the fluid ahead of the wavefront and c_{E} is a slumping constant. Van Ulden states that experiment suggests that the constant C_{E} is approximately unity.

It is assumed that in the first stage the initial gas cloud is a cylinder of radius R, height $H(R)$ and volume $V(R)$ with a front moving at velocity $u_{\mathrm{f}}(R)$ and with changing density $\rho(R)$. Then from the model just given

$$\frac{\mathrm{d}R}{\mathrm{d}t} = u_{\mathrm{f}} \qquad [15.26.3]$$

$$= c_{\mathrm{E}}(\Delta_{\mathrm{c}}' \cdot gH)^{1/2} \qquad [15.26.4]$$

with

$$\Delta_{\mathrm{c}}' = (\rho_{\mathrm{c}} - \rho_{\mathrm{a}})/\rho_{\mathrm{c}} \qquad [15.26.5]$$

where t is the time, Δ_{c}' is the reduced density difference of the cloud, ρ_{a} is the density of air and ρ_{c} is the density of the cloud. The volume V of the cloud is

$$V = \pi R^2 H \qquad [15.26.6]$$

Mixing at the front, or edge, of the cloud is assumed to take place at the rate

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \gamma 2\pi RH\frac{\mathrm{d}R}{\mathrm{d}t} \qquad [15.26.7]$$

where γ is the edge entrainment coefficient. Solution of Equations 15.26.3–15.26.7 gives

$$V/V_o = (R/R_o)^{2\gamma} \qquad [15.26.8]$$

$$H/H_o = (R/R_o)^{2\gamma-2} \qquad [15.26.9]$$

$$\frac{dR}{dt} = \frac{c_E}{R}\left[\frac{gV_o/\pi}{V_o/V + \rho_a/(\rho_o - \rho_a)}\right]^{1/2} \qquad [15.26.10]$$

$$\Delta = \left[1 + \frac{\rho_a V}{(\rho_o - \rho_a)V_o}\right]^{-1} \qquad [15.26.11]$$

where the subscript o denotes time zero and hence the source.

Equation 15.26.10 reduces to

$$\frac{dR}{dt} = \frac{c_E}{R}\left[\frac{(\rho_o - \rho_a)gV_o}{\pi\rho_o}\right] \qquad [15.26.12]$$

if the mixing at the front is negligible or if the term $(\rho_o - \rho_a)/\rho_a$ is small. Therefore Equation 15.26.12 is an adequate approximation in all circumstances. From Equation 15.26.12 the relation between the cloud radius and the time t is

$$R^2 - R_o^2 = 2c_E\left[\frac{(\rho_o - \rho_a)gV_o}{\pi\rho_o}\right]^{1/2} t \qquad [15.26.13]$$

The transition from gravity spread to diffusional mixing is taken to occur at the point where the turbulent energy is equal to the average potential energy difference and hence where

$$2\rho_a u_*^2 = 1/2(\rho_c - \rho_a)gH \qquad [15.26.14a]$$

$$= 1/2\rho_c u_f^2 \qquad [15.26.14b]$$

The condition for transition with $\rho_e \approx \rho_a$ is then

$$u_f = 2u_* \qquad [15.26.15]$$

Van Ulden uses the model just given to calculate the transition radius R_u and height H_u at which condition 15.26.15 applies and the position of the cloud and then applies an area source Gaussian dispersion model for the further determination of concentrations. The cloud radius and height obtained by Van Ulden for the experiment described earlier are shown in Figure 15.76. The fit is much superior to that given by the Gaussian model.

Van Ulden also gave a treatment of a continuous release. The mass flux across the cross-section of the plume at right angles to the wind direction is constant. The area of the cross-section is

$$S = 2LH \qquad [15.26.16]$$

where L is the half-width of the plume and S is the area of the cross-section of the plume. For the source

$$S_o = 2L_oH_o \qquad [15.26.17]$$

and

$$W_o = S_o u \qquad [15.26.18]$$

where u is the mean wind speed and W_o is the volumetric flow from the source.

Then, by an argument similar to that for the instantaneous release,

$$S/S_o = (L/L_o)^{\gamma} \qquad [15.26.19]$$

$$H/H_o = (L/L_o)^{\gamma-1} \qquad [15.26.20]$$

$$u_y = \frac{c_E}{L^{1/2}}\left[\frac{gS_o/2}{S_o/S + \rho_a/(\rho_o - \rho_a)}\right]^{1/2} \qquad [15.26.21]$$

$$\Delta_c' = \left[1 + \frac{\rho_a}{\rho_o - \rho_a}\left(\frac{L}{L_a}\right)^{\gamma}\right]^{-1} \qquad [15.26.22]$$

where u_y is the velocity of the cloud in the crosswind direction.

For the particular case of no mixing ($\gamma = 0$) and hence constant reduced density ($\Delta_c' = \Delta_{co}'$)

$$u_y = \left(\frac{gS_o\Delta_{co}'}{2L}\right)^{1/2} \qquad [15.26.23]$$

15.26.2 Critique of model

In subsequent work, van Ulden has described certain deficiencies in this model and in models by other workers, and has made modifications to his own model. Van Ulden and de Haan (1983) analyse the forces which determine the behaviour of an unsteady-state gravity current, notably the buoyant, viscous and inertial forces, and describe the viscous-buoyant and inertia-buoyant phases. They refer to the finding of Huppert and Simpson (1980) in work on flow of a dense fluid under a lighter fluid in a channel that the velocity of the gravity current is not solely a function of $(g'H)^{1/2}$ and that an important parameter is the fractional depth H/D, where D is the total depth of the channel.

Van Ulden (1984) gives a model for the particular case of two-dimensional flow in the inertia-buoyancy regime. In further critiques, van Ulden (1987, 1988) points out that Equation 15.26.4 is deficient in that it takes no account of the horizontal acceleration of the cloud from rest and therefore does not give conservation of momentum.

Various modellers have described air entrainment at the top and at the edge of the cloud by the relation

$$\frac{dV}{dt} = \pi R^2 u_e + 2\pi RHw_e \qquad [15.26.24]$$

where u_e is the top entrainment velocity and w_e is the edge entrainment velocity. However, proportionality between u_e and u_f violates conservation of energy.

15.26.3 Van Ulden model 2

Van Ulden (1987, 1988) has presented a second model which corrects some of the weaknesses of the initial model just described. The model is again for an instantaneous release in still air.

The model consists of four simultaneous differential equations for the rate of change with time of the radius R, the volume V, the edge velocity u_f and the bulk turbulent kinetic energy T_E. It gives a more fundamental treatment in that the relations for u_f and T_E are based on conservation of momentum and of energy, respectively, and the velocity of entrainment u_e through the top surface of the cloud is obtained from the bulk turbulent velocity $\bar{u}_t$ which itself is derived from the turbulent energy T_E.

The equations for the radius R and the volume V are

$$\frac{dR}{dt} = u_f \qquad [15.26.25]$$

$$\frac{dV}{dt} = \pi R^2 u_e \qquad [15.26.26]$$

For the edge velocity u_f, conservation of radial momentum gives

$$\frac{dM_{rd}}{dt} = F_s + F_d + F_a + F_v \qquad [15.26.27]$$

where F_a is the force due to the reaction of the ambient fluid to the outward radial acceleration of the cloud edge, F_d is the drag force on the cloud edge due to the presence of the quiescent ambient fluid, F_s is the static pressure force due to the negative buoyancy of the cloud, F_v is the force due to vertical acceleration in the cloud and the reaction of the ambient fluid to vertical acceleration of the cloud top and M_{rd} is the radial momentum integral of the cloud. This momentum budget yields a relation of the form

$$\frac{du_f}{dt} = f(g', H, R, u_f, u_e, \rho_c, \rho_a, \bar{\rho}_c, \Delta\bar{\rho}_c) \qquad [15.26.28]$$

where $\bar{\rho}_c$ is the mean density of the cloud and $\Delta\bar{\rho}_c$ is the mean density difference.

The relation for the bulk turbulent kinetic energy T_E is derived from conservation of the total energy in a large control volume containing the cloud and the secondary flows around it. Four types of energy are considered: I_E the internal heat, K_E the kinetic energy of the mean radial and vertical motions, P_E the potential energy and T_E the turbulent kinetic energy. Then

$$\frac{dP_E}{dt} = -G + B \qquad [15.26.29]$$

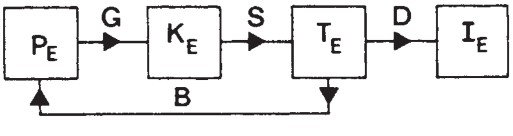
$$\frac{dK_E}{dt} = G - S \qquad [15.26.30]$$

$$\frac{dT_E}{dt} = S - B - D \qquad [15.26.31]$$

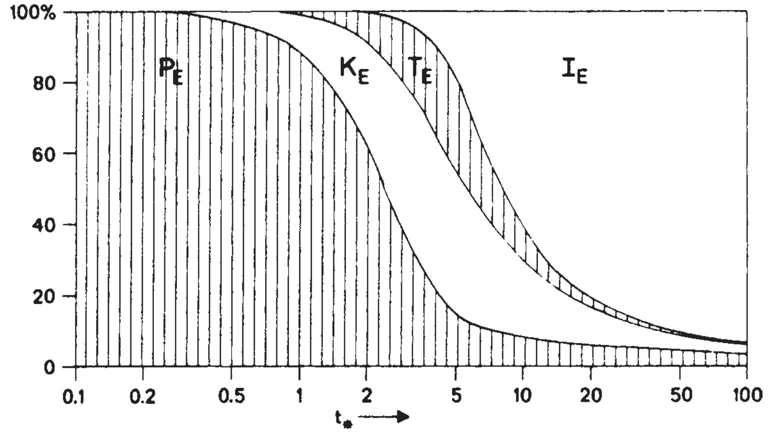
$$\frac{dI_E}{dt} = D \qquad [15.26.32]$$

where B is the rate of buoyant destruction of turbulent energy, which is the conversion of turbulent energy into potential energy by entrainment, D is the rate of dissipation of turbulent energy into internal heat, G is the rate at which gravity transforms potential energy into mean kinetic energy and S is the rate of shear production of turbulent energy. The relationship between these forms of energy is shown in Figure 15.78(a) and their variation with time is shown in Figure 15.78(b). Conservation of energy gives

$$\frac{d(I_E + K_E + P_E + T_E)}{dt} = 0 \qquad [15.26.33]$$



(a)



(b)

__Figure 15.78__ van Ulden's second model of dense gas dispersion – components of energy balance (van Ulden, 1988): (a) relationship between components; (b) change of components with time, t^* is scaled time (Courtesy of Clarendon Press)

This energy budget yields a relation of the form

$$\frac{\mathrm{d}T_\mathrm{E}}{\mathrm{d}t} = f(g, H, R, u_\mathrm{f}, \bar{u}_\mathrm{t}, V, V_\mathrm{o}, u_\mathrm{e}, \rho_\mathrm{c}, \rho_\mathrm{a}, \bar{\rho}_\mathrm{c}, \Delta\bar{\rho}_\mathrm{o}, \mathrm{Ri}_\mathrm{t}) \qquad [15.26.34]$$

where Ri_t is a bulk turbulent Richardson number and $\Delta\bar{\rho}_\mathrm{o}$ is the mean initial density difference for the cloud. For air entrainment, edge entrainment is neglected and top entrainment is obtained using the entrainment model of Diedronks and Tennekes (1984):

$$u_\mathrm{e} = \frac{c_1 \bar{u}_\mathrm{t}}{c_\mathrm{t} + \mathrm{Ri}_\mathrm{t}} \qquad [15.26.35]$$

with

$$\mathrm{Ri}_\mathrm{t} = \frac{g \Delta\bar{\rho}_\mathrm{c} H}{\bar{\rho}_\mathrm{c} \bar{u}_\mathrm{t}^2} \qquad [15.26.36]$$

where c_1 and c_t are constants. The values of c_1 and c_t are 0.2 and 1.5, respectively.

The bulk turbulent velocity $\bar{u}_\mathrm{t}$ is a function of the bulk turbulent kinetic energy T_E:

$$\bar{u}_\mathrm{t} = (2T_\mathrm{E}/\bar{\rho}_\mathrm{c} V)^{1/2} \qquad [15.26.37]$$

The average density $\bar{\rho}_\mathrm{c}$ and density difference $\Delta\bar{\rho}_\mathrm{c}$ of the cloud and average concentration C are

$$\bar{\rho}_\mathrm{c} = \rho_\mathrm{a} + \Delta\bar{\rho}_\mathrm{c} \qquad [15.26.38]$$

$$\Delta\rho = \Delta\bar{\rho}_\mathrm{o} V_\mathrm{o}/V \qquad [15.26.39]$$

$$C = V_\mathrm{o}/V \qquad [15.26.40]$$

assuming $C_\mathrm{o} = 1$.

The model itself assumes a uniform profile of concentration with height. Van Ulden states that, in general, the concentration may be described by a relation of the form

$$C(z)/\bar{C} = f(z/H) \qquad [15.26.41]$$

where $\bar{C}$ is the mean concentration.

Any such relation should be consistent with conservation of mass:

$$\int_0^\infty f(z/H)\,\mathrm{d}(z/H) = 1 \qquad [15.26.42]$$

and with the definition of H, taken as

$$H = 2\int_0^\infty zC(z)\,\mathrm{d}z \bigg/ \int_0^\infty C(z)\,\mathrm{d}z \qquad [15.26.43]$$

Van Ulden quotes as a possible candidate the family of profiles

$$C(z)/\bar{C} = A\exp[-(Bz/H)^s] \qquad [15.26.44]$$

with

$$A = 2s\Gamma(2/s)/[\Gamma(1/s)]^2 \qquad [15.26.45]$$

$$B = 2\Gamma(2/3)/\Gamma(1/s) \qquad [15.26.46]$$

where s is a profile shape factor and A and B are constants. In fitting his model to experimental results, he utilizes a shape factor $s = 1/2$, giving

$$C(z)/\bar{C} = 6\exp[-(12z/H)^{1/2}] \qquad [15.26.47]$$

15.26.4 Extensions of De Nevers

De Nevers (1984b) has described a model of the type given by van Ulden and has extended it to the case of a continuous release and then to a comparison of instantaneous and continuous releases in windless conditions. The treatment is concerned with the short-term behaviour and ignores entrainment of air. Following van Ulden, for an instantaneous release

$$\frac{\mathrm{d}R}{\mathrm{d}t} = c_\mathrm{E}(g'H)^{1/2} \qquad [15.26.48]$$

$$V_\mathrm{o} = \pi R_\mathrm{o}^2 H_\mathrm{o} \qquad [15.26.49a]$$

$$= \pi R^2 H \qquad [15.26.49b]$$

but with

$$g' = \frac{\rho_\mathrm{g} - \rho_\mathrm{a}}{\rho_\mathrm{a}} \qquad [15.26.50]$$

where g′ is the reduced gravity and subscript o denotes time zero. Then, combining Equations 15.26.48 and 15.26.49b

$$\frac{\mathrm{d}R}{\mathrm{d}t} = c_\mathrm{E}\left(\frac{g'V_\mathrm{o}}{\pi R^2}\right)^{1/2} \qquad [15.26.51]$$

Integrating this equation with the initial condition

$$t = t_\mathrm{o}; \quad R = R_\mathrm{o}$$

and taking the initial aspect ratio as

$$R_\mathrm{o} = H_\mathrm{o} \qquad [15.26.52]$$

yields

$$\frac{R^2}{2} = c_\mathrm{E}\left(\frac{g'V_\mathrm{o}}{\pi}\right)^{1/2} t + 1/2\left(\frac{V_\mathrm{o}}{\pi}\right)^{2/3} \qquad [15.26.53]$$

For a continuous release, Equations 15.26.48 and 15.26.49b are again applicable, but in addition

$$V_\mathrm{o} = Qt \qquad [15.26.54a]$$

$$= \pi R^2 H \qquad [15.26.54b]$$

where Q is the volumetric rate of release. Then, combining Equations 15.26.48, 15.26.49b and 15.26.54a

$$\frac{\mathrm{d}R}{\mathrm{d}t} = c_\mathrm{E}\left(\frac{g'Qt}{\pi R^2}\right)^{1/2} \qquad [15.26.55]$$

Integrating this equation with the initial condition

$$t = t_\mathrm{o}; \quad R = 0$$

yields

$$\frac{R^2}{2} = \frac{2c_E}{3}\left(\frac{g'Q}{\pi}\right)^{1/2} t^{3/2} \quad [15.26.56]$$

There is a small transient when expansion by bulk flow from the source exceeds that due to gravity-driven flow, but this is so short it can be neglected.

From Equations 15.26.53 and 15.26.56 and setting $V_o = Qt$

$$\frac{R_i}{R_c} = \left[\frac{3}{2} + \frac{3Q^{1/6}}{4c_E(g')^{1/2}\pi^{1/6}t^{5/6}}\right]^{1/2} \quad [15.26.57a]$$

$$= \left(\frac{3}{2}\right)^{1/2} \quad t \to \infty \quad [15.26.57b]$$

where subscripts c and i denote continuous and instantaneous, respectively. The second term on the right-hand side of Equation 15.26.57a falls rapidly to zero, giving Equation 15.26.57b. From Equations 15.26.54b and 15.26.57b

$$\frac{H_i}{H_c} = \frac{2}{3} \quad [15.26.58]$$

15.26.5 Validation and application

Van Ulden (1974) compared the performance of his first model against the Freon 12 experiment given in his paper, as described in Section 15.22 and shown in Figure 15.76. His work demonstrated that his model was much superior to the Gaussian model in predicting the radius and the height of the cloud, and stimulated work on dense gas dispersion.

15.27 Dispersion of Dense Gas: British Gas/Cremer and Warner Model

The work of van Ulden gave impetus to the development of a number of models of dense gas dispersion. One of the first of these was that by R.A. Cox and Roe (1977) of Cremer and Warner and British Gas, respectively. This model was further developed in treatments by R.A. Cox and Carpenter (1980), C.I. Bradley *et al.* (1983) and Carpenter *et al.* (1987), who refer to it as the British Gas/Cremer and Warner (BG/C&W) model.

15.27.1 Cox and Roe model

The model of R.A. Cox and Roe (1977) is for a continuous release. It follows the same approach as van Ulden in that the cloud is modelled as a sequence of rectangular crosswind slices each of uniform concentration and spreading laterally under gravity. The movement of the cloud edge is

$$\frac{dL}{dt} = (k_E g' H)^{1/2} \quad [15.27.1]$$

where H is the height of the cloud, L is the half-width of the cloud, g' is the reduced gravity and k_E is a spreading constant. The value of the constant k_E is taken as unity, following van Ulden, although there is theoretical and some experimental basis for a value of 2.

For entrainment of air at the cloud edge, the approach followed is that of van Ulden:

$$Q_e = Hw_e \quad [15.27.2]$$

with

$$w_e = \gamma \frac{dL}{dt} \quad [15.27.3]$$

where Q_e is the volumetric flow of air entrained at the edge of the cloud per unit distance crosswind, w_e is the edge entrainment velocity and γ is an edge entrainment coefficient.

In this model account is also taken of entrainment of air at the top of the cloud:

$$Q_t = 2Lu_e \quad [15.27.4]$$

where Q_t is the volumetric flow of air entrained at the top of the cloud per unit distance downwind and u_e is the top entrainment velocity. The rate of change of volume of the cloud is then

$$\frac{dV}{dt} = Q_t + Q_e \quad [15.27.5]$$

where V is the volume of the cloud per unit distance downwind. For the top entrainment velocity u_e

$$u_e = \frac{\alpha u_1}{\mathrm{Ri}} \quad [15.27.6]$$

with

$$\mathrm{Ri} = \frac{g'l}{u_1^2} \quad [15.27.7]$$

where l is a turbulence length scale, Ri is a Richardson number, u_1 is the longitudinal turbulence velocity and α is a top entrainment coefficient. Equation 15.27.6 is valid for moderate values of Ri, but as Ri tends to zero the term (u_e/u_1) tends to a limiting small value.

The longitudinal turbulence velocity u_i may be expressed in the form

$$\frac{u_1}{u} = \frac{u_1}{u_*}\frac{u_*}{u} \quad [15.27.8]$$

where u is the wind speed and u_* is the friction velocity. The ratio (u_1/u_*) has been shown by Monin (1962) to depend primarily on the stability condition. His results indicate the following approximate values:

Stability condition	u_1/u_*
Very stable	3.0
Neutral	2.4
Very unstable	1.6

The ratio (u_*/u) has been shown by O.G. Sutton (1953) to depend primarily on the surface roughness. A typical value for open terrain is 0.1. For the turbulence length scale l, use is made of the results of R.J. Taylor, Warner and Bacon (1970), which show that the parameter varies with the stability condition and the height H of the cloud. For the top entrainment coefficient α work in the literature suggests values ranging from 0.15 to 1.0. A value of 0.5 was obtained by fitting the model to one of the American Gas Association tests for LNG dispersion.

The authors state that in the model the entrained air is assumed to mix adiabatically with the gas and that the effects of water vapour present in the air are taken into account, but give no further details.

15.27.2 Cox and Carpenter model

R.A. Cox and Carpenter (1980) extend the model of Cox and Roe to cover both continuous and instantaneous releases. The situations modelled are shown in Figure 15.79(a) and (b) for the instantaneous and continuous release cases, respectively. The models cover a continuous release in wind and an instantaneous release in still air or in wind, but not a continuous release in still air. The movement of the cloud edge for the two cases is

$$\frac{\mathrm{d}L}{\mathrm{d}t} = (k_{\mathrm{E}} g' H)^{1/2} \quad \text{continuous release} \qquad [15.27.9a]$$

$$\frac{\mathrm{d}R}{\mathrm{d}t} = (k_{\mathrm{E}} g' H)^{1/2} \quad \text{instantaneous release} \qquad [15.27.9b]$$

where R is the radius of the cloud. The value of the constant k_{E} is unity. The entrainment of air at the cloud edge is

$$Q_{\mathrm{e}} = H w_{\mathrm{e}} \quad \text{continuous release} \qquad [15.27.10a]$$

$$Q_{\mathrm{e}} = 2\pi R H w_{\mathrm{e}} \quad \text{instantaneous release} \qquad [15.27.10b]$$

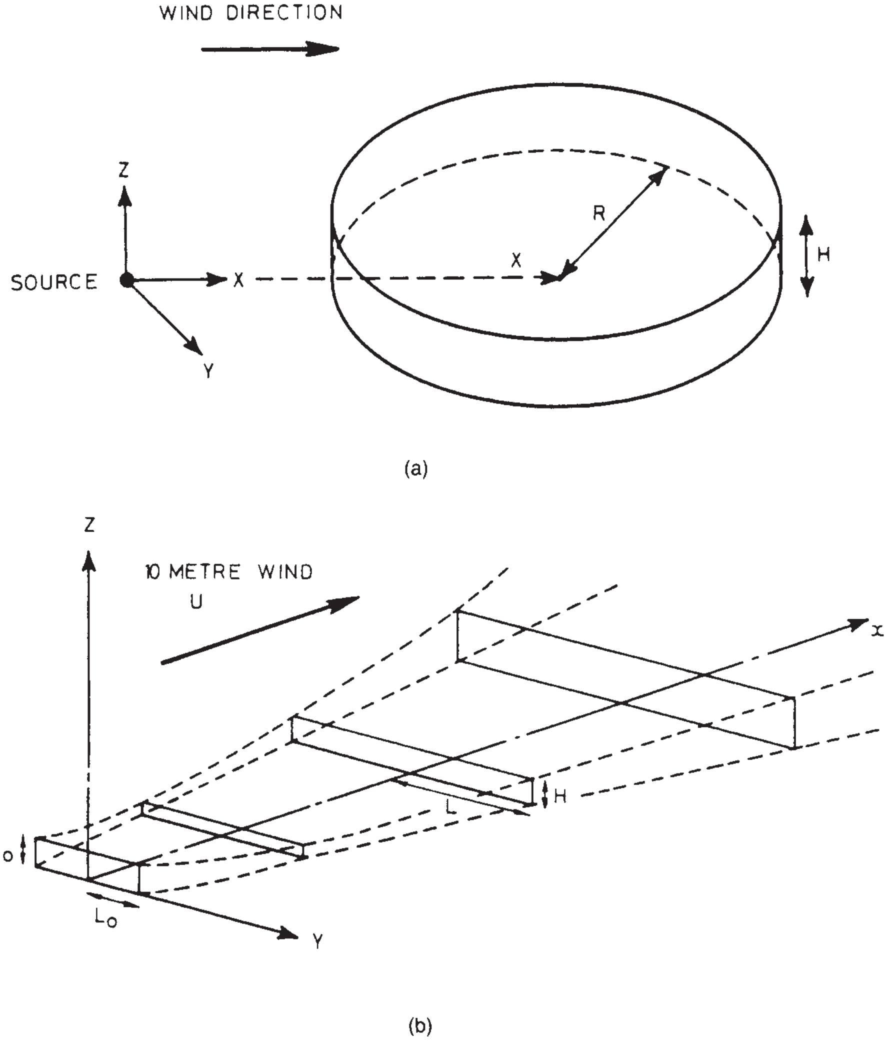


Figure 15.79 Cox and Carpenter model for dense gas dispersion – idealized cloud shapes (R.A. Cox and Carpenter, 1980): (a) instantaneous release; (b) continuous release (Courtesy of Reidel Publishing Company)

where Q_e is the volumetric flow of air entrained at the edge of the cloud, this being the total value for the instantaneous release case and the value per unit distance crosswind for the continuous release case. The edge entrainment velocity w_e is

$$w_e = \gamma \frac{\mathrm{d}L}{\mathrm{d}t} \quad \text{continuous release} \qquad [15.27.11a]$$

$$= \gamma \frac{\mathrm{d}R}{\mathrm{d}t} \quad \text{instantaneous release} \qquad [15.27.11b]$$

The entrainment of air at the cloud top is

$$Q_t = 2Lu_e \quad \text{continuous release} \qquad [15.27.12a]$$

$$Q_t = 2\pi R^2 u_e \quad \text{instantaneous release} \qquad [15.27.12b]$$

where Q_t is the volumetric flow of air entrained at the top of the cloud, this being the total value for the instantaneous release case and the value per unit distance downwind for the continuous release case.

The treatment of the entrainment velocity u_e at the top of the cloud is essentially that given by Cox and Roe. There is a limiting small value β to which the group (u_e/u_1) tends as Ri tends to zero. The values used for α, β and γ are discussed below.

The rate of change of volume of the cloud is

$$\frac{\mathrm{d}V}{\mathrm{d}t} = Q_t + Q_e \qquad [15.27.13]$$

where V is the volume of the cloud, this being the total value for the instantaneous release case and the value per unit distance downwind for the continuous release case.

A more detailed description is given of the heat balance used in the model. Vaporization of liquid spray, condensation of water vapour and heat transfer from the ground to the cloud are taken into account. If the source is not one which generates pure vapour but involves a flashing liquid it is assumed that the liquid flash-off is adiabatic, giving vapour and liquid spray. It is also assumed that half the liquid rains out but that this rainout revaporizes instantly. Thereafter the cloud is assumed to be at the saturated condition as long as liquid still remains. The cloud is assumed to be saturated with water.

For heat transfer from the ground by natural convection

$$Q_{gr} = h_{grn}(T_{gr} - T_c)^{4/3} \qquad [15.27.14]$$

and by forced convection

$$Q_{gr} = 0.5C_f \rho_c c_{pc} u'(T_{gr} - T_c) \qquad [15.27.15]$$

where C_f is a friction factor, c_{pc} is the specific heat of the cloud, h_{grn} is the heat transfer coefficient between the ground and the cloud by natural convection, Q_{gr} is the heat flux from the ground to the cloud, T_c is the temperature of the cloud, T_{gr} is the temperature of the ground, u' is the magnitude of the vector sum of the slumping and wind velocities and ρ_c is the density of the cloud. The friction factor C_f is given by Equation 15.24.17. The value used for the heat flux Q_{gr} is the larger of the values obtained from Equation 15.27.14 for natural convection and Equation 15.27.15 for forced convection. The heat balance on the cloud is then

$$\begin{aligned} m_{vo}h_v(T_o) + m_{lo}h_l(T_o) + m_a h_a(T_a) + m_{wv}h_{wv}(T_a) + Q_{gr} \\ = m_v h_v(T_c) + m_l h_l(T_c) + m_a h_a(T_c) + m_{wv}h_{wv}(T_c) \\ + m_{wl}h_{wl}(T_c) \end{aligned} \qquad [15.27.16]$$

where h is the specific enthalpy of a component, m_i is the mass of component i in the cloud, T_a is the temperature of the air and subscripts a, l, o, v, wl and wv denote air, liquid, source, vapour, liquid water and water vapour, respectively.

The model is extended in the region of passive dispersion. The transition from dense gas to passive dispersion is assumed to occur at the point where the rate of lateral spreading due to turbulence exceeds that due to gravity:

$$\frac{\mathrm{d}L}{\mathrm{d}t} = \frac{\mathrm{d}\sigma_y}{\mathrm{d}t} \quad \text{continuous release} \qquad [15.27.17a]$$

$$\frac{\mathrm{d}R}{\mathrm{d}t} = \frac{\mathrm{d}\sigma_y}{\mathrm{d}t} \quad \text{instantaneous release} \qquad [15.27.17b]$$

where σ is the dispersion coefficient and subscript y denotes crosswind.

Then from this point a continuous release is modelled using the Gaussian model for a finite line source:

$$\chi(x,y,0) = \frac{Q}{(2\pi)^{1/2}\sigma_z l_{vs} u}\left[\operatorname{erf}\left(\frac{l_{vs}/2 - y}{2^{1/2}\sigma_y}\right) + \operatorname{erf}\left(\frac{l_{vs}/2 + y}{2^{1/2}\sigma_y}\right)\right] \qquad [15.27.18]$$

where l_{vs} is the width of the virtual source, Q is the continuous mass rate of release and χ is the concentration (mass per unit volume).

The treatment for an instantaneous release is slightly more complex. The virtual source is represented as a set of 253 instantaneous point sources on a rectangular grid:

$$\chi(x,y,0) = \frac{2Q^* S^*}{253(2\pi)^{3/2}\sigma_y^2 \sigma_z} \qquad [15.27.19]$$

with

$$S^* = \sum_{n=1}^{253} \left\{ -\frac{1}{2}\left[\frac{r(n)}{\sigma_y}\right]^2 \right\} \qquad [15.27.20]$$

where Q^* is the mass released instantaneously and $r(n)$ is the distance downwind from the source n.

The dense phase model gives a uniform cross-sectional concentration profile, whereas the passive model gives a Gaussian concentration profile. The Gaussian model has only two degrees of freedom: the distance of the virtual source upstream of the matching point, and the width of the virtual source. The two cloud parameters selected for matching are the centre line concentration and the cloud width. It is assumed that at the matching point the cloud width is equal to the width at the virtual source plus $2\sigma_y$, where σ_y is the value at the matching point based on its distance from the virtual source.

The authors discuss the calibration of the top entrainment coefficient α, the limiting value β of the group u_e/u_1 and the edge entrainment coefficient γ, and give values of 0.1, 0.15 and 0.6, respectively.

15.27.3 Development of model

Development of the model of Cox and Carpenter has been described by C.I. Bradley *et al.* (1983). A deficiency of that model is the neglect of conservation of momentum and the assumption that the cloud travels at a constant speed equal to that of the wind.

For the cloud from an instantaneous release the rate of change of momentum in the frame of reference of the moving cloud is

$$\frac{d(mu_c)}{dt} = \dot{m}_e u_{av} + \dot{m}_t u_h + D - F \qquad [15.27.21]$$

where D is the drag force on the cloud, F is the friction force on the cloud, m is the total mass in the cloud, m_e is the mass of air entrained at the edge of the cloud, m_t is the mass of air entrained at the top of the cloud, u_{av} is the average wind speed over the cloud height, u_c is the velocity of the cloud and u_h is the wind speed at the cloud height H. The drag force D is

$$D = C_d \int_0^H R\rho_a[u(z) - u_c]|u(z) - u_c|\,dz \qquad [15.27.22]$$

where C_d is a drag coefficient and $u(z)$ is the wind speed at height z. The value of the drag coefficient C_d is taken as 1.0. The friction force F is obtained by analogy with the shear stress τ in the atmospheric boundary layer

$$F = \tau\pi R^2 \qquad [15.27.23]$$

with

$$\tau = \left(\frac{u_*}{u_r}\right)^2 \rho_c u_c^2 \qquad [15.27.24]$$

where u_r is the wind speed at the reference height and τ is the shear stress. The reference height is 10 m. Then, from Equation 15.27.21 the acceleration of the cloud relative to a fixed point is

$$\frac{du_c}{dt} = \frac{1}{\dot{m}}[\dot{m}_e(u_{av} - u_c) + \dot{m}_t(u_h - u_c) + D - F \qquad [15.27.25]$$

For the cloud from a continuous release there is no aerodynamic drag, since the main effect of this force is to reverse the upwind flow and give the plume its initial acceleration. There is, however, an additional term which allows for the interaction of one slice of the plume with another due to the variation of cloud dimensions and density as the plume is carried downwind. The rate of change of momentum is

$$\frac{du_c}{dt} = \frac{1}{\dot{m}}\left\{\frac{d\dot{m}_e}{dt}(u_{av} - u_c) + \frac{d\dot{m}_t}{dt}(u_h - u_c) - 2\tau L u_c - g\frac{d[LH^2(\rho_c - \rho_a)]}{dt}\right\} \qquad [15.27.26]$$

A method is also described of handling a transient release which corresponds to neither of the two ideal cases, i.e. to neither a continuous nor an instantaneous release. A case in point is vaporization from a spill of a cryogenic liquid such as LNG. A suitable approach in such a case may be to model the release as an instantaneous release followed by a continuous release. If successively larger masses of vapour are considered, it is found that for a small amount m_1 the time t_1 for vaporization to occur is so short that the trailing edge of the cloud is still upwind of the source. For a large amount m_3, the time t_3 is so long that the trailing edge has moved downwind of the source. There is some intermediate mass m_2 and time t_2 such that the trailing edge is just on the source. This time t_2 is taken as that at which transition occurs. The instantaneous release model is used up to this time and the continuous release model thereafter.

At low wind speeds this method gives a large instantaneous release and the maximum travel distance to a given concentration is determined by this instantaneous part of the release. At high wind speeds and/or for small releases the maximum travel distance is determined by the continuous part of the release.

For very low wind speeds it can occur that the cloud is diluted below its lower flammability limit before it has moved away from the source. This is an indication that the model is inapplicable and it should not be used.

In a further treatment for an instantaneous release, Carpenter *et al.* (1987) express the average wind speed u_{av} over the cloud height as a function of the wind speed u_h at height H:

$$u_{av} = f u_h \qquad [15.27.27]$$

where f is the wind speed coefficient.

The authors present a further calibration of the parameters α, β, γ and f based on data from the Thorney Island Phase 1 tests, and give values of 0.08, 0.30, 0.65 and 0.55, respectively.

15.27.4 Validation and application

R.A. Cox and Roe (1977) compared predictions from their model with observations in the Matagordo Bay tests. R.A. Cox and Carpenter (1980) used the SS Gadila LNG spill trials to calibrate the parameters in their model. The resultant predicted cloud shape is shown in Figure 15.92(a). Carpenter *et al.* (1987) used the Thorney Island trials to calibrate the parameters in the BG/C&W model.

15.28 Dispersion of Dense Gas: DENZ and CRUNCH

Two models on somewhat similar lines have been developed by the Safety and Reliability Directorate (SRD). The model for an instantaneous release, DENZ, is described by Fryer and Kaiser (1979 SRD R152) and that for a continuous release, CRUNCH, by Jagger (1983 SRD R229). The two models are incorporated in the computer codes of the same name and have been widely used.

15.28.1 DENZ

Kaiser and Walker (1978) have described a model which was a forerunner of DENZ and applied it to releases of liquefied anhydrous ammonia.

DENZ is a model for an instantaneous release of a dense gas. It is described by Fryer and Kaiser (1979 SRD R152). The model is based on three simultaneous differential equations for the radius R of the cloud, the mass m_a of air in the cloud and the temperature T_c of the cloud.

The cloud is assumed to be advected downwind at an advection velocity which corresponds to the mean wind velocity at the half-height of the cloud. This advection velocity is given by

$$u_c(t) = u_r \frac{\ln(H/2z_o)}{\ln(z_r/z_o)} \qquad [15.28.1]$$

where $u_c(t)$ is the mean velocity of the cloud, u_r is the mean wind velocity at the reference height, z_o is the roughness length, z_r is the reference height and H is the height of the cloud. The reference height z_r is 10 m.

The rate of change of the downwind distance $x(t)$ of the centre of the cloud is equal to the advection velocity u_c(f):

$$\frac{dx}{dt} = u_c(t) \qquad [15.28.2]$$

For the radius R of the cloud

$$\frac{dR}{dt} = c_E(g'H)^{1/2} \qquad [15.28.3]$$

The volume V is

$$V = \pi R^2 H \qquad [15.28.4]$$

and c_E is the slumping coefficient.

Equation 15.28.3 is actually cast in the alternative form

$$\frac{dR^2}{dt} = 2c_E\left(\frac{g'V}{\pi}\right)^{1/2} \qquad [15.28.5]$$

For the mass m_a of air entrained

$$\frac{dm_a}{dt} = \pi R^2 \rho_a u_e + 2\pi RH\rho_a w_e \qquad [15.28.6]$$

The edge entrainment velocity w_e is

$$w_e = \gamma \frac{dR}{dt} \qquad [15.28.7]$$

Following van Ulden (1974), the default value of the edge entrainment coefficient γ is taken as zero. Following R.A. Cox and Roe (1977), the top entrainment velocity u_e is obtained from Equation 15.27.6 using the methods given by these authors for relations for the group (u_1/u_*) and for the turbulence length scale l.

Heat transfer between the ground and the cloud is assumed to be by natural convection:

$$Q_{gr} = h_{gr}\Delta T_{gr} \qquad [15.28.8]$$

with

$$\Delta T_{gr} = T_{gr} - T_c \qquad [15.28.9]$$

$$h_{gr} = 0.418\frac{k_f}{L}Z^{1/4}\Delta T_{gr}^{1/4} \quad \text{laminar convection} \qquad [15.28.10a]$$

$$= 0.146\frac{k_f}{L}Z^{1/3}\Delta T_{gr}^{1/3} \quad \text{turbulent convection} \qquad [15.28.10b]$$

$$Z = \left(\frac{L^3\rho_f^2\beta_f g}{\mu_f^2}\Delta T_{gr}\frac{c_{pf}\mu_f}{k_f}\right)^{1/4} \qquad [15.28.11]$$

and with convection turbulent if

$$3 \times 10^{10} > Z\Delta T_{gr} > 2 \times 10^7$$

where c_p is the specific heat, h_{gr} is the heat transfer coefficient between the ground and the cloud, k is the thermal conductivity of the cloud, L is a characteristic dimension of the cloud, Q_{gr} is the heat flux between the ground and the cloud, T_{gr} is the temperature of the ground, ΔT_{gr} is the temperature difference between the ground and the cloud, β is the coefficient of volumetric expansion, μ is the viscosity and subscript f denotes at film temperature $(=(T_c + T_{gr})/2)$.

Equation 15.28.8 gives the heat transfer between the ground and the cloud. Then for the temperature T_c of the cloud

$$\frac{dT_c}{dt} = \frac{m_a c_{pa}\Delta T_a + h_{gr}(\pi R^2)\Delta T_{gr}}{m_a c_{pa} + m_g c_{pg}} \qquad [15.28.12]$$

with

$$\Delta T_a = T_a - T_c \qquad [15.28.13]$$

where m_a is the mass of air, m_g is the mass of gas, ΔT_a is the temperature difference between the air and the cloud, and subscripts a, c and g denote the air, cloud and gas, respectively.

Use is also made of the relations

$$V = \frac{m_a + m_g}{\rho_c} \qquad [15.28.14]$$

$$\rho_c = \frac{m_a + m_g}{(m_a/\rho_a) + (m_g/\rho_g)}\frac{T_a}{T_c} \qquad [15.28.15]$$

For transition from dense gas dispersion to passive dispersion use is made of two alternative criteria. The first criterion is that transition occurs if the following two conditions are satisfied. The first condition is that the rate of increase of the radius due to gravity spreading is less than that due to atmospheric turbulence

$$\frac{dR}{dt} < 2.14\frac{d\sigma_y}{dt} \qquad [15.28.16]$$

For the determination of the term $(d\sigma_y/dt)$ use is made of the treatment by Hosker (1974b):

$$\frac{d\sigma_y}{dt} = C^*\frac{dx}{dt} = C^* u_c \qquad [15.28.17]$$

where u_c is the velocity of the cloud and C^* is a constant. The constant C^* is a function of the stability category and for categories A, B, C, D, E and F has the values 0.22, 0.16, 0.11, 0.08, 0.06 and 0.04, respectively. The second condition is that

$$u_e > u_l \qquad [15.28.18]$$

where u_e is determined from Equation 15.27.6 and u_l is the longitudinal turbulence velocity.

The alternative criterion for transition is based on the density difference $\Delta\rho_c$ for the cloud:

$$\Delta\rho_c < \Delta\rho_r \qquad [15.28.19]$$

where $\Delta\rho_r$ is a reference value. The default value of $\Delta\rho_r$ is 10^{-3} Kg/m^3.

Transition occurs at distance x_{tr} with cloud radius R_{tr} and height H_{tr}. Then assuming a Gaussian distribution the dispersion parameters are:

$$\sigma_{ytr} = R_{tr}/2.14 \qquad [15.28.20]$$

$$\sigma_{xtr} = \sigma_{ytr} \qquad [15.28.21]$$

$$\sigma_{ztr} = H_{tr}/2.14 \qquad [15.28.22]$$

Beyond the transition point

$$\sigma_y^2(x) = \sigma_x^2(x) = \sigma_{ytr}^2 + \sigma_{yH}^2(x - x_{tr}) = (R/2.14)^2 \qquad [15.28.23]$$

$$\sigma_z^2(x) = \sigma_{ztr}^2 + \sigma_{zH}^2(x - x_{tr}) = (H/2.14)^2 \qquad [15.28.24]$$

where subscript H denotes the value given by the Hosker scheme.

The concentration distribution in the cloud is assumed to be Gaussian, even though this is not consistent with the gravity spreading treatment. The concentration is

$$X(x,y,z,t) = \frac{m_g}{2^{1/2}\pi^{3/2}\sigma_y^2\sigma_z}\exp\left\{-\frac{y^2 + [x - x(t)]^2}{2\sigma_y^2} - \frac{z^2}{2\sigma_z^2}\right\} \qquad [15.28.25]$$

where $x(t)$ is the distance to the centre of the cloud at time t.

A simplified model is also given. The model has four stages: (1) formation of the source cylinder, (2) gravity slumping, (3) 'ground hugging' and (4) passive dispersion. Stage 1 involves the formation of the source cylinder. In Stage 2, this cylinder undergoes gravity slumping with little air entrainment; zero entrainment is assumed. The growth of the cloud radius R is given by Equation 15.28.3. The criterion for the end of this stage is that slumping terminates when the cloud height H is comparable to that of the roughness elements of the surface. In Stage 3, the growth of the cloud radius R is again given by Equation 15.28.3. The growth of the cloud height H is taken for all stability categories as one-third of that which would occur with dispersion by atmospheric turbulence for stability category F. The criterion for the end of this stage is that given by Equation 15.28.19. In Stage 4, passive dispersion applies.

Further developments of DENZ are described by Jagger (1985 SRD R277). It is shown by Jagger in this latter work that, on certain simplifying assumptions, it is possible to obtain a solution for the dense gas dispersion phase. Noting that

$$\Delta \cdot V = \Delta_o \cdot V_o \qquad [15.28.26]$$

Equation 15.28.3 may be integrated to give

$$t^2 = R_o^2 + 2c_E At \qquad [15.28.27a]$$

with

$$A = \left(\frac{g_o' V_o}{\pi}\right)^{1/2} \qquad [15.28.27b]$$

where Δ is the reduced density difference and the subscript o denotes the initial value. With minimal approximation, Equation 15.28.6 may be integrated and Equation 15.27.6 utilized to give the following solutions:

$$V = \{[B/(10 - C)][R^5 - R_o^5(R/R_o)^{C/2} + V_o^{1/2}(R/R_o)^{C/2}\}^2 \qquad [15.28.28]$$

$$H = \{[B/10 - C][R^4 - R_o^4(R/R_o)^{C/2-1}/\pi^{1/2} + H_o^{1/2}(R/R_o)^{C/2-1}\}^2 \qquad [15.28.29]$$

with

$$B = \alpha u_1^3\pi^{1/2}/6A^3c_E \qquad [15.28.30]$$

$$C = 2\gamma \qquad [15.28.31]$$

where B and C are parameters.

In windless conditions there is no top entrainment and $B = 0$, so that Equations 15.28.28 and 15.28.29 reduce to

$$V = V_o(R/R_o)^C \qquad [15.28.32]$$

$$H = H_o(R/R_o)^{C-2} \qquad [15.28.33]$$

15.28.2 CRUNCH

The CRUNCH model for an instantaneous release of a dense gas, described by Jagger (1983 SRD R229), is based on three simultaneous differential equations for the half-width L of the cloud, the mass m_a of air in the cloud and the temperature T_c of the cloud.

The cloud is assumed to be advected downwind at an advection velocity $\bar{u}(t)$ which corresponds to the mean wind velocity at the half-height of the cloud. This advection velocity is given by

$$u_c = u_r\frac{\ln(\dot{V}/4Lu_cz_o)}{\ln(z_r/z_o)} \qquad [15.28.34]$$

where u_c is the mean velocity of the cloud, u_r is the mean wind velocity at the reference height, V is the volume of the cloud and z_r is the reference height. The reference height z_r is 10 m.

The rate of change in the downwind distance x is equal to the advection velocity u_c:

$$\frac{dx}{dt} = u_c \qquad [15.28.35]$$

For the half-width L of the cloud

$$\frac{dL}{dt} = c_E(g'H)^{1/2} \qquad [15.28.36]$$

The rate of change in the volume V is

$$\dot{V} = 2LHu_c \qquad [15.28.37]$$

Equation 15.28.36 is recast, utilizing Equations 15.28.35 and 15.28.37, in terms of downwind distance x.

$$\frac{\mathrm{d}L}{\mathrm{d}x} = c_{\mathrm{E}}\left(\frac{g'V}{2Lu_{\mathrm{c}}^{3}}\right)^{1/2} \qquad [15.28.38]$$

For the mass of air entrained per unit distance downwind

$$\frac{\mathrm{d}m_{\mathrm{a}}}{\mathrm{d}t} = 2L\,\mathrm{d}x\,\rho_{\mathrm{a}}u_{\mathrm{e}} + 2H\,\mathrm{d}x\,\rho_{\mathrm{a}}w_{\mathrm{e}} \qquad [15.28.39]$$

where m_{a} is the mass of air.

Equation 15.28.39 is recast in terms of x

$$\frac{\mathrm{d}m_{\mathrm{a}}}{\mathrm{d}t} = 2L\rho_{\mathrm{a}}u_{\mathrm{e}} + 2H\rho_{\mathrm{a}}w_{\mathrm{e}} \qquad [15.28.40]$$

The edge entrainment velocity w_{e} is

$$w_{\mathrm{e}} = \gamma\frac{\mathrm{d}L}{\mathrm{d}t} \qquad [15.28.41]$$

Following Cox and Roe, the top entrainment velocity u_{e} is obtained from Equation 15.27.6 using the methods given by these authors for the group (u_1/u_*) and for the turbulence length scale l. For the latter the following relation is quoted:

$$l = 5.88H^{0.48} \qquad [15.28.42]$$

Equation 15.28.40 is recast, utilizing Equation 15.28.41, to maintain it as a function of x only:

$$\frac{\mathrm{d}\dot{m}_{\mathrm{a}}}{\mathrm{d}x} = 2L\rho_{\mathrm{a}}u_{\mathrm{e}} + \gamma\frac{\dot{V}}{L}\rho_{\mathrm{a}}\frac{\mathrm{d}L}{\mathrm{d}x} \qquad [15.28.43]$$

Heat transfer between the ground and the cloud is treated as in DENZ. Then for the temperature T_{c} of the cloud

$$\frac{\mathrm{d}T_{\mathrm{c}}}{\mathrm{d}x} = \frac{1}{\dot{m}_{\mathrm{a}}c_{\mathrm{pa}} + \dot{m}_{\mathrm{g}}c_{\mathrm{pg}}}\left[(T_{\mathrm{a}} - T_{\mathrm{c}})c_{\mathrm{pa}}\frac{\mathrm{d}\dot{m}_{\mathrm{a}}}{\mathrm{d}x} + 2LQ_{\mathrm{gr}}\right] \qquad [15.28.44]$$

where $\dot{m}_{\mathrm{g}}$ is the mass of gas.

Use is also made of the relations

$$\dot{m} = \dot{m}_{\mathrm{a}} + \dot{m}_{\mathrm{g}} \qquad [15.28.45]$$

where $\dot{m}$ is the total mass in the cloud.

$$\dot{m} = 2LH\rho_{\mathrm{c}}u_{\mathrm{c}} \qquad [15.28.46]$$

$$\dot{V} = \frac{T_{\mathrm{c}}\dot{m}_{\mathrm{a}}}{\rho_{\mathrm{a}}T_{\mathrm{a}}} + \frac{T_{\mathrm{c}}\dot{m}_{\mathrm{g}}}{\rho_{\mathrm{g}}T_{\mathrm{g}}} \qquad [15.28.47]$$

$$\rho_{\mathrm{c}} = \frac{\dot{m}_{\mathrm{a}} + \dot{m}_{\mathrm{g}}}{\dot{V}} \qquad [15.28.48]$$

For transition from dense gas dispersion, use is made of two alternative criteria, which correspond to those in DENZ. For the first criterion the first condition is

$$\frac{\mathrm{d}L}{\mathrm{d}x} < 2.14\frac{\mathrm{d}\sigma_y}{\mathrm{d}x} \qquad [15.28.49]$$

and the second condition is that given in relation 15.28.18. The alternative criterion is that given in relation 15.28.19.

Transition occurs at downwind distance x_{tr} with cloud half-width L_{tr} and height H_{tr}. Then, assuming a Gaussian profile, the dispersion parameters are

$$\sigma_{y\mathrm{tr}} = L_{\mathrm{tr}}/2.14 \qquad [15.28.50]$$

$$\sigma_{y\mathrm{tr}} = H_{\mathrm{tr}}/2.14 \qquad [15.28.51]$$

For the dispersion beyond the transition point the approach used is to utilize two separate virtual sources at locations $x_{\mathrm{v}y}$ and $x_{\mathrm{v}z}$ for crosswind and vertical dispersion, respectively, as shown in Figure 15.80 where $x_{\mathrm{v}y}$ is upwind of the source, whilst $x_{\mathrm{v}z}$ is downwind of it. The determination of these two points is as follows. Use is made of the relations

$$\sigma_{y\mathrm{H}}(X_{\mathrm{v}y}) = \sigma_{y\mathrm{tr}} \qquad [15.28.52]$$

$$\sigma_{z\mathrm{H}}(X_{\mathrm{v}z}) = \sigma_{z\mathrm{tr}} \qquad [15.28.53]$$

where subscript H is the value given by the Hosker scheme. Since this scheme gives σ values which are a function of x, the solution is a trial-and-error one. Beyond the transition point the dispersion is determined using the virtual source at $x_{\mathrm{v}y}$ for the crosswind dispersion and the virtual source at $x_{\mathrm{v}z}$ for the vertical dispersion and with σ values from the Hosker scheme.

The concentration distribution in the cloud is assumed to be Gaussian. The concentration χ is

$$\chi(x,y,z) = \frac{\dot{m}_{\mathrm{g}}}{\pi\sigma_y\sigma_z u_{\mathrm{c}}}\exp\left[-\left(\frac{y^2}{2\sigma_y^2} + \frac{z^2}{2\sigma_z^2}\right)\right] \qquad [15.28.54]$$

On certain simplifying assumptions, it is possible to obtain a solution for the dense gas dispersion phase. One case considered is that in which it is assumed that the advection velocity of the cloud is constant and that the cloud is at ambient temperature, so that heat effects can be neglected. For this case

$$\frac{\mathrm{d}L}{\mathrm{d}x} = A(Lu_{\mathrm{c}}^{3})^{-1/2} \qquad [15.28.55]$$

$$\frac{\mathrm{d}\dot{m}_{\mathrm{a}}}{\mathrm{d}x} = BL(\dot{m}_{\mathrm{a}} + C) + \left[\gamma(\dot{m}_{\mathrm{a}} + C)/L\frac{\mathrm{d}L}{\mathrm{d}x}\right] \qquad [15.28.56]$$

with

$$A = c_{\mathrm{E}}[g\dot{m}_{\mathrm{g}}(1 - \rho_{\mathrm{a}}/\rho_{\mathrm{g}})/2\rho_{\mathrm{a}}]^{1/2} \qquad [15.28.57]$$

$$B = 2\rho_{\mathrm{a}}\alpha u_1^{3}/gl\dot{m}_{\mathrm{g}}(1 - \rho_{\mathrm{a}}/\rho_{\mathrm{g}}) \qquad [15.28.58]$$

$$C = \frac{\dot{m}_{\mathrm{g}}\rho_{\mathrm{a}}}{\rho_{\mathrm{g}}} \qquad [15.28.59]$$

Integration of Equation 15.28.55 gives

$$L = X^{2/3} \qquad [15.28.60]$$

with

$$X = L_{\mathrm{o}}^{3/2} + A'x \qquad [15.28.61]$$

$$A' = \tfrac{3}{2}Au_{\mathrm{c}}^{-3/2} \qquad [15.28.62]$$

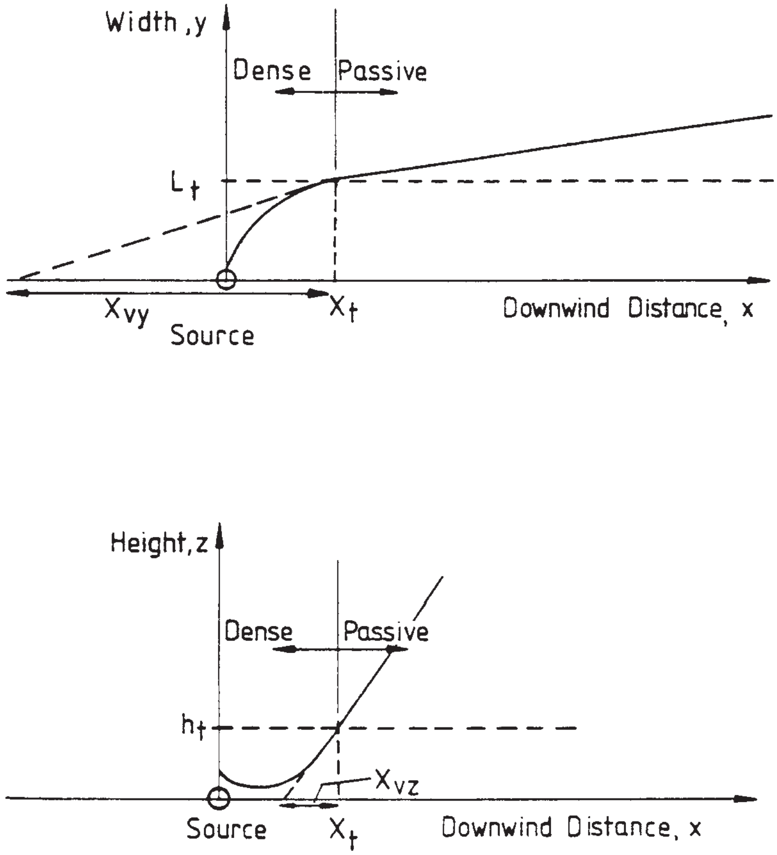

Figure 15.80 *CRUNCH model for dense gas disperion – transition from dense gas to passive dispersion (Dagger, 1983 SRD R229) h, X and subscript t in the figure are denoted in the text by H, x and subscript tr, respectively (Courtesy of the UKAEA Safety and Reliability Directorate)*

where L_o is the half-width of the cloud at the source. Substitution of Equation 15.28.60 in Equation 15.28.56 and integration gives

$$\dot{m}_a = C\{X^{(2/3)\gamma} \exp[3B(X^{5/3} - L_o^{5/2})/5A']/L_o^{\gamma} - 1\} \qquad [15.28.63]$$

For short downwind distances Equation 15.28.63 reduces to

$$\dot{m}_a = \frac{CX^{(2/3)\gamma}}{L_o^{\gamma}} \qquad [15.28.64]$$

A derivation is also given for the case where the advection velocity of the cloud is variable.

15.28.3 Validation and application

Kaiser and Walker (1978) have given a rough comparison of the predictions from their model with the observed clouds in the ammonia release incidents at Potchefstroom in 1973 and Houston in 1976; a further discussion has been given by Fryer and Kaiser (1979 SRD R152). Jagger (1985 SRD R277) has discussed the calibration of DENZ against the van Ulden trial and the Porton Down trials. Jagger (1983 SRD R229) has also compared predictions of CRUNCH for the cloud shape in the SS Gadila trials as shown in Figure 15.92(b).

DENZ and CRUNCH have been widely used. The Second *Canvey Report* gave hazard ranges computed from DENZ and more detailed relations for hazard ranges based on DENZ and CRUNCH have been given by Considine and Grint (1985), as described in Section 15.49. CRUNCH has been used by McQuaid and Fitzpatrick (1983) to model the dispersion of dense gas by a water spray barrier.

15.29 Dispersion of Dense Gas: SIGMET

Most of the early models were box models. Some of these have just been described. The early models also included, however, several if-theory models. Of these, the SIGMET model was particularly influential in the development of the subject.

15.29.1 SIGMET

SIGMET was developed by Science Applications Inc. (SAI) for the US Coast Guard (USCG). It has been described by England *et al.* (1978), and evaluated by Havens, who also gives a description (Havens, 1982a).

The model is intended for investigating the dispersion of a large spill of LNG onto water. The starting point of the model is the set of hydrodynamic equations. In applying these to dense gas dispersion, where the cloud is wide but shallow, a simplification is made which eliminates the equation for the vertical velocity. The governing equations are

$$\frac{\partial(\pi u)}{\partial t}+\frac{\partial(u\pi u)}{\partial x}+\frac{\partial(v\pi u)}{\partial y}+\frac{\partial(\dot{\sigma}\pi u)}{\partial\sigma}+\left(\frac{\partial\phi}{\partial x}+\frac{\sigma}{\rho}\frac{\partial\pi}{\partial x}\right)=0 \qquad [15.29.1]$$

$$\frac{\partial(\pi v)}{\partial t}+\frac{\partial(u\pi v)}{\partial x}+\frac{\partial(v\pi v)}{\partial y}+\frac{\partial(\dot{\sigma}\pi v)}{\partial\sigma}+\left(\frac{\partial\phi}{\partial y}+\frac{\sigma}{\rho}\frac{\partial\pi}{\partial y}\right)=0 \qquad [15.29.2]$$

$$\frac{\partial(\pi h)}{\partial t}+\frac{\partial(u\pi h)}{\partial x}+\frac{\partial(v\pi h)}{\partial y}+\frac{\partial(\dot{\sigma}\pi h)}{\partial\sigma}+\frac{\pi\omega}{\rho}=0 \qquad [15.29.3]$$

$$\frac{\partial(\pi c)}{\partial t}+\frac{\partial(u\pi c)}{\partial x}+\frac{\partial(v\pi c)}{\partial y}+\frac{\partial(\dot{\sigma}\pi c)}{\partial\sigma}=0 \qquad [15.29.4]$$

$$\frac{\partial(\pi)}{\partial t}+\frac{\partial(u\pi)}{\partial x}+\frac{\partial(v\pi)}{\partial y}+\frac{\partial(\dot{\sigma}\pi)}{\partial\sigma}=0 \qquad [15.29.5]$$

with

$$\sigma=\frac{p-p_{\mathrm{t}}}{\pi} \qquad [15.29.6]$$

$$\pi=p_{\mathrm{s}}-p_{\mathrm{t}} \qquad [15.29.7]$$

$$\phi=gz \qquad [15.29.8]$$

where c is the concentration (mass fraction), h is the specific enthalpy, p is the pressure at a given height, p_{s} is the pressure at the surface, p_{t} is the pressure at the top, T is the absolute temperature, ρ is the density, σ is a dimensionless pressure coordinate, ϕ is the geopotential height, w is the substantial pressure derivative, and u, v and ω are the components of the velocity in the alongwind, crosswind and vertical directions, respectively, σ is the substantial derivative in x, y, σ, t coordinates. The sigma coordinate takes the values $\sigma = 0$ at the top and $\sigma = 1$ at the surface.

The hydrostatic relation is

$$\frac{\mathrm{d}z}{\mathrm{d}\sigma}=-\frac{\pi}{g\rho} \qquad [15.29.9]$$

The following supplementary equations are used:

$$h=[c_{\mathrm{pa}}(1-c)+c_{\mathrm{pg}}c]T+WL_{\mathrm{o}}(1-c)f(T) \qquad [15.29.10]$$

$$w=\pi\dot{\sigma}+\sigma\left(\frac{\partial\pi}{\partial t}+u\frac{\partial\pi}{\partial x}+v\frac{\partial\pi}{\partial x}\right) \qquad [15.29.11]$$

where L_{o} is the latent heat of vaporization of water, W is the mass of water per unit mass of air, and the subscripts a and g denote air and gas, respectively.

These equations, which are the set given by England *et al.*, describe the fluid dynamic and thermodynamic processes but do not include the effects of turbulence. Corresponding equations incorporating the turbulence terms, including the eddy diffusivities, are given by Havens. He also gives a diagram showing the boundary conditions for solution of the model equations.

The eddy diffusivities required in the submodel for turbulent mass, momentum and energy transfer, as described by Havens, are obtained as follows.

For the horizontal eddy diffusivities the Reynolds analogy is assumed and the eddy diffusivities for turbulent momentum, mass and energy transfer are taken as equal and are denoted by K_{h}. The vertical diffusivities are likewise assumed equal and are denoted K_{v}. The relation for the vertical diffusion coefficient is

$$K_{\mathrm{v}}=0.45\sigma_{\epsilon}ul \quad u\geq 1\ \mathrm{m/s} \qquad [15.29.12a]$$

$$\phantom{K_{\mathrm{v}}}=0.45\sigma_{\epsilon}l \quad u<1\ \mathrm{m/s} \qquad [15.29.12b]$$

where l is turbulence length scale and σ_{ϵ} is the standard deviation of the wind direction. Tabulated values of l and σ_{ϵ} are given by England *et al.* and a plot for K_{h} is given by Havens. The diffusion coefficient K_{h} is obtained from the vertical diffusion coefficient K_{v} using values of the ratio $K_{\mathrm{h}}/K_{\mathrm{v}}$. Havens gives for this ratio the values shown in Table 15.43, which evidently supersede the table of values given by England *et al.*

Other submodels are those for heat transfer and momentum transfer from the surface to the cloud. For heat transfer

$$q=U(T_{\mathrm{s}}-T_{\mathrm{c}}) \qquad [15.29.13]$$

where q is the heat flux, T_{c} is the temperature of cloud, T_{s} is the temperature of the surface and U is the heat transfer coefficient. The value used for U is 20.4 $\mathrm{W/m^2\,K}$. For momentum transfer

$$\tau_{\mathrm{o}}=C_{\mathrm{d}}\rho u^2 \qquad [15.29.14]$$

where C_{d} is the drag coefficient, u is the velocity and τ_{o} is the shear stress at the surface. The velocity u is that at 1 m height. The value of C_{d} is 0.001.

SIGMET incorporates a source submodel for the spillage of LNG on water. The source is assumed to be a cylindrical pool. The pool radius is determined from the density intrusion model given by Equation 15.24.21. The pool radius is allowed to grow, with a corresponding decrease in height, until a depth is reached at which break-up occurs. After pool break-up, the evaporation rate is determined by the empirical correlation of Feldbauer *et al.* (1972):

$$\dot{m}=\dot{m}_{\max}\exp\left[\frac{0.04}{\rho_{\mathrm{l}}H_{\min}}(t-t_{\max})\right] \qquad [15.29.15]$$

where $H_{\min}$ is the height at break up, $\dot{m}$ is the mass rate of evaporation, $\dot{m}_{\max}$ is the mass rate of evaporation at break-up, t is time, $t_{\max}$ is the time at break-up and ρ_{l} is the density of the liquid.

***Table 15.43** Ratio of horizontal to vertical diffusion coefficients (Havens, 1982a) (Courtesy of Elsevier Science Publishers)*

Stability category	$K_{\mathrm{h}}/K_{\mathrm{v}}$
D	1.0
E	10.0
F	25.0

15.29.2 Validation and application

England *et al.* (1978) give comparisons of the prediction of SIGMET with results of the American Gas Association LNG dispersion trials. They also use SIGMET to simulate an instantaneous spillage of 30,000 m^3 of LNG onto water.

An assessment of SIGMET has been carried out by Havens (1982a), who studied the somewhat similar case of a 25,000 m^3 LNG spill and performed a sensitivity analysis, investigating the effect of spill size, wind velocity and atmospheric stability, and made comparisons between the distance to the lower flammability limit for this dense gas and for a neutrally buoyant gas.

SIGMET, in the version SIGMET-N, was one of four models in a comparative evaluation of models by Havens and co-workers (Havens, 1986; Havens, Spicer and Schreurs, 1987), the other models being ZEPHYR, MARIAH-II and FEM3. SIGMET-N was discarded because the turbulent mixing model did not scale properly and because of the difficulty of controlling numerical 'diffusion'.

15.30 Dispersion of Dense Gas: SLAB and FEM3

A pair of models have been developed at the Lawrence Livermore National Laboratory (LLNL) by Chan, Ermak and coworkers (Ermak, Chan *et al.*, 1982; S.T. Chan, Rodean and Ermak, 1984; Ermak and Chan, 1986, 1988; S.T. Chan, Ermak and Morris, 1987). SLAB is an advanced similarity model and FEM3 a full three-dimensional model.

15.30.1 SLAB

SLAB was originally formulated by Zeman (1982a,b) and its development has been described by Ermak, Chan *et al.* (1982), D.L. Morgan, Kansa and Morris (1984) and Ermak and Chan (1986, 1988).

The SLAB model is for a continuous release. It is a slab model with properties averaged in the horizontal and vertical directions and is thus one dimensional. The model is based on a set of six simultaneous differential equations, for the conservation of total mass, conservation of the material released, conservation of momentum and conservation of energy. These equations are given by Ermak, Chan *et al.* (1982) as a set of six partial differential equations, in time *t* and downwind distance *x*, but subsequently by Ermak and Chan (1986) as six ordinary differential equations in *x*. The latter are

$$\frac{\mathrm{d}(Bhu_c\rho_c)}{\mathrm{d}x} = B_o u_o \rho_o + (Bu_e + hw_e)\rho_a \qquad [15.30.1]$$

$$\frac{\mathrm{d}(Bhu_c p_c \omega)}{\mathrm{d}x} = B_o u_o \rho_o \qquad [15.30.2]$$

$$\frac{\mathrm{d}(Bhu_c\rho_c c_{pc} T_c)}{\mathrm{d}x} = B_o u_o \rho_o c_{po} T_o + (Bu_e + hw_e)\rho_a c_{pa} T_a + Q_{gr} \qquad [15.30.3]$$

$$\frac{\mathrm{d}(Bhu_c^2\rho_c)}{\mathrm{d}x} = -\tfrac{1}{2}[Bh^2(\rho_c - \rho_a)]g + (Bu_e + hw_e)\rho_a u \qquad [15.30.4]$$

$$\frac{\mathrm{d}(Bhu_c u_y \rho_c)}{\mathrm{d}x} = h^2(\rho_c - \rho_a)g \qquad [15.30.5]$$

$$\frac{\mathrm{d}B}{\mathrm{d}x} = \frac{u_y + w_e}{u_c} \qquad [15.30.6]$$

where B is a cloud width parameter, c_p is the specific heat, h is a cloud height parameter, Q_{gr} is the heat flux between the ground and the cloud, T is the absolute temperature, u is the wind velocity, u_c is the velocity of the cloud in the downwind direction, u_e is the vertical entrainment velocity, u_o is the velocity of material at the source, u_y is the velocity of the cloud in the crosswind direction, w_e is the horizontal entrainment rate, ρ is the density, w is the mass fraction of material released and subscripts a, c and o denote the air, cloud and source, respectively.

The following supplementary equation is used:

$$\rho_c T_c = \frac{\rho_a T_a M_o}{M_o + (M_a - M_o)\omega} \qquad [15.30.7]$$

where M is molecular weight.

The vertical entrainment velocity u_e is taken as

$$u_e = \frac{2.7ku^*}{\phi(\mathrm{Ri})} \qquad [15.30.8]$$

where k is the von Karman constant and ((Ri) is the Monin–Obukhov profile function given by Dyer (1974).

The profile function ϕ is

$$\phi = 1 + 5\mathrm{Ri} \qquad \mathrm{Ri} > 0 \qquad [15.30.9a]$$

$$\phi = (1 - 16\mathrm{Ri})^{-p'} \qquad \mathrm{Ri} < 0 \qquad [15.30.9b]$$

where Ri is a Richardson number and p' is an index. The index p' is 1/4 for momentum and 1/2 for species and energy. The horizontal entrainment velocity w_e was given in the earlier versions (Ermak, Chan *et al.,* 1982) as

$$w_e = (1.8)^2(h/B)u_e \qquad [15.30.10]$$

where the term (h/B) implies that at low values of the height the horizontal entrainment rate is low but that it increases as the height increases. In the later version (Ermak and Chan, 1986, 1988) w_e is described as a function of the ground surface friction coefficient and of the Monin–Obukhov length.

The profile of the volumetric concentration C is represented as

$$C(x,y,z) = C(x)C_1(y)C_2(z) \qquad [15.30.11]$$

where C is the volumetric concentration and $C(x)$, $C_1(y)$, $C_2(z)$ are concentration functions. These functions are

$$C(x) = \frac{M_a\omega}{M_o + (M_a - M_o)\omega} \qquad [15.30.12]$$

$$C_1(y) = \frac{1}{4b}\left[\mathrm{erf}\left(\frac{y+b}{2^{1/2}\beta}\right) - \mathrm{erf}\left(\frac{y-b}{2^{1/2}\beta}\right)\right] \qquad [15.30.13]$$

$$C_2(z) = \frac{1}{h}\left(\frac{6}{h}\right)^{1/2}\exp\left(-\frac{3z^2}{2h^2}\right) \qquad [15.30.14]$$

with

$$B^2 = b^2 + 3\beta^2 \qquad [15.30.15]$$

where ω is the mass fraction and b and β are shape parameters. The variation of B with x is given by

Equation 15.30.6, and the variation of b with x is given by

$$\frac{\mathrm{d}b}{\mathrm{d}x} = \frac{bu_y}{Bu_\mathrm{c}} \qquad [15.30.16]$$

The horizontal concentration profile is uniform when $\beta = 0$ and approaches a Gaussian one as $\beta \gg b$. The ratio of β to b remains constant under the influence of the horizontal velocity u_y. It is the horizontal entrainment rate w_e which causes an increase in β and results in a crosswind Gaussian profile.

The cloud shape parameters B, b and h are defined by Equations 15.30.15, 15.30.13 and 15.30.14, and are related to the velocities u_y, w_e and u_e by Equations 15.30.6, 15.30.16 and 15.30.2. The parameters B and h are related to the dispersion parameters as follows:

$$\sigma_y^2 = 3B^2 \qquad [15.30.17]$$

$$\sigma_z^2 = 3h^2 \qquad [15.30.18]$$

15.30.2 FEM3

Accounts of FEM3 have been given by Ermak, Chan *et al.* (1982), S.T. Chan and Ermak (1984), S.T. Chan, Rodean and Ermak (1984) and Ermak and Chan (1986, 1988).

The FEM3 model is also for a continuous release. It is a full three-dimensional model. The model is based on a set of four simultaneous differential equations, in terms of tensor quantities, for the conservation of total mass, conservation of the material released, conservation of momentum and conservation of energy. The equations are

$$\nabla \cdot (\rho_\mathrm{c}\mathbf{u}) = 0 \qquad [15.30.19]$$

$$\frac{\partial(\rho_\mathrm{c}\mathbf{u})}{\partial t} + \rho_\mathrm{c}\mathbf{u}\cdot\nabla\mathbf{u} = -\nabla p + \nabla\cdot(\rho_\mathrm{c}\mathbf{K}^m\cdot\nabla\mathbf{u}) + (\rho_\mathrm{c} - \rho_\mathrm{h})\mathbf{g} \qquad [15.30.20]$$

$$\frac{\partial\theta}{\partial t} + \mathbf{u}\cdot\nabla\theta = \nabla\cdot(\mathbf{K}^\theta\cdot\nabla\theta) + \frac{c_\mathrm{pg} - c_\mathrm{pa}}{c_\mathrm{pc}}(\mathbf{K}^\omega\cdot\nabla\omega)\cdot\nabla\theta + S \qquad [15.30.21]$$

$$\frac{\partial\omega}{\partial t} + \mathbf{u}\cdot\nabla\omega = \nabla\cdot(\mathbf{K}^\omega\cdot\nabla\omega) \qquad [15.30.22]$$

with

$$\mathbf{u} = (u, v, \omega) \qquad [15.30.23]$$

$$\rho_\mathrm{c} = \frac{M_\mathrm{g}M_\mathrm{a}P}{RT[M_\mathrm{g} + (M_\mathrm{a} - M_\mathrm{g})\omega]} \qquad [15.30.24]$$

$$c_\mathrm{pc} = c_\mathrm{pa}(1-\omega) + c_\mathrm{pg}\omega \qquad [15.30.25]$$

where p is the pressure deviation from an adiabatic atmosphere at rest with corresponding density ρ_h, P is the absolute pressure, S is the temperature source term (e.g. latent heat), θ is the potential temperature deviation from an adiabatic atmosphere, ω is the mass fraction of material released, $\mathbf{g}$ is the acceleration due to gravity, $\mathbf{K}^m$, $\mathbf{K}^\theta$ and $\mathbf{K}^\omega$ are the diagonal eddy diffusion tensors for the momentum, energy and mass fraction, respectively, $\mathbf{u}$ is a velocity tensor, and subscript $\mathbf{g}$ denotes material released. The numerical solution of these equations has been described by S.T. Chan, Rodean and Ermak (1984).

FEM3 is based on a generalized anelastic approximation, adapted from Ogura and Phillips (1962), which allows large density changes to be handled whilst precluding sound waves. The approximation is the use of Equation 15.30.19 instead of

$$\nabla\cdot(\rho_\mathrm{c}\mathbf{u}) + \frac{\partial\rho_\mathrm{c}}{\partial t} = 0 \qquad [15.30.26]$$

In FEM3 turbulence is treated using the if-theory approach. The eddy diffusion tensors are associated with three diffusion coefficients, two horizontal and one vertical. The latter is particularly important. In the earlier versions (Ermak, Chan *et al.*, 1982) the vertical diffusion coefficient K_v was taken as

$$K_\mathrm{v} = K_\mathrm{a}(1-\omega) + K_\rho\omega \qquad [15.30.27]$$

where K_a is the ambient vertical diffusion coefficient, K_v is the vertical diffusion coefficient and K_ρ is a dense-layer diffusion coefficient. Two submodels were used for K_ρ, one based on a Richardson number and one on a mixing length.

In the later versions (Ermak and Chan, 1988) three submodels are given for the vertical diffusion coefficient. In the first submodel

$$K_\mathrm{v} = \frac{k[(u_{*\mathrm{c}}z)^2 + (\omega_{*\mathrm{c}}h)^2]^{1/2}}{\phi(\mathrm{Ri})} \qquad [15.30.28]$$

with

$$u_{*\mathrm{c}} = u^*|u_\mathrm{c}/u| \qquad [15.30.29]$$

where u_* is the friction velocity, $u_{*\mathrm{c}}$ is the cloud friction velocity, $w_{*\mathrm{c}}$ is a cloud 'convection velocity' and $\phi(\mathrm{Ri})$ is the Monin–Obukhov profile function. The cloud convection velocity is a function of the temperature difference between the ground and the cloud.

The horizontal diffusion coefficient K_h is taken as

$$K_\mathrm{h} = \frac{\beta^* k u_{*\mathrm{c}} z}{\phi} \qquad [15.30.30]$$

where β^* is an empirical coefficient. The value of β^* is taken as 6.5.

15.30.3 Validation and application

Ermak, Chan and coworkers (Ermak, Chan *et al.*, 1982; S.T. Chan, Rodean and Ermak, 1984; Ermak and Chan, 1986; Koopman, Ermak and Chan, 1989) compared predictions from SLAB and FEM3 with observations from the Burro trials. D.L. Morgan, Kansa and Morris (1984) have compared the predictions of SLAB with observations from the Burro and Coyote trials and Blewitt, Yohn and Ermak (1987) have compared its predictions with observations from the Goldfish trials. Touma *et al.* (1991) have compared the performance of this model with that of other models in relation to the Burro, Desert Tortoise and Goldfish trials.

15.31 Dispersion of Dense Gas: HEGADAS and Related Models

A series of models have been developed by Shell, leading to the model HEGADAS and then to the model system

HGSYSTEM. The first of these models was that of Te Riele (1977), which was followed by the model of Colenbrander (1980) and then HEGADAS itself. HEGADAS is complemented by the front-end model HEGABOX.

Another major model, DEGADIS, developed by Havens and coworkers is based on HEGADAS.

15.31.1 Te Riele model

The model described by Te Riele (1977) is for a continuous release. It is based on two simultaneous partial differential equations for conservation of mass and of momentum. The assumption is made that the take-up of material into the ambient flow field and the dispersion of material within this field are independent. Other assumptions are the Reynolds analogy and the Boussinesq approximation. The basic equations are:

$$\frac{\partial \rho u}{\partial x} = \frac{\partial}{\partial y}\left(K_y \frac{\partial \rho}{\partial y}\right) + \frac{\partial}{\partial z}\left(K_z \frac{\partial \rho}{\partial z}\right) \qquad [15.31.1]$$

$$\frac{\partial \rho u^2}{\partial x} = \frac{\partial}{\partial y}\left(K_y \frac{\partial \rho u}{\partial y}\right) + \frac{\partial}{\partial z}\left(K_z \frac{\partial \rho u}{\partial z}\right) \qquad [15.31.2]$$

where K is the eddy diffusion coefficient, u is the wind speed, ρ is the density of the cloud and subscripts x and y denote in the downwind and crosswind directions, respectively.

The assumption that the wind speed is independent of the take-up of material, the presence of the dense gas layer and the density gradients in the ambient flow field gives

$$\frac{\partial u}{\partial x} = \frac{\partial u}{\partial y} = 0 \qquad [15.31.3]$$

It can be shown from Equations 15.31.1–15.31.3 that

$$K_z = \frac{\rho_a \tau_o}{\rho^2}\left(\frac{\partial u}{\partial x}\right)^{-1} \qquad [15.31.4]$$

where τ_o is the shear stress acting on the upwind ground surface, and subscript a denotes air. Then from Equation 15.31.4 it is possible to derive the shear stress acting on the top of the plume, which gives

$$\tau_{gr} = \frac{\rho_a}{\rho_{gr}}\tau_o \qquad [15.31.5]$$

where ρ_{gr} is the density downwind and τ_{gr} is the shear stress acting on the downwind ground surface.

For the relation between density and concentration it is assumed that the ambient air and the dense gas are ideal gases with the same molecular specific heats and that equalization of temperature and density occur only through convection originating in atmospheric turbulence. Then

$$\frac{c}{\rho} = \frac{1}{\rho_a + (1 - \rho_a/\rho_g)} \qquad [15.31.6]$$

where c is the concentration (mass per unit volume) and subscript g denotes material released.

The prime purpose of the model is to determine concentrations downwind of an area source such as that from an evaporating pool of liquefied gas. This source is modelled as a rectangular area source of length L_s and half-width B_s and mass rate of release per unit area Q''. Figure 15.81 shows the general form of the model, in the later version HEGADAS.

For the concentration profile it is assumed that there is a middle part of half-width b in which the dispersion occurs in the vertical direction but not in the horizontal direction. The width of this middle part reduces due to mixing at the crosswind edges of the plume and thus decreases from a value of $2B$ at the source to zero at some point downwind. A concentration profile is assumed which in the vertical direction is Gaussian throughout but which in the crosswind direction has Gaussian features at the crosswind edges, but becomes fully Gaussian only when the middle part disappears:

$$\frac{c}{c_A} = \exp\left[-\left(\frac{z}{\sigma_z}\right)^s\right] \qquad |y| < b \qquad [15.31.7a]$$

$$\frac{c}{c_A} = \exp\left[-\left(\frac{|y| - b}{\sigma_y}\right)^r - \left(\frac{z}{\sigma_z}\right)^s\right] \qquad |y| \geq b \qquad [15.31.7b]$$

where c_A is the ground level concentration on the centre line, and r and s are shape factors for the crosswind and vertical concentration profiles, respectively.

This approach ensures a seamless transfer from the dense gas dispersion regime to the passive dispersion regime and avoids the need to define a transition point and to use separate models for the two regimes.

From Equations 15.31.1–15.31.4 and 15.31.6 the integral form of the mass and momentum balances can be derived:

$$\int_0^{y_{Ls}}\left[\frac{\partial}{\partial x}\left(\int_0^\infty cu\,\mathrm{d}z\right)\right]\mathrm{d}y = \left(\int_0^\infty K_y \frac{\partial c}{\partial y}\mathrm{d}z\right)_{y=y_{Ls}} + \int_0^{y_{Ls}} Q\,\mathrm{d}y \qquad [15.31.8]$$

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\int_0^\infty \int_0^\infty cu^2\,\mathrm{d}y\,\mathrm{d}x\right) = \int_0^\infty \frac{c_{gr}}{\rho_{gr}}\tau_o\,\mathrm{d}y \qquad [15.31.9]$$

where the subscript gr denotes ground level.

Equation 15.31.8 is used with three different values of the limit y_{Ls}. These are:

Total mass balance: $y_{Ls} \rightarrow \infty$
Mass balance on middle part: $y_{Ls} < b;\ b > 0$
Mass balance for determination of σ: $y_{Ls} = b + 0.5(2)^{1/2}\sigma_y$

This therefore gives a set of four equations, the three versions of Equations 15.31.8 and 15.31.9, which are used to determine the four variables c_A, b, σ_y and σ_z.

The parameters necessary for this model include: the wind velocity u; the shape parameters r and s; the vertical eddy diffusion coefficient K_y; the upstream shear stress τ_o; and the mass rate of release per unit area Q''.

Wind velocity

For the wind velocity u use is made of the vertical wind velocity profile given in Equation 15.24.6 in the form

$$u = u_r\left(\frac{z}{z_r}\right)^{\alpha'} \qquad [15.31.10]$$

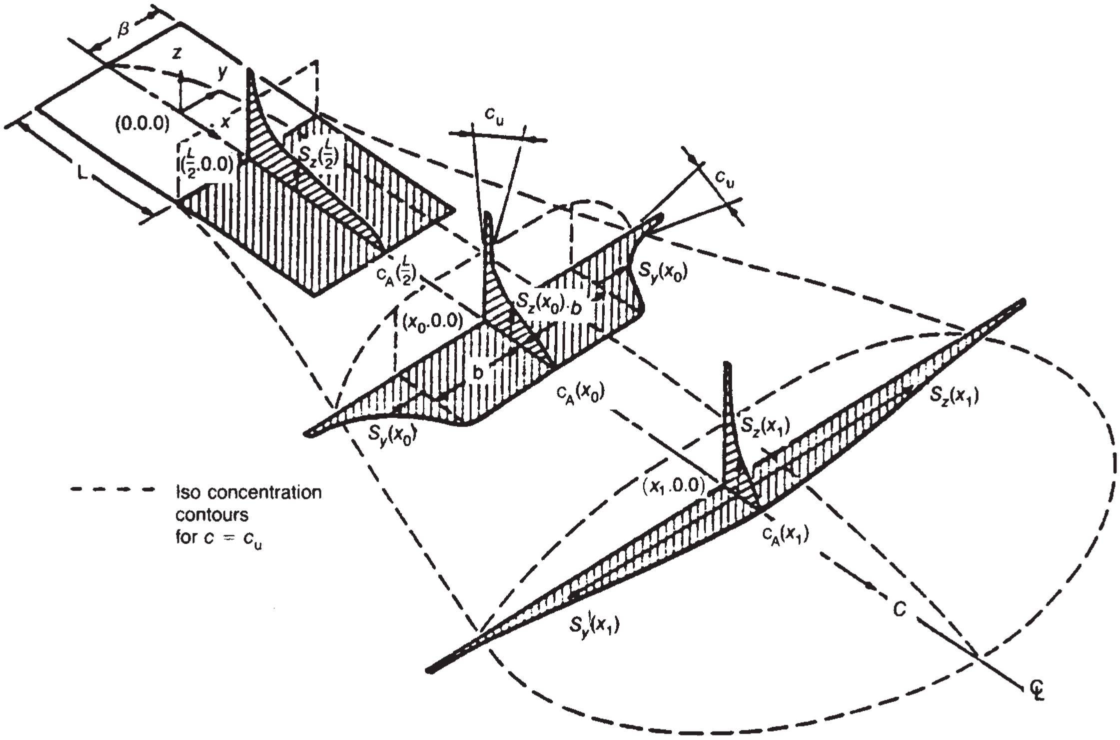

Figure 15.81 HEGADAS model for dense gas dispersion – idealized cloud shapes (Puttock, 1987c) (Courtesy of the American Institute of Chemical Engineers)

where u_r is the wind speed at reference height z_r and α' is an index. For the friction velocity use is made of Equation 15.24.7.

Shape parameters and eddy crosswind diffusivity

The parameters r, s and K_y are obtained by applying Equations 15.31.1, 15.31.4, 15.31.6 and 15.31.10 to the case of a point source with release of a neutrally buoyant gas ($b = 0, \rho = \rho_a$). This yields

$$r = 2 \qquad [15.31.11a]$$

$$s = 1 + 2\alpha \qquad [15.31.11b]$$

$$K_y = K_o^* \left(\frac{W_b}{B_s}\right)^{\gamma'} \left(\frac{z}{z_r}\right)^{\alpha'} \qquad [15.31.12]$$

with

$$K_o^* = \left[\frac{\delta'(\pi)^{1/2}}{2B_s}\right]^{1/\beta'} \frac{2B_s^2 u_r \beta'}{\pi} \qquad [15.31.13]$$

$$W_b = b + \frac{\pi^{1/2}}{2}\sigma_y \qquad [15.31.14]$$

$$\gamma' = 2 - 1/\beta' \qquad [15.31.15]$$

where K_o^* is the vertical eddy diffusion coefficient at reference height z_r acting on a concentration profile of width $2B$, W_b, is the half-width of the crosswind concentration profile, and β', γ and δ' are constants. The constants β' and δ' are obtained from the relation for the crosswind dispersion coefficient for a point source:

$$\sigma_y = \delta' x \beta' \qquad [15.31.16]$$

Table 15.44 gives the values of the shape parameter α' for the wind velocity profile given by Te Riele. The parameters β' and δ' are obtained from Equation 15.31.16, which corresponds in general form to a number of correlations for the crosswind dispersion coefficient.

Shear stress

For the shear stress τ_o the relation used is

$$\tau_o = 0.16 \frac{\rho_a u_r^2}{\ln^2(z_r/z_o)} \qquad [15.31.17]$$

where z_o is the roughness length.

Take-up flux

For the flux of material taken up into the ambient atmosphere, or take-up flux, Q″ there is a certain maximum value

Table 15.44 *Wind velocity profile shape parameter (after Te Riele, 1977) (Courtesy of DECHEMA)*

Stability category	*Shape parameter, α'*
A	0.02
B	0.05
C	0.09
D	0.14
E	0.20
F	0.28

Q''_{max}. This maximum value is obtained from Equation 15.31.5 which yields

$$\tau_{\mathrm{gr}} = Q''_{\mathrm{max}} \frac{\int_{\mathrm{o}}^{\infty} cu \, \mathrm{d}z}{\int_{\mathrm{o}}^{\infty} c \, \mathrm{d}z} \qquad [15.31.18]$$

Then the value of Q″ is given by

$$Q'' = Q''_{\mathrm{o}} \quad Q''_{\mathrm{max}} > Q''_{\mathrm{o}} \qquad [15.31.19a]$$

$$= Q''_{\mathrm{max}} \quad Q''_{\mathrm{max}} \leq Q''_{\mathrm{o}} \qquad [15.31.19b]$$

where Q''_{o} is the mass flux of material from the source.

The model consists of Equations 15.31.8 and 15.31.9 with the supplementary Equations 15.31.6, 15.31.7 and 15.31.10–15.31.12 together with the three values of the integration limit y_{Ls}. It yields the four parameters c_{A}, b, σ_y and σ_z.

The dimensionless groups which govern dense gas dispersion are given as:

$$\alpha'; \quad \gamma'; \quad \frac{Q''L_{\mathrm{s}}}{\rho_{\mathrm{g}} u_{\mathrm{r}} z_{\mathrm{r}}}; \quad \frac{\tau_{\mathrm{o}} L_{\mathrm{s}}}{\rho_{\mathrm{g}} u_{\mathrm{r}}^2 z_{\mathrm{r}}}; \quad \frac{K_{\mathrm{o}}^* L_{\mathrm{s}}}{B_{\mathrm{s}}^2 u_{\mathrm{r}}}; \quad \frac{\rho_{\mathrm{g}}}{\rho_{\mathrm{a}}}$$

15.31.2 Colenbrander steady-state model

The further development of the Te Riele model has been described by Colenbrander (1980). The principal features which he describes are developments in: the source term; the treatment of the four parameters – centreline concentration c_{A} half-width of the middle part b, cross-wind dispersion parameter S_y and vertical dispersion parameter S_z; and in the criterion for transition to passive dispersion.

Source term

An evaporating pool may generate above itself a gas blanket. The condition for formation of such a gas blanket is that the rate of vapour evolution per unit area Q''_{p} exceeds the ambient take-up rate per unit area Q''_{max} of vapour. Where this is the case, the gas blanket grows until the area of the cloud is such that the rate of ambient take-up rate equals the rate of input into the cloud. If the rate of vapour evolution is less than the ambient take-up rate, a gas blanket does not form.

For the case where $Q''_{\mathrm{p}} > Q''_{\mathrm{max}}$, the ambient take-up rate Q″ is constrained to be

$$Q'' = Q''_{\mathrm{max}} \qquad [15.31.20]$$

It is shown by a mass balance that

$$Q_{\mathrm{max}} = \frac{\rho_{\mathrm{E}} u_{\mathrm{r}} S_z^{1+\alpha'}}{(1+\alpha') z_{\mathrm{r}}^{\alpha'} L} \qquad [15.31.21]$$

where ρ_{E} is the density at emission conditions and S_z is evaluated at $x = 0.5L$. The length L and half-width B of the gas blanket are obtained from

$$Q''_{\mathrm{p}} L_{\mathrm{b}} B_{\mathrm{p}} = Q''_{\mathrm{max}} LB \qquad [15.31.22]$$

where B_{p} is half-width of the pool and L_{p} is the length of the pool. The centre line ground level concentration c_{A} is

$$c_{\mathrm{A}} = \rho_{\mathrm{E}} \qquad [15.31.23]$$

For the case where $Q''_{\mathrm{p}} < Q''_{\mathrm{max}}$, the ambient take-up rate is

$$Q = Q''_{\mathrm{p}} \qquad [15.31.24]$$

The length L and half-width B of the gas blanket are

$$L = L_{\mathrm{P}} \qquad [15.31.25]$$

$$B = B_{\mathrm{P}} \qquad [15.31.26]$$

The centre line ground level concentration c_{A} is obtained from the relation

$$Q''_{\mathrm{p}} = \frac{c_{\mathrm{A}} u_{\mathrm{r}} S_z^{1+\alpha'}}{(1+\alpha') z_{\mathrm{r}}^{\alpha'} L} \qquad [15.31.27]$$

where S_z is evaluated at $x = 0.5L$.

The foregoing applies to a rectangular source. It is convenient in dealing with the effective source constituted by a gas blanket to work in terms of a circular source. Assuming that the rectangle is a square, the radius R of this source is then

$$R = \frac{1}{\pi^{1/2}} L \qquad [15.31.28]$$

If there is a gas blanket, the radius $R_{\mathrm{b}}(t)$ of the blanket is taken as having a minimum value $R_1(t)$ and as growing at the rate

$$\frac{\mathrm{d}R_{\mathrm{b}}(t)}{\mathrm{d}t} = c_{\mathrm{E}} [g' H_{\mathrm{b}}(t)]^{1/2} \qquad [15.31.29]$$

where H_{b} is the height of the 100% gas blanket.

The value of $Q''_{\mathrm{max}}(t)$ is obtained from the mass balance

$$\frac{\mathrm{d}}{\mathrm{d}t} (\pi R_{\mathrm{b}}^2(t) H_{\mathrm{b}}(t) \rho_{\mathrm{E}}) = \pi R_1^2(t) Q''_{\mathrm{p}} - R_{\mathrm{b}}^2(t) Q''_{\mathrm{max}}(t) \qquad [15.31.30]$$

For a spreading pool of radius Ri(t)

$$Q''_{\mathrm{p}} = \frac{Q_{\mathrm{p}}(t)}{\pi R_1^2(t)} \qquad [15.31.31]$$

where Q_{p} is the total mass rate of evaporation.

Vertical dispersion parameter

The vertical concentration distribution given by Equation 15.31.7a satisfies the two-dimensional diffusion equation

$$u \frac{\partial c}{\partial x} = \frac{\partial}{\partial z} \left(K_z \frac{\partial c}{\partial z} \right) \qquad [15.31.32]$$

with

$$K_z = \frac{ku_* z}{\phi(\mathrm{Ri}_*)} \qquad [15.31.33]$$

$$\mathrm{Ri}_* = \frac{g' H_{\mathrm{eff}}}{u_*^2} \qquad [15.31.34]$$

where H_{eff} is the effective height of the cloud, Ri_* is a Richardson number, k is the von Karman constant and $\phi(\mathrm{Ri}_*)$ is the Monin–Obukhov profile function.

Then from Equations 15.31.7a, 15.31.10, 15.31.32 and 15.31.33

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{S_z}{z_\mathrm{r}}\right)^{1+\alpha'} = \frac{k}{z_\mathrm{r}}\frac{u_*}{u_\mathrm{r}}\frac{(1+\alpha')^2}{\phi(\mathrm{Ri}_*)} \qquad [15.31.35]$$

The ratio (u_*/u_r) is obtained from the logarithmic wind velocity profile Equation 15.24.7. Equation 15.31.35 describes the vertical growth of a plume for the two-dimensional case of a plume of constant width. It is generalized for a dense gas plume which spreads laterally to yield

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[B_{\mathrm{eff}}\left(\frac{S_z}{z_\mathrm{r}}\right)\right]^{1+\alpha'} = \frac{k}{z_\mathrm{r}}\,\frac{u_*}{u_\mathrm{r}}\,\frac{(1+\alpha')^2 B_{\mathrm{eff}}}{\phi(\mathrm{Ri}_*)} \qquad [15.31.36]$$

with

$$B_{\mathrm{eff}} = b + \frac{\pi^{1/2}}{2} S_y \qquad [15.31.37]$$

where B_{eff} is the effective half-width of the plume.

Crosswind dispersion parameter

The crosswind concentration distribution given by Equation 15.31.7b with $z = 0$ satisfies the two-dimensional diffusion equation

$$u\frac{\partial c}{\partial x} = \frac{\partial}{\partial y}\left(K_y \frac{\partial c}{\partial y}\right) \qquad [15.31.38]$$

with

$$K_y = K_\mathrm{o} u W_\mathrm{b}^{\gamma''} \qquad [15.31.39]$$

where W_b, is the half-width of the cloud, K_o is a constant and γ'' is an index. Then, again from Equations 15.31.7b, 15.31.38 and 15.31.39,

$$S_y \frac{\mathrm{d}S_y}{\mathrm{d}x} = \frac{4\beta'}{\pi} W_\mathrm{b}^2 \left[\frac{\delta'(\pi/2)^{1/2}}{W_\mathrm{b}}\right]^{1/\beta'} \qquad [15.31.40]$$

For $b = 0$, Equation 15.31.40 describes the lateral growth of a plume for the case of a plume where the width of the middle part is zero. In the generalization for a dense gas plume with a finite middle part, Equation 15.31.40 still applies but with finite b in Equation 15.31.37.

Width of middle part

The growth of the effective half-width B_{eff} is

$$\frac{\mathrm{d}B_{\mathrm{eff}}}{\mathrm{d}t} = c_\mathrm{E}(g' H_{\mathrm{eff}})^{1/2} \qquad [15.31.41]$$

with

$$H_{\mathrm{eff}} = \frac{\Gamma(1/(1+\alpha'))}{1+\alpha'} S_z \qquad [15.31.42]$$

$$\frac{\mathrm{d}B_{\mathrm{eff}}}{\mathrm{d}x} = \frac{1}{u_{\mathrm{eff}}}\frac{\mathrm{d}B_{\mathrm{eff}}}{\mathrm{d}t} \qquad [15.31.43]$$

with

$$u_{\mathrm{eff}} = \frac{\int_0^\infty cu\,\mathrm{d}z}{\int_0^\infty c\,\mathrm{d}z} \qquad [15.31.44]$$

$$u_\mathrm{r}\left(\frac{S_z}{z_\mathrm{r}}\right)^{\alpha'} \frac{1}{\Gamma(1/(1+\alpha'))} \qquad [15.31.45]$$

where u_{eff} is the effective local cloud velocity.

The half-width b of the middle part is obtained from Equation 15.31.37 with B_{eff} obtained from Equation 15.31.43.

Centre-line concentration

For the centre-line concentration c_A the integral mass balance with substitution of the similarity profiles for c and u yields

$$c_\mathrm{A} = \frac{Q(1+\alpha')z_\mathrm{r}^{\alpha'}}{u_\mathrm{r} S_z^{1+\alpha'}(b + 0.5\pi^{1/2} S_y)} \qquad [15.31.46]$$

The foregoing treatment does not allow for dispersion in the along-wind direction, which can be significant. In order to allow for this a correction is derived which when applied to the centreline ground level concentration c_A yields a concentration c'_A corrected for this effect.

Transition conditions

Transition to passive dispersion occurs when $b = 0$ at downwind distance x_{tr}. A virtual source is assumed to exist at x_v. The dispersion parameter S_y is

$$S_y = 2^{1/2}\delta'(x + x_\mathrm{v})^{\beta'} \qquad [15.31.47]$$

The downwind distance x_v, of the virtual source is obtained from Equation 15.31.47 by setting $x = x_{\mathrm{tr}}$. At transition

$$S_y = 2^{1/2}\sigma_y \qquad [15.31.48]$$

15.31.3 Colenbrander quasi-steady-state model

Colenbrander has also described a method of accommodating within his model a transient release. The scenario of concern is the evaporation of a liquefied gas from a spreading pool. The author gives a source model which defines as a function of time both the rate of release $Q(t)$ and the radius of the pool $R(t)$.

He then applies to this source the concept of 'observers'. A series of observers is envisaged as passing over the source at fixed time intervals. A given observer i passes over at a velocity $u_i(t)$ which is time dependent. The observer velocity increases with downwind distance and at a given distance χ the velocity of all observers is the same ($u_i(x) = u_{i+1}(x)$). It is implied in this that at a given time the velocity of observer i is greater than that of the succeeding observer ($u_i(t) > u_{i+1}(\mathrm{t})$). A detailed derivation of the velocity $u_i(t)$ of passage is given by the author.

There is then derived for each observer i a corresponding set of source parameters. If the times when observer i passes over the upwind and downwind edges of the source are t_{1i}, and t_{2i}, respectively, and if $x_i(t)$ is the location of the observer at time t, the local half-width $B'_{\mathrm{s}i}(t)$ is

$$B'_{\mathrm{s}i}(t) = [R^2(t) - x_i^2(t)]^{1/2} \qquad [15.31.49]$$

Then

$$A_{\mathrm{s}i} = \int_{t_u}^{t_{2i}} u_i(t) B'_{\mathrm{s}i}(t)\,\mathrm{d}t \qquad [15.31.50]$$

$$L_{\mathrm{s}i} = x_i(t_{2i}) - x_i(t_{1i}) \qquad [15.31.51]$$

$$B_{\mathrm{s}i} = A_{\mathrm{s}i}/L_{\mathrm{s}i} \qquad [15.31.52]$$

$$Q_i'' B_{\mathrm{s}i} L_{\mathrm{s}i} = \int_{t_{1i}}^{t_{2i}} Q_i''(t) u_i(t) B'_{\mathrm{s}i}(t)\,\mathrm{d}t \qquad [15.31.53]$$

where for observer i, $A_{\mathrm{s}i}$ is the half-area of the source, $B_{\mathrm{s}i}$ is the half-width of the source, $L_{\mathrm{s}i}$ the length of the source and Q_i'' the average take-up flux.

Then for any specified time t_{s} the concentration distribution in the plume may be determined. At this time for observer i the location $x_i(t_{\mathrm{s}})$ is calculated and the plume parameters c_{A}, b, S_y and S_z are obtained as functions of this distance. A steady-state calculation is then performed, utilizing Equation 15.31.7, to obtain the concentration attributable to this observer. The calculation is repeated for all observers.

15.31.4 HEGADAS

As already described, HEGADAS is a development of the models of Te Riele (1977) and Colenbrander (1980). Accounts of this development have been given by Colenbrander and Puttock (1983, 1984) and Puttock (1987b,c, 1989). Further enhancements of the model have been described by Witlox (1991).

The basic HEGADAS model is for a continuous release of dense gas. The source is assumed to be an area source. The plume from this source is modelled as consisting of a middle part which has a uniform crosswind concentration and an outer part which has Gaussian features. The middle part initially constitutes the whole plume, but eventually disappears completely so that the plume assumes a fully Gaussian form. The development of the plume is illustrated in Figure 15.81. The model is a prime example of an advanced similarity model.

HEGADAS originally had two versions. The first, HEGADAS-S, is the steady-state model for a continuous release; this is the basic model just described. The other version, HEGADAS-T, is the quasi-steady-state model for a transient release, utilizing the Observer* concept.

In a subsequent version of the model, described by Colenbrander and Puttock (1983, 1984), enhancements were incorporated to take account of heat transfer between the ground, or water, surface and the cloud. The fifth version, HEGADAS-5, described by Witlox (1991), deals with interfacing with other source models and gives a model for vertical sources and an improved gas blanket model, and contains improved treatments of gravity spreading and of crosswind and along-wind dispersion and of time step selection. It also contains an HF thermodynamics model.

Witlox describes particularly the interface of HEGADAS-5 with the jet/plume model PLUME. Transition is taken as occurring when the jet/plume velocity is close to the wind velocity at centroid height and the air entrainment rate of the plume model is close to that of the dense gas model. There is also an advection criterion which stops the transition if the cloud becomes too buoyant. The PLUME model gives averaged values of the density, concentration, velocity and enthalpy. The matching of these variables between the two models is discussed in detail by the author.

The gas blanket model, as originally formulated, exhibited oscillatory behaviour and has been modified to correct this. A model is also given for a vertical source in terms of a breakpoint. Using this model, breakpoint data are specified for a series of times for the effective half-width and for any two of the following: the effective cloud height, the mass flow of gas and the centre line ground level concentration of gas.

The treatment of crosswind gravity spreading in HEGADAS-5 recognizes that gravity spreading undergoes a collapse beyond which the degree of gravity spreading is much reduced. This effect has been shown in wind tunnel work by R.L. Petersen and Ratcliff (1989) and is dealt with by P.T. Roberts, Puttock and Blewitt (1990). For the crosswind dispersion coefficient S_y use is made of an alternative formula for a_y due to Briggs.

The HEGADAS-5 model gives the four dependent variables: crosswind dispersion coefficient S_y, vertical dispersion coefficient S_z, effective half-width of cloud B_{eff} and centre line ground level concentration c_{A}. It contains five ordinary differential equations for the variables S_y, S_z, B_{eff}, H_{e} and $y_{\mathrm{w}3}$, where H_{e} is the surface heat transfer and $y_{\mathrm{w}3}$ is the mole fraction of surface water vapour. The earlier versions of the program were sensitive to the choice of time interval for solution of the equations. HEGADAS-5 contains automatic time interval selection.

HEGADAS-5 incorporates a model of HF thermodynamics. This is described by Puttock *et al.* (1991a,b).

Vertical dispersion

In this later work the vertical dispersion is expressed in terms of the top entrainment velocity u_{e}:

$$u_{\mathrm{e}} = \frac{(1+\alpha')ku_*}{\phi(\mathrm{Ri}_*)} \qquad [15.31.54]$$

with Ri_* defined by Equation 15.31.34.

Improved relations are also given for the Monin–Obukhov profile function $\phi(\mathrm{Ri}_*)$:

$$\phi(\mathrm{Ri}_*) = 0.74 + 0.25\mathrm{Ri}_*^{0.7} + 1.2\times 10^{-7}\mathrm{Ri}_*^3 \quad \mathrm{Ri}_* \geq 0 \qquad [15.31.55a]$$

$$= \frac{0.74}{1+0.65|\mathrm{Ri}_*|^{0.6}} \quad \mathrm{Ri}_* < 0 \qquad [15.31.55b]$$

Equation 15.31.55a applies to stable conditions and is based on work by McQuaid (1976b) and Kranenburg (1984), and Equation 15.31.55b applies to unstable conditions and is based on fitting data from the Prairie Grass experiments.

Heat transfer

For heat transfer between the ground and the cloud, expressions are given for both the natural and forced convection cases. For natural convection the expression given for this heat flux Q_{gr} is

$$Q_{\mathrm{gr}} = 0.14\left[\frac{\alpha_{\mathrm{Tc}}^2 \beta_{\mathrm{c}} g}{\nu_{\mathrm{c}}}(\rho_{\mathrm{c}} c_{\mathrm{pc}})^3\right]^{1/3}(T_{\mathrm{gr}} - T_{\mathrm{c}})^{4/3} \qquad [15.31.56]$$

with, for an ideal gas,

$$\beta_{\mathrm{c}} = 1/T_{\mathrm{c}} \qquad [15.31.57]$$

where C_{f} is a friction factor (=($2u_*/u_{\mathrm{c}}^2$, u_{c} is the velocity of the cloud, α_{Tc} is the thermal diffusivity of the cloud, β_{c} is the coefficient of volumetric expansion and ν_{c} is the kinematic viscosity of the cloud. For forced convection the heat flux is given as

$$Q_{\mathrm{gr}} = 1/2\left(\frac{\alpha_{\mathrm{Tc}}}{\nu_{\mathrm{c}}}\right)^{2/3} C_{\mathrm{f}} \rho c_{\mathrm{pc}} u_{\mathrm{c}}(T_{\mathrm{gr}} - T_{\mathrm{c}}) \qquad [15.31.58]$$

15.31.5 HEGABOX

HEGADAS models for a continuous release of dense gas the gravity spreading of the gas in the lateral direction. But for an instantaneous release, or for a non-instantaneous release in low wind, there is also strong gravity spreading along the direction of the wind. This aspect is taken care of by HEGABOX, which is used as a front-end addition to HEGADAS to cater for such cases. HEGABOX has been described by Puttock (1987c, 1988a).

In HEGABOX, the cloud from an instantaneous release is treated as a cylinder of uniform concentration. The gravity spreading and air entrainment are modelled as follows:

$$\frac{\mathrm{d}R}{\mathrm{d}t} = c_{\mathrm{E}}(g'H)^{1/2} \qquad [15.31.59]$$

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \pi R^2 u_{\mathrm{e}} + 2\pi R H w_{\mathrm{e}} \qquad [15.31.60]$$

The value of c_{E} is taken as 1.15.

For the edge entrainment velocity w_{e}

$$w_{\mathrm{e}} = \gamma\frac{\mathrm{d}r}{\mathrm{d}t} \qquad [15.31.61]$$

where γ is the edge entrainment coefficient.

For the top entrainment velocity u_{e}

$$u_{\mathrm{e}} = \frac{k u_{*\mathrm{I}}}{\phi(\mathrm{Ri}_{*\mathrm{I}})} \qquad [15.31.62]$$

with

$$u_{*\mathrm{I}} = \frac{k u_{\mathrm{B}}}{\ln(H/z_{\mathrm{o}}) - 1} \qquad [15.31.63]$$

$$\phi(\mathrm{Ri}_{*\mathrm{I}}) = (1 + 0.8\mathrm{Ri}_{*\mathrm{I}})^{1/2} \qquad [15.31.64]$$

$$\mathrm{Ri}_{*\mathrm{I}} = \frac{g'H}{u_{*\mathrm{I}}^2} \qquad [15.31.65]$$

where u_{B} is a bulk cloud velocity and $u_{*\mathrm{I}}$ is an internal velocity scale. The internal velocity scale $u_{*\mathrm{I}}$ is chosen to be consistent with the uniform density assumed over the height of the cloud.

The bulk cloud velocity u_{B} is determined as follows. Strictly, this quantity should be obtained from conservation of momentum, but there are a number of aspects such as the effective velocity of the air entrained in the cloud, which are not well understood. The approach taken is therefore a semi-empirical one. The cloud acquires momentum from the entrainment of air passing over it. There is evidence that the effective air velocity u_{A} 'seen' by the cloud bears a constant ratio to the average air velocity over the height H of the cloud and that this ratio is of the order of 0.7. Furthermore, the cloud must eventually accelerate to the velocity of the ambient air.

These features are taken into account by using the following relations:

$$u_{\mathrm{B}} = f(u_{\mathrm{A}}) \qquad [15.31.66]$$

$$u_{\mathrm{A}} = \left(0.7 + \frac{0.3}{1 + \mathrm{Ri}_*}\right)\frac{1}{H}\int_0^H u(z)\,\mathrm{d}z \qquad [15.31.67]$$

with

$$\mathrm{Ri}_* = \frac{g'H}{u_*^2} \qquad [15.31.68]$$

If HEGABOX is used as a front end for HEGADAS, transition is taken to occur at a transition value of $\mathrm{Ri}_{\mathrm{I}}^*$. This value is taken as 10.

At transition the cylindrical cloud is divided into slices with an observer at each slice, as shown in Figure 15.82. The parameters with which an observer starts are as follows. The half-width b of the middle part is equal to the cloud width at that point. The width parameter S_y is initially zero. The height parameter S_z is obtained from the height H. The centre line ground level concentration c_{A} is set equal to the uniform concentration c.

The transition from HEGABOX to HEGADAS is illustrated by the example shown in Figure 15.83.

15.31.6 HGSYSTEM

A set of models named HGSYSTEM has been developed, built around HEGADAS. These models were originally created specifically for releases of hydrogen fluoride and for this case the model system is called HFSYSTEM and the constituent models mainly bear the prefix HF. The models were subsequently generalized to give a set for an ideal gas. HGSYSTEM has been described in outline by Puttock *et al.* (1991a,b) and in detail by MacFarlane *et al.* (1990), Rees (1990) and Witlox *et al.* (1990). HFSYSTEM contains source models for an unpressurized source and for a pressurized source.

For an unpressurized source the model used is EVAP, which describes evaporation from a pool and which contains two options. The first models evaporation from a pool of fixed size or a spreading pool on land. Evaporation is assumed to be mass transfer limited. The second option models evaporation from a spreading pool on water. Evaporation is assumed to be heat transfer limited.

For a pressurized source at ground level the model used is HFSPILL. This gives the flow of a time-varying release of gas, subcooled liquid or two-phase flashing liquid. The models used are of an accuracy matched to that of the models for the later dispersion phase.

For a pressurized release from an elevated source the model used is HFPLUME. This models the airborne, touchdown and slumping phases of the plume. An account of the generalized model PLUME is given in Section 15.44. Each of these three source models is designed to interface with HEGADAS.

As stated, the models in HFSYSTEM have been generalized to form the set of models for an ideal gas given in HGSYSTEM. This model system also contains an alternative model PGPLUME for passive dispersion. The models in HGSYSTEM are intended to give reasonable accuracy in the near field. One aim is to allow prediction of conditions both at the inlet and outlet of a mitigation system.

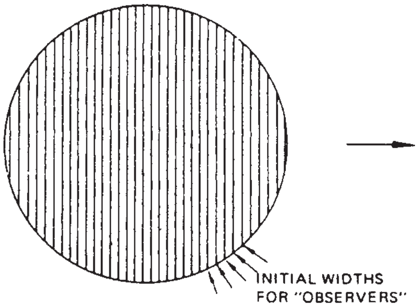

Figure 15.82 *HEGADAS model for dense gas dispersion – initial locations of Observers' (Puttock, 1987c) (Courtesy of the American Institute of Chemical Engineers)*

15.31.7 Validation and application

Te Riele (1977) compared predictions from his model with observations in the Bureau of Mines, van Ulden, and SS Gadila trials. The latter is shown in Figure 15.92(c). Colenbrander (1980) used the Matagordo Bay trials for comparison with predictions from his model.

Validations of the various versions of HEGADAS include comparison of predictions from the model with observations from the Maplin Sands trials by Colenbrander and Puttock (1983) and Puttock (1987c).

Puttock (1987c, 1988a) has compared predictions of HEGABOX/HEGADAS with observations from the Maplin Sands and Thorney Island Phase I trials.

J.L. Woodward *et al.* (1982) have compared the performance of HEGADAS with that of other models in relation to the Matagordo Bay and Porton Down trials, and S.R. Hanna, Strimaitis and Chang (1991b) its performance against other models for nine sets of trials, including the Porton Down, Maplin Sands, Thorney Island Phase I, Burro, Coyote, Desert Tortoise and Goldfish trials.

15.32 Dispersion of Dense Gas: DEGADIS

15.32.1 DEGADIS

As described above, the related model DEGADIS has been developed by Havens and coworkers (Havens, 1985, 1986; Spicer and Havens, 1986, 1987). DEGADIS is based on HEGADAS, but differs in several respects and, in particular, it incorporates its own source, vertical entrainment and heat transfer models. DEGADIS is for a continuous release but may be adapted to time-varying releases, and an instantaneous release, by treating these as a series of quasi-steady-state releases.

The source model used in DEGADIS has been described by Spicer and Havens (1986). It describes the transition by

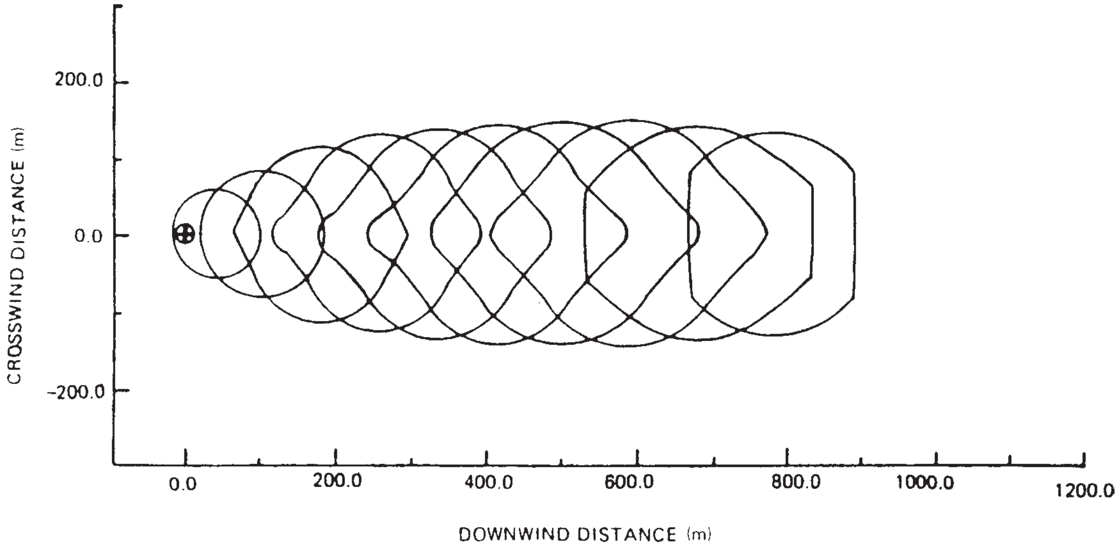

Figure 15.83 *HEGABOX/HEGADAS model for dense gas dispersion – prediction of combined model for cloud development for Thorney Island trial 14 (Puttock, 1987c), Contours are for 500 ppm ground level concentration shown at 20-s intervals from time of release; 20 and 40 s contours are from HEGABOX, remainder from HEGADAS (Courtesy of Reidel Publishing Company)*

gravity slumping from a cloud of high aspect ratio to one of low aspect ratio and to gravity spreading.

The source model includes the following treatment of heat transfer from the ground surface to the cloud. Relations are given for both natural convection and forced convection. For natural convection, use is made of Equation 15.24.14. The authors state that for the hydrocarbon gases methane and propane this equation can be written as

$$h_{\mathrm{gr}} = 18\left[\left(\frac{\rho}{M}\right)^2 \Delta T\right]^{1/3} \qquad [15.32.1]$$

For heat transfer by forced convection, use is made of Equation 15.24.18. Then utilizing Equation 15.31.10 to give at height H

$$u = u_{\mathrm{r}}\left(\frac{H}{z_{\mathrm{r}}}\right)^{\alpha'} \qquad [15.32.2]$$

and taking Pr = 0.741, Equation 15.32.1 yields

$$h_{\mathrm{gr}} = \left[1.22\frac{u_*^2}{u_{\mathrm{r}}}\left(\frac{z_{\mathrm{r}}}{H}\right)^{\alpha'}\right]\rho c_{\mathrm{p}} \qquad [15.32.3]$$

Another feature of DEGADIS is the correlation used for vertical dispersion in the stratified flow phase. The correlation is based on analysis of data obtained by McQuaid (1976b) in wind tunnel experiments and other data by Lofquist (1960) and Kantha, Phillips and Azad (1977) and is shown in Figure 15.84. The vertical entrainment velocity u_{e} is given by Equation 15.31.54 but with $\alpha' = 0$, so that

$$\frac{u_{\mathrm{e}}}{u_*} = \frac{k}{\phi(\mathrm{Ri}_*)} \qquad [15.32.4]$$

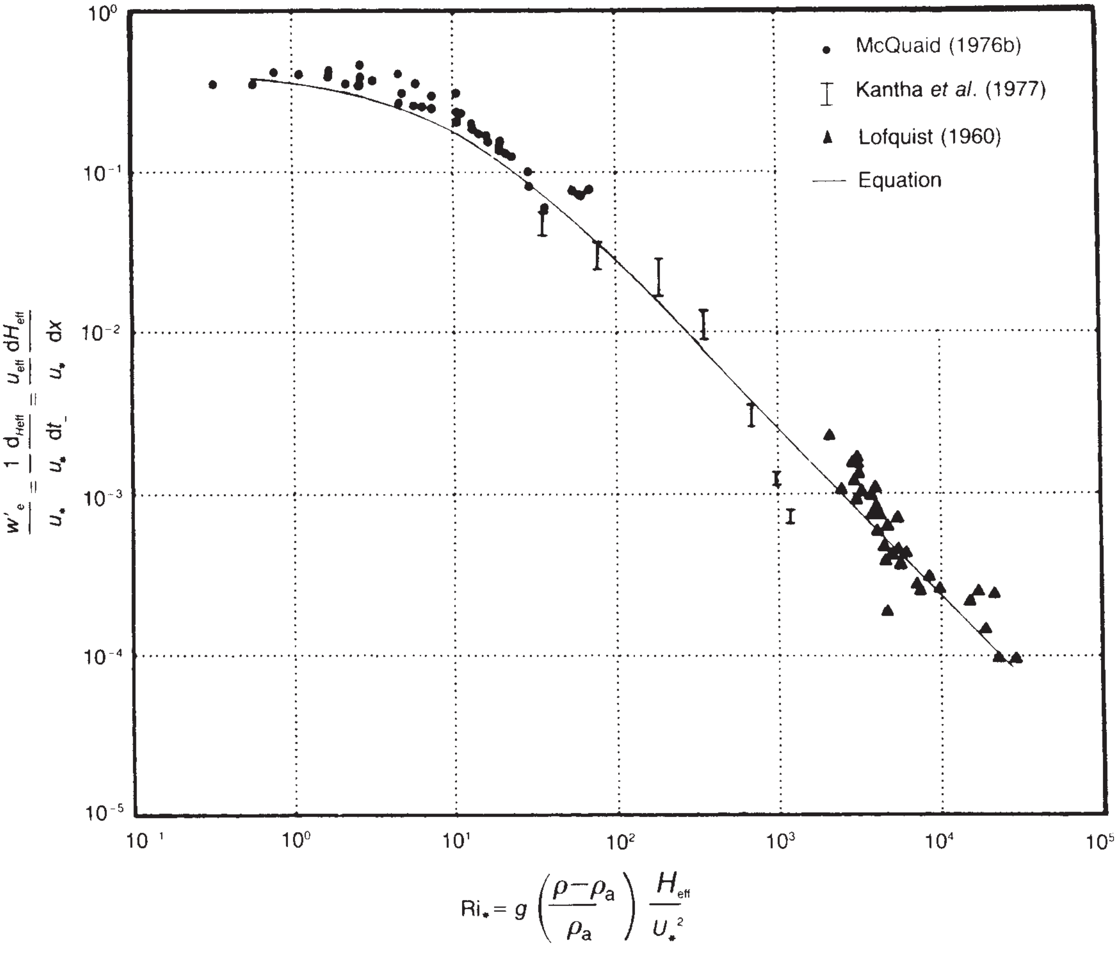

***Figure 15.84** Correlation of vertical entrainment velocity with bulk Richardson number (Spicer and Havens, 1986) (Courtesy of Elsevier Science Publishers) H_{eff}, height at which concentration is one-tenth of the maximum value; u_{eff}, effective advection velocity; $w'_e = dH_{eff}/dt$*

with the following alternative relation used for the profile function $\phi(\mathrm{Ri}_*)$:

$$\phi(\mathrm{Ri}_*) = 0.88 + 0.099\mathrm{Ri}_*^{1.04} + 1.4 \times 10^{-25}\mathrm{Ri}_*^{5.7} \quad \mathrm{Ri}_* \geq 0 \qquad [15.32.5a]$$

$$\frac{0.88}{1 + 0.65|\mathrm{Ri}_*|^{0.6}} \quad \mathrm{Ri}_* < 0 \qquad [15.32.5b]$$

where Ri_* is a modified Richardson number.

In later treatments by the authors (Spicer and Havens, 1987) the last term in Equation 15.32.5a is zero. The correlation has the properties that

$$\frac{u_{\mathrm{e}}}{u_*} \rightarrow \frac{0.35}{0.88} = 0.4 \quad \mathrm{Ri}_* \rightarrow 0 \qquad [15.32.6a]$$

$$\propto \frac{1}{\mathrm{Ri}_*} \qquad \mathrm{Ri}_* \rightarrow \infty \qquad [15.32.6b]$$

taking the value of k for Equation 15.32.6a as 0.35. Equation 15.32.6a corresponds to the passive dispersion limit. Account is also taken of the enhancement of vertical mixing by the convective turbulence due to heat transfer.

15.32.2 Validation and application

Havens and co-workers (Spicer and Havens, 1985, 1986, 1987; Havens, 1986, 1992; Havens *et al.*, 1991) have compared predictions of DEGADIS with observations from the Matagordo Bay, Maplin Sands, Thorney Island Phase I, Burro, Coyote, Desert Tortoise, Eagle and Goldfish trials, and Blewitt, Yohn and Ermak (1987) have compared its predictions against the Goldfish trials. Touma *et al.* (1991) have compared the performance of the model with that of other models in relation to the Burro, Desert Tortoise and Goldfish trials, and S.R. Hanna, Strimaitis and Chang (1991b) have compared its performance against other models for nine sets of trials, including the Porton Down, Maplin Sands, Thorney Island Phase I, Burro, Coyote, Desert Tortoise and Goldfish trials.

15.33 Dispersion of Dense Gas: SLUMP and HEAVYGAS

Another pair of models are SLUMP and HEAVYGAS developed at WS Atkins. They have been described by Deaves (1983a,b, 1987a,b). SLUMP is a box model and HEAVYGAS an if-theory model with $\kappa{-}\epsilon$ modification.

15.33.1 SLUMP

SLUMP is described by Deaves (1987a), who refers to the equation set for box models formulated by Wheatley and Webber (1984 CEC EUR EN 9592) and deals particularly with the treatment in his model of slumping velocity, cloud advection and transition to passive dispersion.

15.33.2 HEAVYGAS

An account of HEAVYGAS has been given by Deaves (1983a). He has also described its subsequent development (Deaves, 1983b, 1984, 1985, 1987a,b, 1989b). The basic equations of the model are:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_j}(\rho u_j) = 0 \qquad [15.33.1]$$

$$\frac{\partial(\rho u_j)}{\partial t} + \frac{\partial}{\partial x_j}(\rho u_i u_j) = -\frac{\partial \rho}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\mu \frac{\partial u_i}{\partial x_j}\right) + \Delta\rho g_i \qquad [15.33.2]$$

$$\frac{\partial \rho\phi}{\partial t} + \frac{\partial}{\partial x_j}(\rho u_j \phi) = \frac{\partial}{\partial x_j}\left(\Gamma_\phi \frac{\partial \phi}{\partial x_j}\right) + S_\phi \qquad [15.33.3]$$

where p is the pressure, t is the time, u is the velocity, x is the distance, μ is the viscosity, ρ is the density, ϕ is any scalar quantity and subscripts i and j denote the i and j directions, respectively. S_ϕ and Γ_ϕ are functions which vary with the quantity ϕ. Equation 15.33.3 is the general equation for any scalar quantity. Thus if it is used for concentration, $S_\phi = 0$ and Γ_ϕ is the eddy diffusion coefficient.

The model incorporates the $\kappa{-}\epsilon$ modification. The quantities κ and ϵ may be obtained from Equation 15.33.3 with γ adjusted to give the usual form of the $\kappa{-}\epsilon$ turbulence model equations and with γ either given as a function of κ and ϵ:

$$\Gamma_\phi = c_\phi \frac{\kappa^2}{\epsilon} \qquad [15.33.4]$$

where c_ϕ is a constant or defined in some other way such as a function of height for each stability category. The model is formulated in both two - and three-dimensional forms. The relative merits of the two forms has been discussed by Deaves (1987a). In essence, two-dimensional modelling is much simpler and is usually sufficient, but three-dimensional modelling may be required in special cases.

15.33.3 Validation and application

The predictions of HEAVYGAS have been compared with the results of Thorney Island Phase II trials 5 and 21 without and with a solid fence (Deaves, 1987a) and trial 29 with a single building (Deaves, 1984, 1985).

HEAVYGAS has been used to model a number of applications which exploit the ability of this type of model to deal with situations other than flat, unobstructed terrain. It has been used to model the dispersion of chlorine within a building (Deaves, 1983a) and the effect of water spray barriers on the dispersion of a plume of carbon dioxide (Deaves, 1983a,b, 1984). These studies are described in Sections 15.40 and 15.53, respectively.

It has also been applied to problems arising in safety cases (Deaves, 1987, 1989a,b). These include: the release of chlorine into and then from a building; the effect of individual buildings on hazard ranges for chlorine; and the effect of a whole plant site on hazard ranges for ammonia. Accounts of this work are given in Section 15.40.

15.34 Dispersion of Dense Gas: Workbook Model

A unified methodology for dense gas dispersion is given in the *Workbook on the Dispersion of Dense Gases* (Britter and McQuaid, 1988). The work was supported, though not necessarily endorsed, by the Health and Safety Executive and was closely associated with the Thorney Island trials.

15.34.1 Basic model

The basic model is a similarity relation and consists of a correlation of dimensionless groups. This relation is

$$\begin{aligned}\frac{C}{C_{\mathrm{o}}} = f\Bigg[&\frac{x}{D}, \frac{y}{D}, \frac{z}{D}, \frac{tu_{\mathrm{ref}}}{D}, \frac{q_{\mathrm{o}}(t)}{u_{\mathrm{ref}}D^2}\\ &\text{or } \frac{Q_{\mathrm{o}}^{1/3}}{D}, \frac{u_{\mathrm{ref}}^2}{gD}, \frac{\rho_{\mathrm{o}}}{\rho_{\mathrm{a}}}, \frac{z_{\mathrm{o}}}{D}, \frac{l_{\mathrm{i}}}{D}, G\\ &\text{or } \frac{Q_{\mathrm{o}}^{1/3}}{D}, \text{ atmospheric stability}\Bigg] \qquad [15.34.1]\end{aligned}$$

where C is the volumetric concentration, C_{o} is the volumetric concentration of the initial release, D is a characteristic dimension of the source, g is the acceleration due to gravity, G is the source geometry, l_{i} is the length scale of the turbulence in the atmospheric boundary layer, $q_{\mathrm{o}}(t)$ is the volumetric rate of release of material, Q_{o} is the volume of material released, u_{ref} is a characteristic mean velocity, ρ_{a} is the density of air, ρ_{o} is a characteristic density of the material released, and x, y and z are the distances in the downwind, crosswind and vertical directions, respectively.

The influence of some of the items in Equation 15.34.1 is relatively weak and in order to obtain a sufficient data set the following are disregarded: (l_{i}/D), (z_{o}/D), G and atmospheric stability. This then yields

$$\frac{C}{C_{\mathrm{o}}} = f\left[\frac{x}{D}, \frac{y}{D}, \frac{z}{D}, \frac{tu_{\mathrm{ref}}}{D}, \frac{q_{\mathrm{o}}(t)}{u_{\mathrm{ref}}D^2}\right] \quad \text{or} \quad \frac{Q_{\mathrm{o}}^{1/3}}{D}, \frac{u_{\mathrm{ref}}^2}{gD}, \frac{\rho_{\mathrm{o}}}{\rho_{\mathrm{a}}} \qquad [15.34.2]$$

15.34.2 Model for continuous release

For a continuous release the concentration of interest is the time mean concentration $\bar{C}$. From Equation 15.34.2

$$\frac{\bar{C}}{C_{\mathrm{o}}} = f\left[\frac{x}{D}, \frac{y}{D}, \frac{z}{D}, \frac{q_{\mathrm{o}}}{u_{\mathrm{ref}}D^2}, \frac{u_{\mathrm{ref}}^2}{gD}, \frac{\rho_{\mathrm{o}}}{\rho_{\mathrm{a}}}\right] \qquad [15.34.3]$$

For the maximum time mean concentration $\bar{C}_{\mathrm{m}}$ on the centre line of the cloud

$$\frac{\bar{C}_{\mathrm{m}}}{C_{\mathrm{o}}} = f\left[\frac{x}{D}, \frac{q_{\mathrm{o}}}{u_{\mathrm{ref}}D^2}, \frac{u_{\mathrm{ref}}^2}{gD}, \frac{\rho_{\mathrm{o}}}{\rho_{\mathrm{a}}}\right] \qquad [15.34.4]$$

Since the number of terms in Equation 15.34.4 is still too high for the data set available, two further approximations are called in aid. One is the Boussinesq approximation, in which the density variation is neglected in the inertial terms but is retained in the buoyancy terms. This means in effect that the problem is restricted to the case where formally $[(\rho_{\mathrm{o}}-\rho_{\mathrm{a}})/\rho_{\mathrm{a}}] \ll 1$ and, in practice, $[(\rho_{\mathrm{o}}-\rho_{\mathrm{a}})/\rho_{\mathrm{a}}] < 1$; the value of $[(\rho_{\mathrm{o}}-\rho_{\mathrm{a}})/\rho_{\mathrm{a}}]$ for the initial release tends to approximate to unity or less. The Boussinesq approximation allows the terms (u_{ref}^2/gD) and $(\rho_{\mathrm{o}}/\rho_{\mathrm{a}})$ to be replaced by $(u_{\mathrm{ref}}^2/g'_{\mathrm{o}})$ with

$$g'_{\mathrm{o}} = \frac{g(\rho_{\mathrm{o}} - \rho_{\mathrm{a}})}{\rho_{\mathrm{a}}} \qquad [15.34.5]$$

where g'_{o} is the reduced gravity of the initial release.

The other approximation invoked is to neglect the characteristic dimension D of the source. D has progressively less effect as the distance x from the source increases, and becomes insignificant at about $x > 5D$.

With these simplifications, Equation 15.34.4 reduces to

$$\frac{\bar{C}_{\mathrm{m}}}{C_{\mathrm{o}}} = f\left[\frac{x}{(q_{\mathrm{o}}/u_{\mathrm{ref}})^{1/2}} \frac{g'_{\mathrm{o}}q_{\mathrm{o}}/u_{\mathrm{ref}}^3}{(q_{\mathrm{o}}/u_{\mathrm{ref}})^{1/2}}\right] \qquad [15.34.6a]$$

$$= f\left[\frac{x}{(q_{\mathrm{o}}/u_{\mathrm{ref}})^{1/2}}\phi\right] \qquad [15.34.6b]$$

with

$$\phi = \left(\frac{g_{\mathrm{o}}'^2 q_{\mathrm{o}}}{u_{\mathrm{ref}}^5}\right)^{1/5} \qquad [15.34.7]$$

where ϕ is a stability parameter. The power 1/5 is introduced solely to give convenient numbers.

Equation 15.34.6b can be recast in the more useful form

$$\frac{x_n}{(q_{\mathrm{o}}/u_{\mathrm{ref}})^{1/2}} = f(\phi) \qquad [15.34.8]$$

where x_n is the distance at which the concentration is the fraction n of the initial concentration $\bar{C}_{\mathrm{m}}/C_{\mathrm{o}}$.

Downwind distance to a given concentration

The correlation of the data based on Equation 15.34.8 is shown in Figure 15.85(a). The correlation is intended to apply to the long-term average concentrations. It is based on both laboratory and full-scale trial data. Justifications of the correlation itself and of the limit of effectively passive dispersion are given in Appendices C and E of the report, respectively. The correlation is valid within the limits

$$0.002 \le \frac{\bar{C}_{\mathrm{m}}}{C_{\mathrm{o}}} \le 0.1; \quad 0 \le \phi \le 4$$

There are two useful relations which can be obtained from Figure 15.85(a). One is

$$\frac{x_n}{(q_{\mathrm{o}}/u_{\mathrm{ref}})^{1/2}} = A\phi^{-1/2} \quad \phi \ge 1 \qquad [15.34.9]$$

or

$$x = Aq_{\mathrm{o}}^{0.4}(g'_{\mathrm{o}})^{-0.2} \qquad [15.34.10]$$

where A is given by Figure 15.85(b). This equation shows a quite strong dependence of the distance x to a particular concentration on source strength q_{o}. It also shows that the distance decreases as the stability parameter ϕ increases. The interpretation is that increased lateral spread more than compensates for the inhibition of vertical mixing. The other relation is

$$x = 17.5\left(\frac{\bar{C}_{\mathrm{m}}}{C_{\mathrm{o}}}\right)^{-1/2}\left(\frac{q_{\mathrm{o}}}{u_{\mathrm{ref}}}\right)^{1/2} \quad 0 < \phi < 3 \qquad [15.34.11]$$

Thus the distance depends only on the length scale $(q_{\mathrm{o}}/u_{\mathrm{ref}})^{1/2}$.

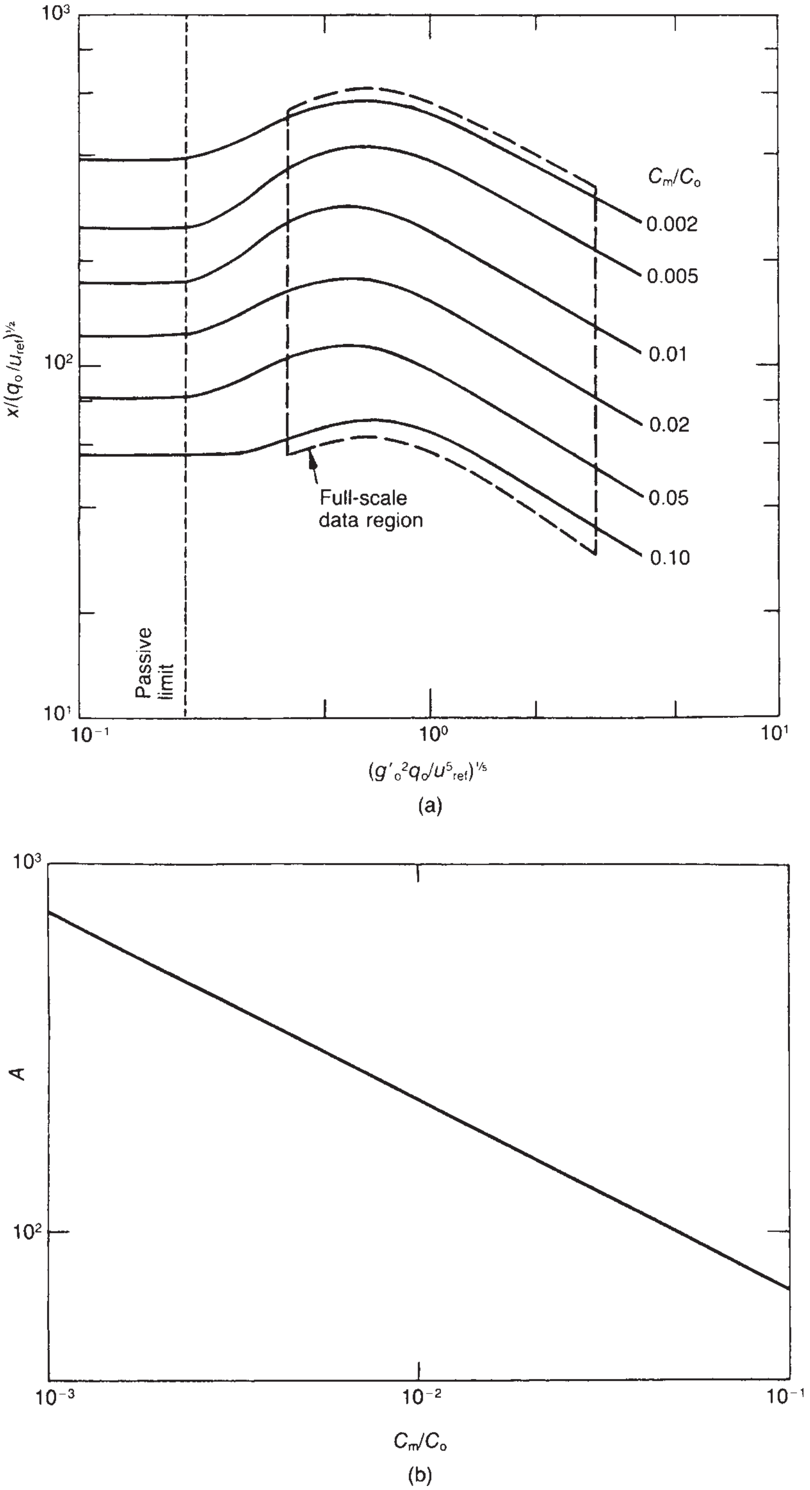

Figure 15.85 *Workbook method for dense gas dispersion – correlation for continuous release (Britter and McQuaid, 1988; reproduced by permission): (a) correlation; (b) parameter A*

For low concentrations outside the range of validity given, the suggestion made is that Equation 15.34.10 may be extrapolated, but still subject to the limits on ϕ.

Area bounded by a given concentration

A method is also given to obtain the area bounded by a given concentration. On the basis of modelling and experiment the dimensions of the cloud are found to be approximately as follows:

$$L_u = D/2 + 2l_b \qquad [15.34.12]$$

$$L_h = L_{ho} + 2.5 l_b^{1/3} x^{2/3} \qquad [15.34.13]$$

with

$$l_b = \frac{q_o g_o'}{u_{ref}^3} \qquad [15.34.14]$$

$$L_{ho} = D + 8l_b \qquad [15.34.15]$$

where l_b is the buoyancy length scale, L_h is the half-width of the plume, L_{ho} is the half-width of the plume at the source and L_u is the upwind extent of the plume.

For the height of the plume, from conservation of mass

$$L_v = \frac{q_o}{u_{ref} L_h} \qquad [15.34.16]$$

where L_v is the height of the plume.

Equation 15.34.16 assumes that the concentration is homogenous throughput the plume. In fact, the concentration varies with height, but the exact vertical profile is uncertain and variable. There is experimental evidence that the bulk of the material is contained within a height of $2(q_o/u_{ref}L_h)$.

Since Equation 15.34.16 is unduly conservative, an alternative approach is also given. This is to locate, for the concentration of interest, the lateral boundaries of the cloud at the distance $(2/3)x_n$ and to join these boundary points with x_n, as shown in Figure 15.86.

15.34.3 Model for instantaneous release

For an instantaneous release the case considered is a source of unit aspect ratio. This allows the external length scale D to be equated with the internally set length scale $Q_o^{1/3}$.

Then, following an approach similar to that for the continuous case,

$$\frac{C_m}{C_o} = f\left(\frac{x}{Q_o^{1/3}}, \frac{u_{ref}^2/g_o'}{Q_o^{1/3}}\right) \qquad [15.34.17]$$

$$= f\left(\frac{x}{Q_o^{1/3}}, \psi\right)$$

with

$$\psi = \left(\frac{g_o' Q_o^{1/3}}{u_{ref}^2}\right)^{1/2} \qquad [15.34.18]$$

where ψ is a stability parameter. Again the power 1/2 is used solely to give convenient numbers. Then,

$$\frac{x_n}{Q_o^{1/3}} = f(\psi) \qquad [15.34.19]$$

In this case, since $D = Q_o^{1/3}$, the assumption that the effect of D can be neglected is not necessary.

Downwind distance to a given concentration. The correlation based on Equation 15.34.19 is shown in Figure 15.87(a). The correlation is intended to apply to the ensemble average of the maximum short-time (0.6 s) mean concentrations. It is based on both laboratory and full-scale trial data. Justifications of the correlation itself and of the limit of effectively passive dispersion are given in Appendices D and E of the report, respectively. The correlation is valid within the limits

$$0.001 \le \frac{C_m}{C_o} \le 0.1; \quad 0.7 \le \psi \le 10$$

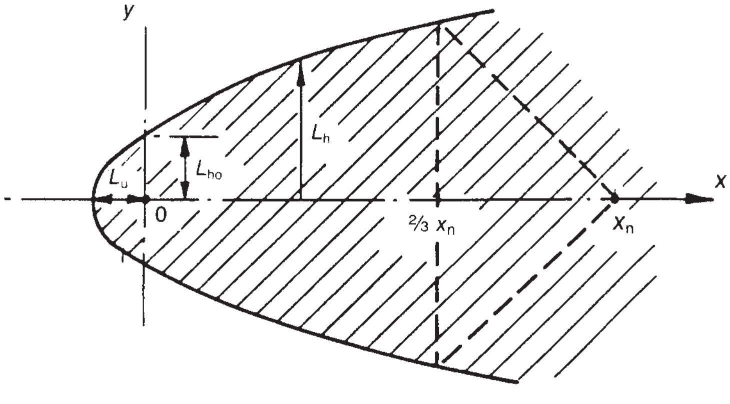

Figure 15.86 *Workbook method for dense gas dispersion – area covered by concentration contour for continuous release (Britter and McQuaid, 1988; reproduced with permission)*

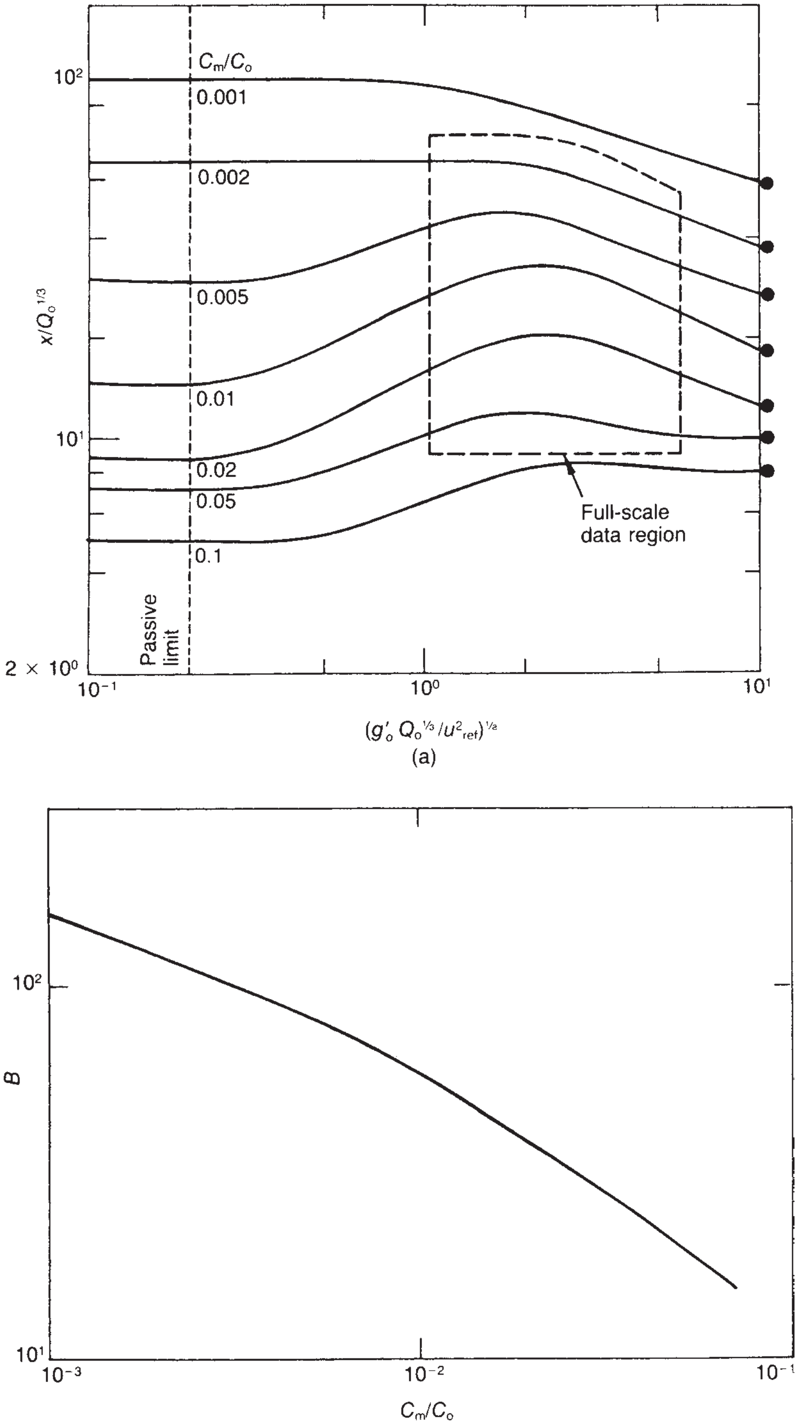

(a)

(b)

Figure 15.87 *Continued*

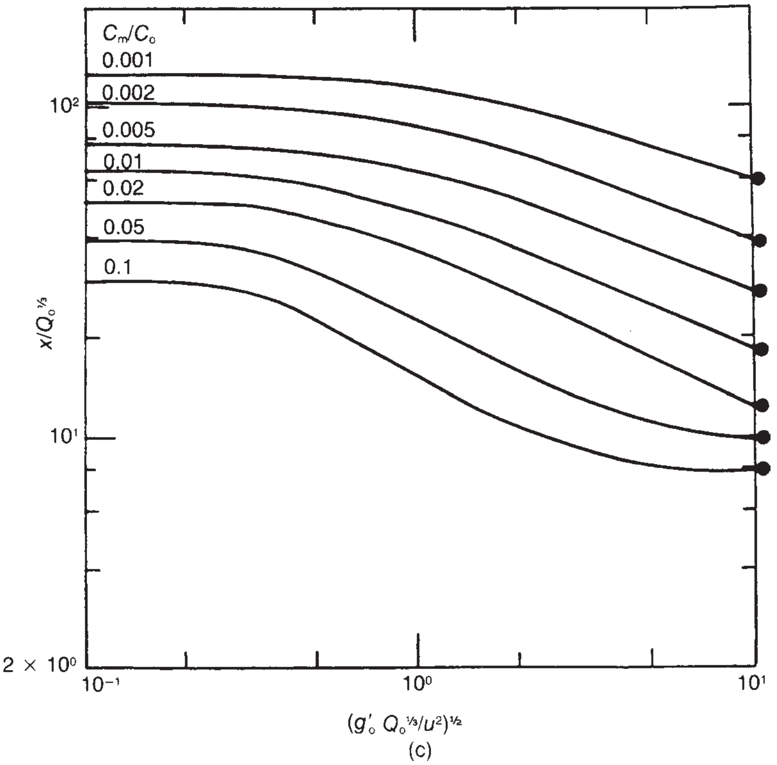

***Figure 15.87** Workbook method for dense gas dispersion – correlation for instantaneous release (Britter and McQuaid, 1988; reproduced with permission): (a) correlation; (b) parameter B; (c) correlation if initial dilution already taken into account*

There are again two useful relations which can be obtained from Figure 15.87(a). One is

$$\frac{x_n}{Q_o^{1/3}} = B\psi^{1/2} \quad 0.001 \leq \frac{C_m}{C_o} \leq 0.002;\ 2 \leq \psi \leq 10 \qquad [15.34.20]$$

or

$$x = BQ_o^{1/4} g_o'^{-1/4} u_{\mathrm{ref}}^{1/2} \qquad [15.34.21]$$

where B is given by Figure 15.87(b). This equation shows a rather weaker dependence on source strength of the distance x to a given concentration compared with the continuous case. The other relation is

$$x = 2.8\left(\frac{C_m}{C_o}\right)^{-1/2} \quad 1 < \psi < 5 \qquad [15.34.22a]$$

$$= 1.8\left(\frac{C_m}{C_o}\right)^{-1/2} \quad \psi \to \infty \qquad [15.34.22b]$$

For low concentrations outside the range of validity given, the suggestion made is that Equation 15.34.21 may be extrapolated, but subject still to the limits on ψ.

For the case where there has already been significant dilution of the cloud and consequent cloud acceleration the *Workbook* proposes the modification shown Figure 15.87(c).

The *Workbook* also gives for an instantaneous release the correlation shown in Figure 15.88 obtained from the Thorney Island trials for $1 < \psi < 5$.

Area swept by a given concentration

For the area swept by a given concentration the method is as follows. A model is used which is based on gravity slumping

$$\frac{dR}{dt} = c_E(g'H)^{1/2} \qquad [15.34.23]$$

with

$$g' = \frac{g(\rho - \rho_a)}{\rho} \qquad [15.34.24]$$

where H is the height of the cloud, R is the radius of the cloud and C_E is the slumping constant. The value of the constant c_E is 1.07. By conservation of buoyancy

$$g'Q = g_o'Q_o \qquad [15.34.25]$$

Also

$$H = Q/\pi R^2 \qquad [15.34.26]$$

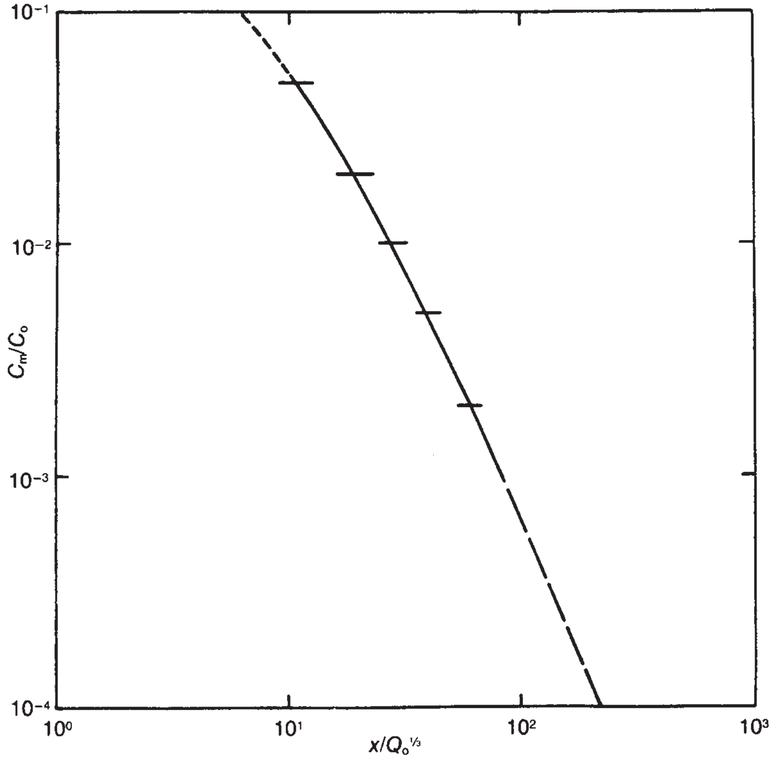

***Figure 15.88** Workbook method for dense gas dispersion–variation of maximum concentration with scaled distance, Thorney Island instantaneous release trials (see text) (Britter and McQuaid, 1988; reproduced with permission)*

where Q is the volume of the cloud. Integration of Equation 15.34.23 gives

$$R(t) = [R_o + 1.2(g'_o Q_o)^{1/2} t]^{1/2} \qquad [15.34.27]$$

where R_o is the initial radius. The advection velocity of the cloud is taken as $0.4u_{\text{ref}}$. At a distance x the arrival time t_a of the leading edge of the cloud is given by

$$x = 0.4u_{\text{ref}} t_a + R(t_a) \qquad [15.34.28]$$

and the departure time t_d of the trailing edge by

$$x = 0.4u_{\text{ref}} t_d + R(t_d) \qquad [15.34.29]$$

Now consider any time t_c between the arrival time t_a and the departure time t_d. For this time t_c the distance x_c of the leading edge is

$$x_c = 0.4u_{\text{ref}} t_c + R(t_c) \qquad [15.34.30]$$

where $x_c = x$, $t_c = t_a$ and $x_c > x$, $t_c > t_a$. Then for a given concentration C of interest, the value of x_c is obtained from the correlation given in Figure 15.87(a), or the equivalent equations, t_c is obtained from Equation 15.34.30 and the cloud half-width y_c is obtained from

$$y_c = R(t_c) \qquad [15.34.31]$$

The area required is a parabola enclosing the source and closed off at the downwind end by an arc of radius $R(t_c)$.

By conservation of mass, the cloud height H is

$$H = \frac{C_o Q_o}{\pi R^2 C} \qquad [15.34.32]$$

In practice, the bulk of the material is contained within twice this height.

15.34.4 Criterion for type of release

The criterion used to distinguish between a continuous and an instantaneous release is based on the group $(u_{\text{ref}} T_o/x)$ or, alternatively, $(u_* T_o/x)$.

An effectively continuous plume may be assumed if

$$\frac{u_{\text{ref}} T_o}{x} \geq 2.5 \qquad [15.34.33a]$$

or

$$\frac{u_* T_o}{x} \geq 0.15 \qquad [15.34.33b]$$

where u_* is the friction velocity. This criterion applies on the centre line of the cloud. Larger values apply off the centre line.

Relation 15.34.33 implies that the distance x at which the release can be regarded as continuous recedes closer to the source as the duration T_o of the release decreases. For distances greater than those given by relation 15.34.33, the assumption of a continuous source overestimates the concentration. An effectively instantaneous release may be assumed if

$$\frac{u_{\mathrm{ref}} T_o}{x} < 0.6 \qquad [15.34.34a]$$

or

$$\frac{u_* T_o}{x} < 0.04 \qquad [15.34.34b]$$

In the region

$$0.6 \leq \frac{u_{\mathrm{ref}} T_o}{x} \leq 2.5$$

the release is a transient one, being neither effectively continuous nor instantaneous.

15.34.5 Treatment of transient release

A transient release, as just defined, may be treated by considering it first as a quasi-continuous release and then as a quasi-instantaneous one. Taking first the quasi-continuous approach, a release of quantity Q_o over a release duration T_o has an effective release rate q_o. This release rate may be utilized in the continuous release correlation to obtain a value of the concentration. This approach neglects the effect of longitudinal dispersion and will overestimate the concentration. Alternatively, the release may be treated as a quasi-instantaneous one with quantity release Q_o. This approach will again give an overestimate of the concentration. The recommendation is then to take as the upper bound of concentration the lower of the two concentrations obtained by these two methods.

This treatment is based on the assumption that the material is transported downwind by the ambient velocity only. But such transport occurs also due to the buoyancy induced motion. For the ambient velocity the time scale is x/u_{ref} and for buoyancy-driven velocity it is $x^2/(g'_o Q_o)^{1/2}$. Then for an instantaneous release the additional criterion which must be met is

$$\frac{(g'_o Q_o)^{1/2} T_o}{x^2} \leq 0.6 \qquad [15.34.35]$$

By a similar argument for a continuous release the buoyancy-driven time scale is $x^{1/3}/(g'_o q_o)^{1/3}$ and the additional criterion is

$$\frac{(g'_o q_o)^{1/3} T_o}{x^{4/3}} \geq 2.5 \qquad [15.34.36]$$

As an illustration, consider the example given in the *Workbook*. This is the determination of the concentration ratio C_m/C_o at a distance of 200 m for a release of a total of 2000 m^3 of dense gas with initial reduced gravity 10 m/s^2 with a wind speed at reference height of 2 m/s for some release time T_o such that the release is truly neither instantaneous nor continuous. The procedure is as follows. First the release is treated as if it were an instantaneous one. For an instantaneous release $\psi = 5.6$ and $x/Q_o^{1/3} = 15.9$, so that from the correlation for an instantaneous release $C_m/C_o = 0.04$. Then the release is treated as a continuous one, with a release rate q_o of $2000/T_o$ m^3/s. A series of values of C_m/C_o are determined using the correlation for a continuous release. The results are shown in Figure 15.89. The figure also shows the limits determined from relations 15.34.35 and 15.34.36.

15.34.6 Criterion for effectively passive dispersion

The criterion used for effectively passive dispersion is for a continuous release

$$\left(\frac{g'_o q_o}{u_{\mathrm{ref}}^3} \times \frac{1}{D}\right)^{1/3} \leq 0.15 \qquad [15.34.37]$$

and for an instantaneous release

$$\frac{(g'_o Q_o^{1/3})^{1/2}}{u_{\mathrm{ref}}} = \frac{(g'_o Q_o/u_{\mathrm{ref}}^2)^{1/2}}{Q_o^{1/3}} \leq 0.20 \qquad [15.34.38]$$

The justification of these criteria is given in Appendix A of the report.

For the case of an instantaneous release where the aspect ratio of the cloud is not unity, the suggestion made is that $Q_o^{1/3}$ be replaced by the initial height.

15.34.7 Thermodynamic and heat transfer effects

In the treatment so far described, it is assumed that the temperature of the release corresponds to ambient temperature, the relevant release temperature being that which pertains after the source effects have subsided and any aerosol has evaporated. If this is not the case, there are two additional effects, one thermodynamic and one of heat transfer, for which allowance needs to be made.

The first effect relates to the non-linear variation of temperature and density with volume fraction (or mole fraction) where the species have different molar specific heats. Considering the initial concentrations, the non-isothermal initial volume is V_o and the isothermal initial volume $V_o T_a/T_o$, where T_a and T_o are the absolute temperature of the air and the initial release, respectively, so that the isothermal concentration C_i and the non-isothermal concentration C_{ni} are

$$C_{ni} = \frac{V_o}{V_o + V_a} \qquad [15.34.39]$$

and

$$C_i = \frac{V_o T_a/T_o}{V_o T_a/T_o + V_a} \qquad [15.34.40]$$

where subscripts a, i and ni denote ambient, isothermal and non-isothermal, respectively. Hence

$$C_i = \frac{C_{ni}}{C_{ni}(1 - C_{ni})(T_a/T_o)} \qquad [15.34.41]$$

For example, for LNG at −162°C (111 K) and with ambient temperature of 17°C (290 K), a non-isothermal

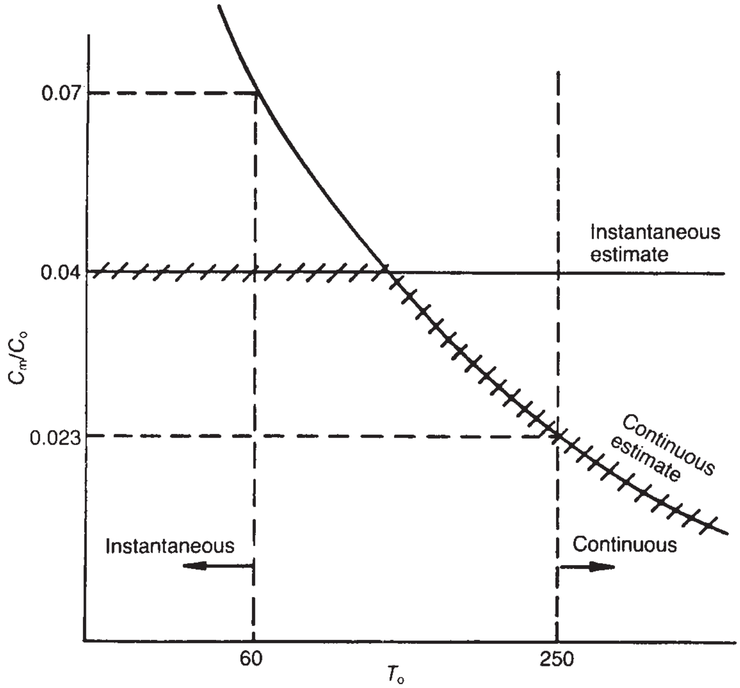

Figure 15.89 *Workbook method for dense gas dispersion – treatment for transient release (Britter and McQuaid, 1988; reproduced with permission)*

concentration of 0.05 in Equation 15.34.41 gives an isothermal concentration of 0.02.

The *Workbook* states that this effect is probably not significant for most hazardous materials, but it is for methane and hydrogen. It suggests that it be handled by determining the following two limiting cases (Cases A and B). For Case A the source density difference and volume, or volumetric flow, are used in the correlations. For Case A the density difference at the concentration of interest and the volume which satisfies mass conservation are obtained. A revised source density difference, source temperature and source volume, or volumetric flow, are then determined based on mass conservation, pure species at the source, adiabatic mixing and a constant molar specific heat equal to that of the ambient air, and used in the correlations.

These two limiting cases (A and B) are then compared. If the difference is small, the effect is unimportant. If it is neither large nor small, say a factor 2, the more pessimistic estimate is used. If it is large, say more than a factor of 2, further investigation may be warranted.

The second effect relates to heat transfer. This occurs by (a) air entrainment, (b) heat transfer at the surfaces of the cloud, particularly the lower surface and (c) latent heat exchange due to condensation and re-evaporation of water vapour. There is some uncertainty as to the effect of such heat transfer. Although it is usually assumed that it works to reduce the downwind extent of the cloud, it is not certain that this is universally the case; there may be parameter ranges where the reverse could be so, particularly if the sole effect of heat transfer is on density. This is a reflection of the uncertainty concerning the relative effects of inhibition of vertical mixing and of increase in the top area of the cloud. The authors' correlations suggest that this may vary with the stability condition.

This effect is handled in the *Workbook* by determining the following two limiting cases (Cases A and B). For Case A the source density difference and volume, or volumetric flow, are used in the correlations. For Case B the conditions of Case A are taken as the starting point. It is then assumed that heat addition at the source raises the cloud temperature to the ambient temperature. The revised source density difference and volume, or volumetric flow, obtained from this temperature are then used in the correlations. These two limiting cases (A and B) are then compared, the approach being identical to that used for the thermodynamic effect.

15.34.8 Concentration vertical profile

This basic method provides an estimate of the alongwind concentration profile but not of the crosswind or vertical concentration profiles and implies by default that the concentration is uniform in both these directions.

For crosswind concentration, the Thorney Island trials confirm that the assumption of uniform concentration is reasonable near the source where density effects are dominant. However, further from the source the cloud becomes diffuse at the edges. A criterion for the development of these diffuse edges has been given by Britter and Snyder (1988). This is the condition $(g'_m h)^{1/2} u^*$, where g'_m is the reduced gravity corresponding to the maximum concentration and h is a measure of plume height.

For a continuous release, the development of diffuse edges is due partly to true plume dilution and partly to meandering. For an instantaneous release, the equivalent to meandering is the difference between different members of an ensemble of trials at the same nominal conditions. It is necessary to decide whether the frame of reference is to be a fixed point one or a relative one such as that obtained by overlaying the centres of mass of the ensemble members.

For vertical concentration, the trials show clearly that the profile is not uniform. The variation of the vertical concentration can be represented by the relation

$$C \propto \exp(-z^n) \qquad [15.34.42]$$

In the Gaussian models used for passive dispersion the profile is normal with $n = 2$. A value of $n = \infty$ corresponds to a uniform distribution. The *Workbook* suggests that a more appropriate value of n is about 1.5. It also states that where density effects are strong, there is evidence pointing to a still smaller value of n.

In any event, there is in dense gas dispersion a very rapid change in concentration close to the surface. Implications of this are that it is necessary to exercise care in specifying a ground level concentration and that such a concentration may not be that most relevant to hazard assessment.

15.34.9 Dispersion at buildings and obstacles

The treatment of the effect of buildings and obstacles in the *Workbook* is limited to releases upwind and releases in the immediate lee. The *Workbook* treatment of these two cases is described in Section 15.40. Broadly, the effect of a building or obstacle on a release upwind is to reduce the concentration at a given distance. The evidence is that, even close to the face, the upwind concentration is not increased and that downwind it is significantly reduced.

15.34.10 Dispersion in complex terrain

The treatment of complex terrain in the *Workbook* is limited, but consideration is given to two bounding cases. One is where the topographical feature is large compared to the scale of the release and the other where it is small. If the feature is large relative to the scale of the release, the topography will tend to reduce locally at the source to a relatively simple feature, typically a slope.

If the feature is small relative to the scale of the release, the dense gas will tend to flow around it. For the case where the cloud or plume is very wide compared with the feature, the *Workbook* gives the following criterion for the cloud to flow over or around the feature:

Flow over crest of feature:

$$\frac{u^2}{g'h} \gg 2\left(\frac{h_c}{h} - 1\right)$$

Flow around feature:

$$\frac{u^2}{g'h} \ll 2\left(\frac{h_c}{h} - 1\right)$$

where h_c is the height of the crest.

15.34.11 Concentration and concentration fluctuations

The *Workbook* discusses concentration and its definition and use in models, including the *Workbook* correlations, and considers concentration fluctuations. The *Workbook* treatment of concentration is described in Section 15.45. The concentration used in the *Workbook* correlations is defined in Section 15.34.2 for a continuous release and in Section 15.34.3 for an instantaneous release. For a continuous release the concentration in the *Workbook* correlations is the long-term average, whilst for an instantaneous release it is the ensemble average of the maximum short-time (0.6 s) mean concentrations.

15.34.12 Validation and application

The *Workbook* includes a section on comparisons between, on the one hand, the predictions of its correlations and, on the other, observations from the field trials on LNG and liquefied propane at Maplin Sands, the Burro trials at the Nevada Test Site on LNG, the Thorney Island trials on Freon, and the chlorine trials at Lyme Bay, and the predictions of other models for these trials. The models include the following: the Germeles – Drake model; SLAB and FEM3; the BG/C&W model; HEGADAS; DEGADIS; a model by Wheatley *et al.* (1987 SRD R438); and a correlation by the Center for Chemical Process Safety (CCPS, 1987/2). Figure 15.90 shows a comparison given in the *Workbook* between the predictions of its correlation and those of DEGADIS for continuous releases of propane in the Maplin Sands trials. A comparison is also made between the prediction of the correlations and the observed cloud dimensions in the Potchefstroom incident (Lonsdale, 1975).

In estimating the distance to the LFL, the Workbook correlations were generally in good agreement. However, the correlations are essentially for gas clouds at ambient temperature and are not intended to handle very cold clouds such as those formed by LNG. The predictions for the Burro trials were conservative, even after utilizing the cold gas correction to the isothermal correlation.

15.35 Dispersion of Dense Gas: DRIFT and Related Models

A family of dense gas dispersion models based on a set of fundamental conservation equations has been developed by the SRD. The work is described in the following reports: *Mathematical Modelling of Two-phase Release Phenomena in Hazard Analysis* (Webber *et al.*, 1992 SRD R584), *Description of Ambient Atmospheric Conditions for the Computer Code DRIFT* (Byrne *et al.*, 1992 SRD R553), *A Differential Phase Equilibrium Model for Clouds, Plumes and Jets* (Webber and Wren, 1993 SRD R552), A *Model of a Dispersing Dense Gas Cloud and the Computer Implementation DRIFT.* I, *Near-instantaneous Releases* (Webber *et al.*, 1992 SRD R586) and *A Model of a Dispersing Dense Gas Cloud and the Computer Implementation DRIFT. II, Steady Continuous Releases* (Webber *et al.*, 1992 SRD R587). These reports may be summarized as

Source term	R584
Ambient atmospheric model	R553
Differential phase equilibrium model	R552
Integral dispersion model: near-instantaneous release	R586
Integral dispersion model: steady continuous release	R587

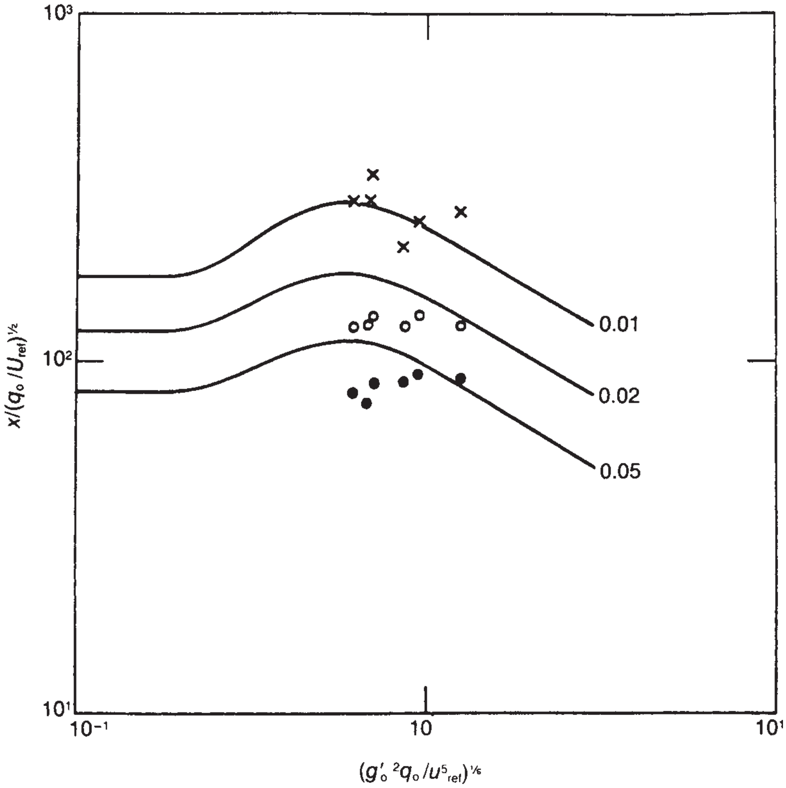

Figure 15.90 *Workbook method for dense gas dispersion–comparison of predictions of Workbook correlation with those of DEGADIS for Maplin Sands continuous propane spills (Britter and McQuaid, 1988; reproduced with permission)*

15.35.1 Source term model

The source term model is given in R584, which is in four parts: (1) modelling of two-phase jets; (2) modelling jets in ambient flow; (3) differential phase equilibrium model for clouds, plumes and jets and (4) dynamics of two-phase catastrophic releases. The third part is the same as R552.

15.35.2 Differential phase equilibrium model

The differential phase equilibrium model given in R552 is a simple two-phase model of the thermodynamics of the cloud. It provides a module which covers this aspect only and is intended to be used in combination with a set of fluid flow models which cover aspects such as the source term, air entrainment and deposition. The model can handle dry or moist air and contaminants which are immiscible with water or water soluble. The report includes a treatment of hydrogen fluoride in moist air.

15.35.3 Ambient atmospheric conditions model

The model for ambient atmospheric conditions described in R553 supplies the meteorological parameters required by the DRIFT model. The DRIFT model requires the following meteorological parameters: the roughness length z_o, the friction velocity u^* and the Monin–Obukhov length scale L_s (or rather the reciprocal $1/L_s$). The two latter quantities are obtained from the ambient atmospheric conditions model.

This model gives three schemes for determining $1/L_s$. The first is the Monin–Obukhov scheme itself and the other two schemes are named after Pasquill and Holtslag. In the Pasquill scheme use is made of the relationship given by Colder (1972) between z_o and $1/L_s$, which has been described in Section 15.12. The graph given in Figure 15.45 by Colder is fitted by the following equation:

$$1/L_s = (1/L_{ref})[\log_{10}(z_o/z_{ref})] \qquad [15.35.1]$$

where L_s is the length scale (m), z_o is the roughness length and L_{ref} (m) and z_{ref} (m) are the corresponding reference values. The two latter quantities are functions of the Pasquill stability class:

Pasquill stability category	L_{ref} (m)	z_{ref} (m)
A	33.162	1117
B	32.258	11.46
C	51.787	1.324
D	∞	–
E	–48.330	1.262
F	–31.325	19.36

The Holtslag scheme (Holtslag and van Ulden, 1983) involves the estimation of the sensible heat flux H, which is a function of the solar radiation and the albedo of the surface. The length scale L_s is obtained from Equation 15.12.46.

For al three schemes the friction velocity u^* is obtained from the wind speed at the height of interest using the similarity profile of Businger *et al.* (1971).

15.35.4 DRIFT: near-instantaneous release

The dense gas dispersion model itself is DRIFT (Dense Releases Involving Flammables or Toxics), an integrated model which is described in two reports: the near-instantaneous release version in R586 and the steady continuous release version in R587. The DRIFT models have similarities to the earlier SRD models DENZ and CRUNCH, but represent a significant advance on these. They incorporate both a more comprehensive thermodynamic module and improved models for the dispersion processes.

It is convenient to describe first the near-instantaneous model. The model uses the coordinate system (ξ, y, z) of Wheatley (1986 SRD R445), where y is the crosswind coordinate, z is the vertical coordinate and ξ is a coordinate described as the downwind coordinate relative to the skewed cloud axis. This allows for the case where the cloud is not a right cylinder but 'leans over'. The variable ξ is defined as

$$\xi = x' - \zeta(z - Z) \qquad [15.35.2]$$

with

$$x' = x - X \qquad [15.35.3]$$

where x (is a relative coordinate (m), X is the downwind coordinate of the cloud centre (m), Z is the vertical coordinate of the cloud centroid (m), ζ is a measure of the skewness of the cloud and ξ is a downwind coordinate relative to the skewed cloud axis (m).

A characteristic feature of the model is the way in which the air entrainment is modelled. Use is made of a general profile which comprehends both the top-hat and Gaussian approaches. This means that it is possible to dispense with arbitrary definitions of the cloud boundary, such as a concentration which is one-tenth that of the centre line concentration and that there is seamless transfer between the dense gas and passive gas dispersion regimes.

The concentration is expressed as

$$C = C_m F_h(\xi, y) F_v(z) \qquad [15.35.4]$$

with

$$F_h(\xi, y) = \exp\{-[(\xi/a_1)^2 + (y/a_z)^2]^{w/2}\} \qquad [15.35.5]$$

$$F_v(z) = \exp[-(z/a_3)^s] \qquad [15.35.6]$$

where C is the concentration, C_m is the ground level centre concentration and a_1, a_2, a_3, s and w are parameters.

The DRIFT model contains a model of the atmosphere with profiles of the wind speed and the diffusion coefficient and relationships for the moisture content. Essentially, the model may be regarded as a framework which takes care of the basic conservation relations and into which can be slotted models for the cloud dynamics and cloud thermodynamics. The former includes models for lateral spreading, air entrainment and vertical diffusion, downwind travel, and so on.

For the cloud thermodynamics there is a basic homogeneous equilibrium model. Models are also provided covering a number of additional options such as moist air, contaminant immiscible with or miscible in water and for ammonia and hydrogen fluoride. It will be apparent from this description that the model has the ability to accommodate new models both for cloud dynamics and cloud thermodynamics as these may be developed.

15.35.5 DRIFT: steady continuous release

The second DRIFT model, for a steady continuous release, which is described in R587, is essentially similar, but utilizes variables representing mass flux rather than mass, and so on. Apart from this the two versions, and the reports R586 and R587, are very similar.

15.35.6 Validation and application

Accounts of the application and validation of DRIFT do not as yet seem to have appeared.

15.36 Dispersion of Dense Gas: Some Other Models and Reviews

Several other models, or sets of models, and reviews of models merit brief mention. The field trials referred to in this account are described in Sections 15.37 and 15.38.

15.36.1 Eidsvik model

Another early and influential box model was that by Eidsvik (1979, 1980). The model utilizes the basic box model Equations 15.24.24 and 15.24.25. The vertical entrainment velocity is taken to be a function of a characteristic vertical turbulent velocity and the Richardson number.

15.36.2 Fay and Ranck model

Another box model frequently mentioned is that by Fay and Ranck (1983). This again uses the same two basic box model equations. The vertical entrainment velocity is taken as the product of the friction velocity and a function of the Richardson number.

15.36.3 TNO models

Several models for dense gas dispersion have been developed at TNO. One of these is the model described by van Buijtenen (1980). This models the dispersion as an initial phase of slumping without entrainment of air followed by a phase in which gas is 'picked off' into the air from the top of the cloud. Its subsequent dispersion is modelled as passive dispersion from a number of sources on the top of the cloud. A further account of TNO dense gas dispersion models is given by Verhagen and Buytenen (1986).

15.36.4 TRANSLOC

One of the early if-theory models for dense gas dispersion, SIGMET, has already been described. Another early if-theory model was TRANSLOC, produced at the Battelle Institute at Frankfurt, and described by Schnatz and Flothman (1980). Further information on TRANSLOC is given in the comparative review by Blackmore, Herman and Woodward (1982).

15.36.5 VKI models

The von Karman Institute (VKI) in Belgium has produced a number of models for dense gas dispersion. Early work was done by Foussat (1981). Van Dienst *et al.* (1986) have described subsequent work. Further development includes the BITC model referred to below.

15.36.6 BITC model

The Bureau International Technique du Chlore (BITC) and the VKI have developed a model for dense gas dispersion, with particular reference to chlorine. An account of the model is given by Vergison, van Dienst and Easier (1989). The BITC model is a three-dimensional one.

15.36.7 ZEPHYR

A further if-theory model is ZEPHYR, developed by Energy Resources Co. (ERCO) for Exxon Research and Engineering, as described by McBride (1981). The comparative review by Blackmore, Herman and Woodward (1982) gives further information on ZEPHYR. It is one of the models considered in the comparison of model predictions and results of the field trials at Matagordo Bay and Porton Down described by J.L. Woodward *et al.* (1982).

15.36.8 MARIAH and MARIAH-II

MARIAH is a if-theory model developed for Exxon Research and Engineering by Daygon-Ra. Descriptions have been given by Taft (1981) and Taft, Ryne and Weston (1983). MARIAH is one of the models included in the comparative review by Blackmore, Herman and Woodward (1982). The comparison given by J.L. Woodward *et al.* (1982) of model predictions with the results of the field trials at Matagordo Bay and Porton Down includes those of MARIAH.

Havens, Schreuers and Spicer (1987) have described an updated version, MARIAH-II, and given a comparison of its predictions with results of the Thorney Island field trials.

15.36.9 DENS20

DENS20 is an advanced slab model which has been described by Meroney (1984a). He gives comparisons of the prediction of the model with results both from wind tunnel experiments and from the Porton Down and Burro trials.

15.36.10 MERCURE-GL

The MERCURE-GL (GL = gaz lourd) model has been developed at Electricite de France (EOF) and described by Riou (1987, 1988) and Riou and Saab (1986). MERCURE-GL, which is a three-dimensional model, is a development of the non-hydrostatic model MERCURE (Caneffl *et al.*, 1985). The accounts by Riou (1987, 1988) and Riou and Saab (1986) include comparisons of model predictions with results of the Thorney Island trials.

15.36.11 DISP2

DISP2 is a pair of advanced box models, one for an instantaneous release and one for a continuous release, developed at ICI. Accounts have been given by Fielding, Preston and Sinclair (1986) and Preston and Sinclair (1987). The latter describe the calibration of the model against the results of the Thorney Island trials.

15.36.12 CCPS correlation

The CCPS (1987/2) has obtained expressions for the dilution ratio V/V_o, including the following relation obtained from dimensional analysis:

$$\frac{V}{V_o} = f\left(\frac{x}{V_o^{1/3}}\right) \qquad [15.36.1]$$

where V is the volume of the cloud and subscript o denotes initial. They obtain a fit to the Thorney Island Phase I instantaneous releases with the correlation

$$\frac{V}{V_o} = \left(\frac{x}{V_o^{1/3}}\right)^{1.5} \qquad [15.36.2]$$

or

$$\frac{C}{C_o} = \left(\frac{x}{V_o^{1/3}}\right)^{-1.5} \qquad [15.36.3]$$

where C is the volumetric concentration.

15.36.13 Reviews of model characteristics

A number of reviews have been published in which the characteristics, as opposed to performance, of dense gas dispersion models are compared. These include reviews by Blackmore, Herman and Woodward (1982), Webber (1983 SRD R243), Wheatley and Webber (1984 CEC EUR 9592 EN) and the CCPS (1987/2).

Characteristics typically considered in such reviews include:

(1) Source elevation: ground level, elevated.
(2) Source dimensions: point, line, area, spreading pool.
(3) Source type: jet, plume, evaporating pool.
(4) Type of release: instantaneous, continuous, transient.
(5) Meteorological conditions: wind speed, including calm conditions; stability conditions; atmospheric humidity.
(6) Topography: flat, sloping terrain; open, obstructed terrain.
(7) Type of model: modified Gaussian, box, if-theory, other.
(8) Submodels of model: gravity-driven flow; momentum relations; cloud advection; air entrainment; heat transfer.
(9) Model outputs: cloud width, height; concentration profiles vs downwind distance, crosswind distance, time.

Reviews of the performance of dense gas dispersion models are considered in Section 15.41.

15.36.14 Webber generalized box model

Webber (1983 SRD R243) has given a generalized box model in the form of a set of dimensionless equations. The basic box model equations, corresponding to Equations 15.24.24 and 15.24.25, are given as

$$\frac{d\hat{r}}{dt} = \frac{1}{2\hat{r}} \qquad [15.36.4]$$

$$\frac{\mathrm{d}\hat{v}}{\mathrm{d}t} = \frac{2\hat{v}}{\hat{r}}\left(\frac{u_{\mathrm{E}}t_{\mathrm{o}}}{R_{\mathrm{o}}}\right) + \hat{r}^2\left(\frac{u_{\mathrm{T}}t_{\mathrm{o}}}{H_{\mathrm{o}}}\right) \qquad [15.36.5]$$

with

$$\hat{r} = R/R_{\mathrm{o}} \qquad [15.36.6]$$

$$\hat{h} = H/H_{\mathrm{o}} \qquad [15.36.7]$$

$$\hat{v} = V/V_{\mathrm{o}} \qquad [15.36.8]$$

$$\hat{t} = t/t_{\mathrm{a}} \qquad [15.36.9]$$

$$t_{\mathrm{o}} = \frac{R_{\mathrm{o}}}{2u_{\mathrm{f}}(0)} \qquad [15.36.10]$$

where H is the height of the cloud, R is the radius of the cloud, t is the time, t_{o} is an initial time scale, u_{t} is the cloud front velocity, V is the volume of the cloud, $\hat{h}$, $\hat{r}$, $\hat{t}$ and $\hat{v}$ are normalized values of H, R, t and V, respectively and o denotes initial.

Integration of Equation 15.36.4 gives

$$\hat{r} = (1 + \hat{t})^{1/2} \qquad [15.36.11]$$

Dividing Equation 15.36.5 by Equation 15.36.4 yields

$$\frac{\mathrm{d}\hat{v}}{\mathrm{d}\hat{r}} = 2\alpha\hat{v}\hat{u}_{\mathrm{E}} + 2\beta\hat{r}^3\hat{u}_{\mathrm{T}} \qquad [15.36.12]$$

with

$$\alpha = \frac{u_{\mathrm{E}}}{u_{\mathrm{f}}(0)} \qquad [15.36.13a]$$

$$= 2t_{\mathrm{o}}\frac{u_{\mathrm{E}}(0)}{R_{\mathrm{o}}} \qquad [15.36.13b]$$

$$\beta = \frac{1}{2}\,\frac{u_{\mathrm{T}}(0)}{2u_{\mathrm{f}}(0)}\frac{R_{\mathrm{o}}}{H_{\mathrm{o}}} \qquad [15.36.14a]$$

$$= t_{\mathrm{o}}\frac{u_{\mathrm{T}}(0)}{H_{\mathrm{o}}} \qquad [15.36.14b]$$

$$\hat{u}_{\mathrm{E}} = \frac{u_{\mathrm{E}}}{u_{\mathrm{E}}(0)} \qquad [15.36.15]$$

$$\hat{u}_{\mathrm{T}} = \frac{u_{\mathrm{T}}}{u_{\mathrm{T}}(0)} \qquad [15.36.16]$$

where u_{E} is the edge entrainment velocity, u_{T} is the top entrainment velocity, $\hat{u}_{\mathrm{E}}$ and $\hat{u}_{\mathrm{T}}$ are normalized values of u_{E} and u_{T}, respectively, and α and β are parameters. Webber then classifies models according to the dependency of $\hat{u}_{\mathrm{E}}$ and $\hat{u}_{\mathrm{T}}$ on $\hat{v}$.

15.37 Dispersion of Dense Gas: Field Trials

As already indicated, there have been a large number of field trials conducted on the dispersion of dense gases. Accounts of such field trials have been given by Puttock, Blackmore and Colenbrander (1982), McQuaid (1984b), Koopman, Ermak and Chan (1989) and Havens (1992), and also by Blackmore, Herman and Woodward (1982) and Koopman *et al.* (1986).

A summary of these trials is given in Table 15.45 and details of some of the principal trials are given in Table 15.46. Details of the Porton Down, Maplin Sands and Thorney Island trials are given separately below.

15.37.1 Early work

A series of experiments on dispersion of chlorine over water were carried out at Lyme Bay in 1927 (McClure, 1927). A summary of these trials has been given by Wheatley *et al.* (1988 SRD R438).

In 1967, some chlorine dispersion experiments were conducted at the Chemical Defence Establishment (CDE), Porton Down, for ICI and BP. Other than this, there appears to have been little work on dense gas dispersion prior to 1970.

In 1966–67, Air Products carried out experiments in which liquid oxygen was spilled into a bund and a steady continuous release maintained using a water spray and the oxygen concentration in the gas plume was measured (Lapin and Foster, 1967).

Some 18 experiments in which about 0.2 m^3 of LNG was spilled into a 2 m^2 bund with three types of surface were carried out in 1968 for the American Gas Association (AGA) by Thomson Ramo Woolridge (TRW) (Seargeant and Robinett, 1968). The vaporization rate decreased over the course of the experiment. Measurements were taken of the methane concentration in the plume. The correlation presented gives the concentration decreasing proportionately with downwind distance.

15.37.2 Bureau of Mines trials

The Bureau of Mines (BM) performed a series of trials in 1970–72 involving the vaporization and dispersion of LNG following spillage on water, as reported by Burgess and coworkers (Burgess, Murphy and Zabetakis, 1970 BM RI 7448, S 4105; Burgess, Biordi and Murphy, 1972 BM PMSRS 4177). In the 1970 work, some 51 trials were conducted in which LNG was spilled instantaneously on water and the pool spread and vaporization were measured; measurements of gas dispersion were not taken. Four trials were also carried out with continuous spillage of LNG and in these the gas dispersion was measured. The Pasquill–Gifford relations were used to model the dispersion, the data being correlated by taking the ratio σ_y/σ_z as 5, indicating a relatively flat cloud. A further 13 continuous spillage experiments were done in 1972, of which six were usable. The ratio σ_y/σ_z was again high.

15.37.3 Esso/API trials

In 1971, a series of spillages of LNG onto the sea were carried out in Matagordo Bay, Texas, by Esso under the auspices of the AGA (Feldbauer *et al.*, 1972). The concentration of methane in the cloud was measured. There were 10 smaller experiments of about 0.9 m^3 and seven larger ones of between 2.5 and 10.2 m^3; the former were virtually instantaneous and the latter nearly so. Again high values of the ratio a_y/a_z in the Pasquill–Gifford model were obtained. Downwind concentrations obtained in these tests are shown in Figure A7.3.

15.37.4 Gaz de France trials

A series of 40 experiments involving the instantaneous spillage of LNG into a bund were performed in 1972 at Nantes by Gaz de France to investigate vaporization, dispersion and combustion (Humbert-Basset and Montet, 1972). Most of the tests involved the spillage of 3 m^3 into bunds with areas 9–200 m^3. The vaporization rate decreased with time. There was also a test with a continuous release of 10 m^3/h.

[c] Area of NTS known as Frenchman Flat.

These trials showed several features of interest. Following the spillage the vaporization was initially very rapid but then fell to a lower, plateau value. The initial visible cloud was observed to separate from the steady plume. The flammable region was always contained within the visible cloud. In a number of tests the cloud tended to lift off the ground in its later stages.

15.37.5 SS Gadila trials

In 1973, larger scale trials of spillage of LNG onto the sea were performed by Shell from the SS Gadila, a LNG carrier (Kneebone and Prew, 1974; Te Riele, 1977). The vessel was being commissioned and the purpose of the trials was to confirm recommended procedures for jettisoning cargo in an emergency. The study of gas dispersion was not a main intent, but photographs were taken of the cloud. There were six tests lasting some 10 min and involving releases of up to 200 m^3. The liquid was ejected from a nozzle at the stern 18 m above the water. It is believed that vaporization was complete before the jet reached the water surface. In two of the tests the ship was stationary and in the others it was moving at up to 10.5 knots. The wind speed at 30 m was 1.9–5.1 m/s with a stable atmosphere. The relative humidity was 80–85%.

Two trials, tests 4 and 6, have proved of particular interest. In test 4, the flow was 7.6 m/min (53.5 kg/s) of LNG with a wind speed of 5.1 m/s. The visible cloud was 1370 m long, although with considerable inhomogeneity beyond 1000 m. The plume had a maximum width of 300 m at 750 m downwind. Its height was about 8–10 m. This test is shown in Figure 15.91.

In test 6, the flow was 19.3 m^3/h (136.5 kg/s) with a wind speed of 3.9 m/s. The plume was more coherent and had a visible length of 2250 m, which was still increasing at the end of the test. It had a maximum continuous width of 550 m and a height of about 10–12 m. The outline of the plume is

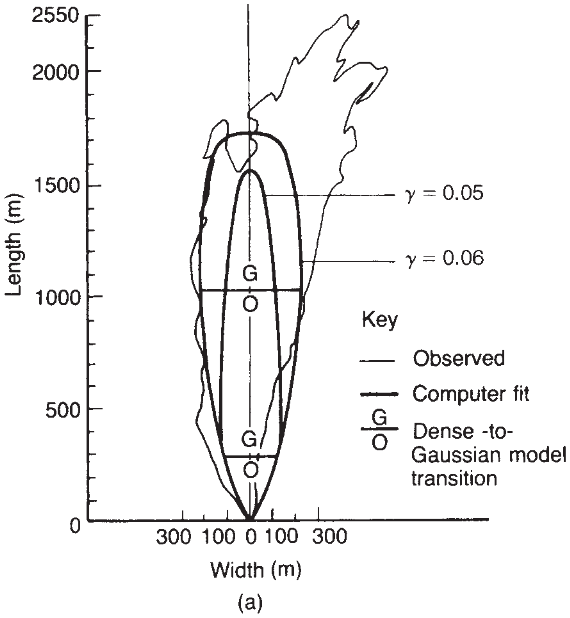
15.37.6 Dutch Freon 12 trial

The first trial involving the virtually instantaneous release of a dense gas at atmospheric pressure and temperature, as opposed to an evaporating liquefied gas, was conducted in 1973 by the Directorate General of Labour (DGL) of the Dutch Ministry of Social Affairs. This experiment has been described by van Ulden (1974) and Buschmann (1975), and also by Te Riele (1977). The release was 1000 kg of Freon 12 which has a relative density of 4.2. The wind speed at 10 m was 3 m/s and the stability was neutral.



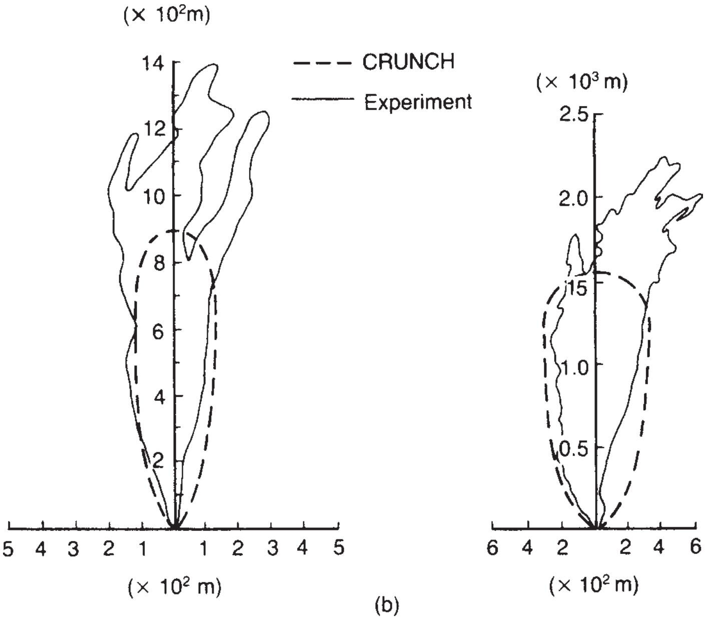


Figure 15.92 Continued

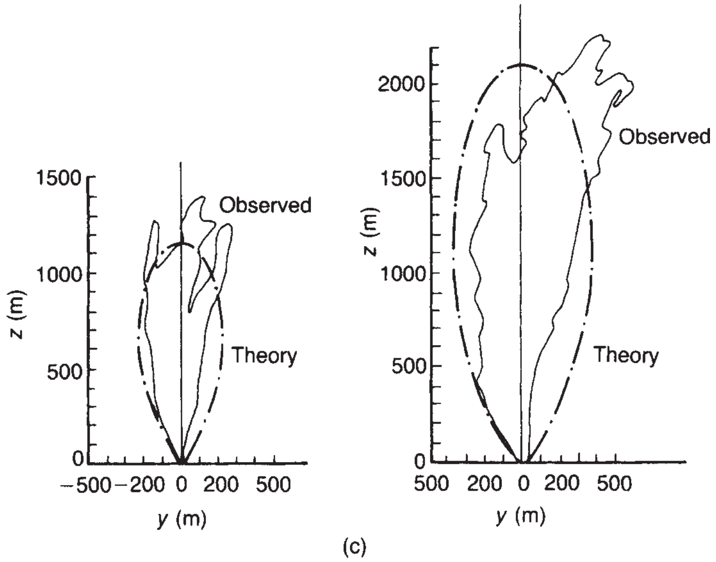

Figure 15.92 *SS Gadila trials on dense gas dispersion at sea–plume from continuous spill of LNG and comparison of observed cloud contour with model predictions of contour: (a) prediction of Cox and Carpenter model for trial 6 (R.A. Cox and Carpenter, 1980) Courtesy of Reidel Publishing Company); (b) prediction of CRUNCH for trials 4 and 6 (Jagger 1983 SRD R229) Courtesy of UKAEA Safety and Reliability Directorate); (c) prediction of te Riele model for trials 4 and 6 (te Riele, 1977) (Courtesy of DECHEMA)*

On release, there was rapid and intensive mixing with air and after some 5 s the estimated volume of the gas–air mixture was 2400 m^3. The shape of the cloud was roughly cylindrical with some elongation along the direction of the wind. Its height fell from an initial value of 5 m to a minimum of 0.2 m before increasing again, reaching 10 m at 1000 m downwind. Its radius increased rapidly with distance at first with the rate of increase then reducing.

The height and radius of the cloud are shown in Figure 15.76. The radius is much greater and the height much less than predicted for passive dispersion of a cloud of neutral buoyancy.

15.37.7 AGA/Battelle trials

In 1974, further experiments on the spillage of LNG into bunds were conducted near Capistrano, California, by Battelle Columbus Laboratories sponsored by the AGA (Duffy, Gideon and Puttnam, 1974). There were 42 trials, of which 14 involved ignition and 28 dispersion. Of the latter, 17 were with a 2 m bund, 9 with a 6 m bund and 2 with a 24 m bund. The test approximated an instantaneous spill, the release being made over 20–30 s. The results were marred by a tendency for the liquid to spill outside the bund. A correlation was derived for maximum downwind concentration in terms of bund area and wind velocity.

15.37.8 Porton Down trials

In 1976–78, a series of trials were conducted at the Chemical Defence Establishment for the HSE involving the virtually instantaneous release of a dense gas at atmospheric pressure and temperature. These have been described by Picknett (1981), and also by McQuaid (1979b).

Five sites were used: two flat with short grass, one flat with rough grass and two sloping with short grass. The source was a 40 m^3 collapsible tent. The gas released was a mixture of Refrigerant 12 and air, with relative densities varying from 1.03 to 4.2. Coloured smoke was also added to make the cloud more visible.

Selected experiments in the Porton trials are given in Table 15.47. The experiments were designed to yield pairs of trials which differed in one feature only and thus demonstrated the effect of that feature. Picknett gives tables of such trial pairs showing the effect of relative density, roughness length, ground slope and wind speed. Picknett describes the behaviour of the dense gas in these trials. The effect of density is seen in trial 8 which was conducted in still air. The cloud kept its original shape momentarily after the collapse of the tent and then gravity caused an accelerating flow downwards to the ground, followed by a billowing, outwards motion involving considerable mixing with air. The cloud then expanded as a horizontal disc but with a raised annular rim. This rim was highly turbulent and persisted for some seconds before the turbulence and the rim itself collapsed. These features are illustrated in Figure 15.93. There followed a phase in which the cloud height remained virtually constant, but the area of the cloud grew almost linearly, as shown in Figure 15.94.

The effect of wind, as in trial 36, was to cause the cloud to spread initially upwind somewhat and to assume downwind a horseshoe shape, as shown in Figure 15.95. At first the width exceeded the length, but this then reversed. Initially the cloud velocity was much less than the wind speed, but the cloud underwent a gradual acceleration.

The initial violent motion of the cloud caused rapid dilution. In trial 8 the gas concentration fell from an initial value of 30 to 3% in 6 s. In wind the rate of dilution was even higher.

The concentration of gas in the cloud initially was very inhomogeneous. In trial 8 in still air the concentration

39	1.03	Flat	10	1.8	E–F	Initial density near neutral

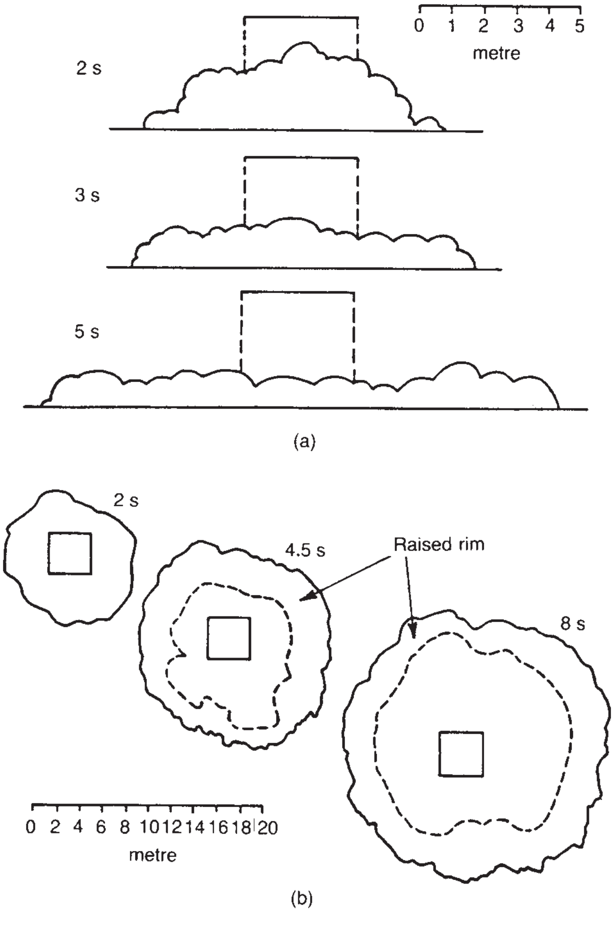

Figure 15.93 *Porton Down trials on dense gas dispersion with Refrigerant 12 – growth of cloud in trial 8–1 (Picknett, 1981): (a) elevation view; (b) plan view (Courtesy of Pergamon Press)*

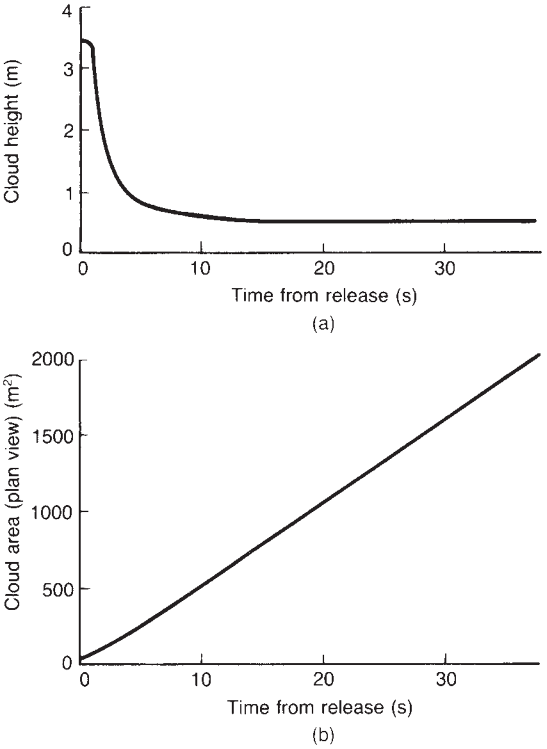

Figure 15.94 Porton Down trials on dense gas dispersion with Refrigerant 12 – growth of cloud in trial 8–2 (Picknett, 1981) (Courtesy of Pergamon Press)

measured near the ground fluctuated by a factor of 2 or more within 10 s. In trials 6 and 12 with wind the behaviour of the concentration varied with the measurement distance. In trial 6, at a point near the source the vertical concentration profile at 5 s was concave, but eventually a profile was established in which the concentration decreased monotonically with height, as shown in Figure 15.96(a). In trial 12, at a distance of 25 m the profile at 10 s was convex, but again in due course a monotonically decreasing profile was established, as shown in Figure 15.96(b).

The effect of slope was very large for a release in still air. In wind the effect was less marked. The main feature was that with wind blowing uphill and the cloud flowing downhill, the two opposing effects suppressed the formation of the raised rim and gave instead a tongue flowing along the ground and a reverse, uphill flow above the tongue. The cloud soon became dilute enough for the wind to carry it uphill.

15.37.9 China Lake trials: Avocet, Burro and Coyote series

The Naval Weapons Center (NWC) test facility at China Lake, California, has been the site of several series of dense gas dispersion trials. Accounts of the facility have been given by Ermak *et al.* (1983). Much of the work at this site has been sponsored by the Department of Energy (DoEn) and conducted by the Lawrence Livermore National Laboratory (LLNL).

The Avocet series was a set of four trials involving spillage onto water of some 4.5 m^3 of LNG over about 1 min. The main purpose of these trials, described by Koopman, Bowman and Ermak (1980), was the development of the test facility.

In 1980, the Burro series of trials was performed involving the continuous release onto water of up to 40 m^3 of LNG over periods up to 3.5 min. These tests are therefore classed as continuous releases. They have been described by Ermak, Chan *et al.* (1982) and Koopman *et al.* (1982). Selected trials are summarized in Table 15.48.

The experiments were well instrumented and obtained a fairly comprehensive set of measurements, including turbulence and concentration fluctuations in the plume.

Figure 15.97(a) shows the plume in Burro 8 after 30 s and Figure 15.97(b) the plume in Burro 6 after quasi-steady state had been reached. Analyses of the results of the Burro trials have been given by Koopman *et al.* (1982) and by Ermak, Chan *et al.* (1982). The latter have given comparisons of the results with predictions from the Germeles-Drake model and from SLAB and FEM3.

Further analyses have been reported by Koopman, Ermak and Chan (1989). Concentration contours in the Burro trial 8 are shown in Figure 15.98. Figure 15.98(a) gives the observed crosswind elevation view contours at a downwind distance of 140 m at 180 s. Figures 15.98(b) and (c) give the predictions of FEM3 for flat terrain and variable terrain, respectively. Figures 15.98(d) and (e) show the observed and predicted plan view contours.

The Burro tests were followed in 1981 by the Coyote series which were concerned primarily with rapid phase transition (KPT) and with ignition.

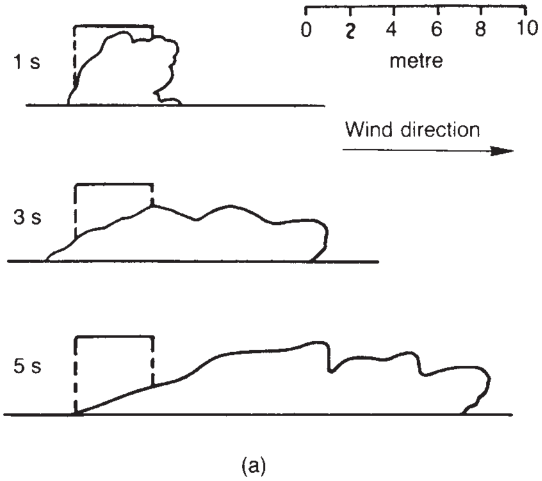
15.37.10 Maplin Sands trials

In 1980, a series of trials was carried out by Shell at Maplin Sands. Accounts of the work has been given by Puttock and coworkers (Puttock, Blackmore and Colenbrander, 1982; Puttock, Colenbrander and Blackmore, 1983, 1984; Colenbrander and Puttock, 1984).

Figure 15.99 shows the site used for the trials. The liquefied gases were released onto water from a pipeline terminating in a downwards-pointing pipe and measurements were taken by instruments located on pontoons placed in arcs around the release point.

Two series of trials were carried out, one with propane and one with LNG. The experiments were mainly continuous spills but, for both gases, some trials with instantaneous spills were conducted. A total of 34 trials were performed, of which 11 involved ignition. Table 15.49 gives details of some of the trials selected by the authors as providing results useful for dispersion work.

The propane trials with continuous spills, of which there were 11, have been described by Puttock, Colenbrander and Blackmore (1983). The two trials not shown in Table 15.49 are trial 42, an underwater release, and trial 50, an ignited release. Two experiments in particular are described. In trial 46 the wind speed was 8.1 m/s and in trial 54 3.8 m/s. Figure 15.100(a) and (b) show the corresponding comparisons between the outline of the observed plume and the contour predicted by HEGADAS.



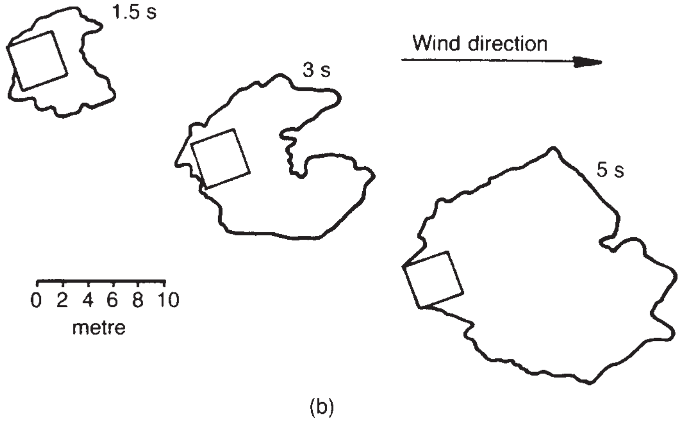


Figure 15.95 *Porton Down trials on dense gas dispersion with Refrigerant 12 – growth of cloud in trial 36 (Picknett, 1981): (a) elevation view; (b) plan view (Courtesy of Pergamon Press)*

An account of the three propane trials with instantaneous spillage has been given by Puttock, Blackmore and Colenbrander (1982). Trial 60 was performed with a very low wind speed of 1.2 m/s and gave an almost circular cloud. In trial 63 the wind speed was 3.5 m/s, and thus also fairly low. The cloud started off roughly circular and very shallow, then moved off with the wind, with a raised head around the edge, and growing in height as it moved.

The LNG trials have been described by Puttock, Blackmore and Colenbrander (1982), Puttock, Colenbrander and Blackmore (1984) and Puttock (1987c). There were 13 continuous spills, of which the authors describe three in particular: trials 15, 29 and 56. Figure 15.101 shows a comparison for the latter between the outline of the observed plume and the contour predicted by HEGADAS.

Of the instantaneous LNG spills, trials 22 and 23 were considered of particular value. The wind speed in these trials was 5 m/s and thus higher than in the propane instantaneous spills. Compared with the latter the cloud produced was very elongated and more like that from a continuous spill. Figure 15.102 shows the development of the cloud in trial 22 together with a comparison of the contour predicted by HEGADAS.

15.37.11 Thorney Island trials

The Thorney Island trials were a progression from the Porton Down trials and again involved release of a dense gas at atmospheric pressure and temperature. Most of the releases were instantaneous. The second series involved obstructions and a building. A third series was done with continuous releases. The Thorney Island trials are described in Section 15.38.

15.37.12 NTS trials: Desert Tortoise and Eagle series

The experimental work described so far has been concerned with dispersion of dense gases in general and of

hydrocarbons in particular. More recently, there has been growing interest in other hazardous materials, especially toxic liquefied gases.

Much of this work has been done at the Nevada Test Site (NTS). This site includes the area of Frenchman Flat which is the location of the Liquefied Gaseous Fuels Spill Test Facility (LGFSTF). This facility, and some of the test programmes conducted there, have been described by Leone (1990), and also by Koopman, Ermak and Chan (1989).

In 1983, the Desert Tortoise series of trials involving liquid ammonia were carried out at the NTS by the LLNL for the US Coast Guard and The Fertilizer Institute (TFI). These have been described by Goldwire (1986) and Koopman *et al.* (1986), and also by Koopman, Ermak and Chan (1989). A summary of the Desert Tortoise trials is given in Table 15.50. There were four trials, all approximating continuous spills. The accounts concentrate mainly on the largest release, trial 4. In this experiment 60 m^3 of liquid ammonia at 171 psia and 24°C was released at a rate of 9.5 m^3/min into air at 30.8°C and relative humidity 21% with a wind speed of 4.5 m/s and stability category E. The release was from a horizontal pipe 0.8 m above the ground surface and pointing downwind. The adiabatic flash was estimated to give 17% vapour and 83% spray.

Most of the ammonia remained airborne as vapour and spray but, in contrast to the smaller releases, a large pool of liquid formed and persisted for about 8 min. The pool temperature was measured as −52°C at 3 m and −63°C at 9 m downwind. Mass balances on the plume showed that the proportion of material released which passed the 100 m and 800 m arcs was about 70%; 30% was unaccounted for. At the 100 m point, small puffs of boiled-off vapour were seen on and off at least 1100 s after the start.

The jet persisted beyond the 100 m arc. The movement of the plume was dominated by the jet and dense gas features. At the 100 m arc the plume was about 70 m wide and

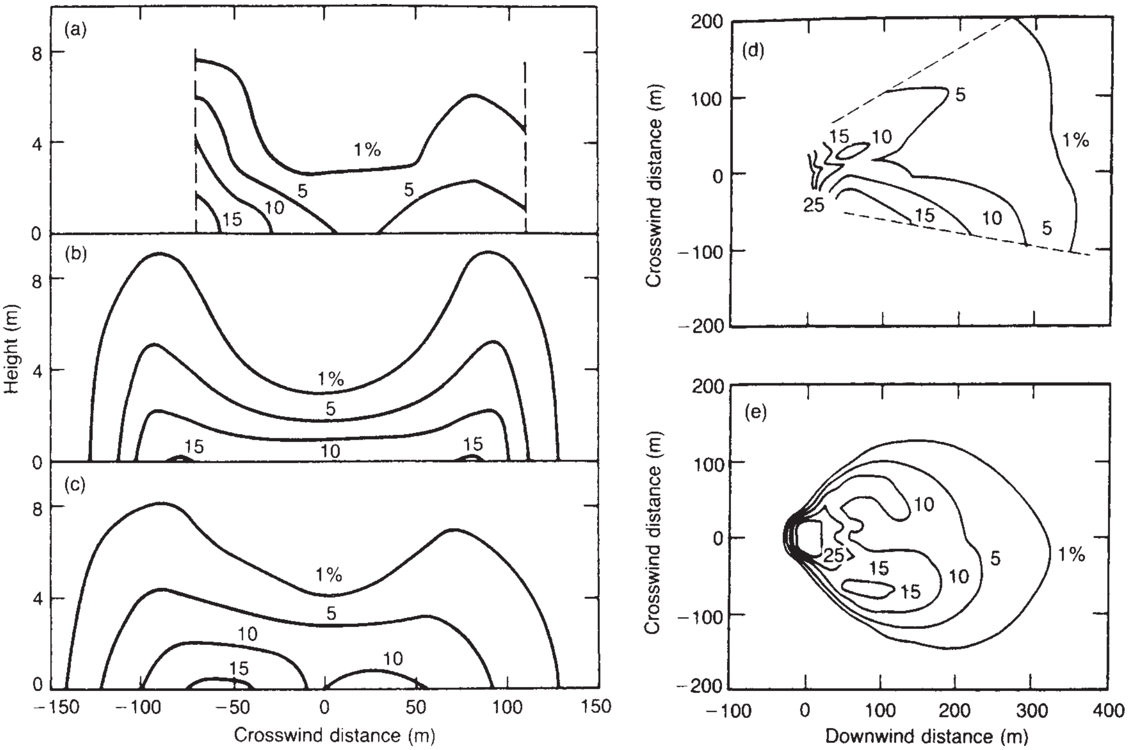

Figure 15.98 Nevada Test Site trials, Burro series, on dense gas dispersion with LNG (Koopman, Ermak and Chan, 1989) – trial 8: (a) observed crosswind elevation view of concentration contours 140 m downwind after 180 s; (b) predictions of FEM3 of crosswind elevation view of concentration contours 140 m downwind after 180 s with flat terrain; (c) predictions of FEM3 of crosswind elevation view of concentration contours 140 m downwind after 180 s with variable terrain; (d) observed plan view of concentration contours at 1 m above ground level at 180 s; (e) predictions of FEM3 of plan view of concentration contours at 1 m above ground level at 180 s with variable terrain (Courtesy of Elsevier Science Publishers)

generally less than 6 m high. At the 800 m arc the width had increased to about 400 m, but the height was still about 6 m. The ammonia fog persisted beyond 400 m.

The values given for the maximum gas concentrations vary slightly. Koopman *et al.* state that this concentration was 10% at 100 m, 1.6% at 800 m and 0.53% at 2800 m. The crosswind elevation of the concentration contours at the 800 m arc given by Goldwire is shown in Figure 15.103.

The boiling point of ammonia is −33.4°C. The temperature of the plume rose to −7°C at 100 m and to 23°C at 800 m, compared with the ambient air temperature of 32.8°C. The surface heat flux was determined as 2.2 kW/m^2.

The Eagle trial series, performed by LLNL for the US Air Force, involved spillages of nitrogen tetroxide and followed straight on from the Desert Tortoise series. It has been described by McRae and coworkers (McRae *et al.*, 1984; McRae, 1986).

15.37.13 NTS trials: Goldfish series

In 1986, the Goldfish series of trials involving liquid hydrogen fluoride was carried out at the Frenchman Flat area of the NTS for Amoco by LLNL and Amoco. An account of these has been given by Blewitt *et al.* (1987a), and also by Koopman, Ermak and Chan (1989).

A summary of the Goldfish trials is given in Table 15.51. There were six trials, all approximating continuous spills, three concerned with dispersion and three with water spray barriers. Of the former group, the first was an exploratory test. The main dispersion trials, therefore, were trials 2 and 3.

The liquid hydrogen fluoride was released as a horizontal jet. The adiabatic flash was estimated to give some 20% vapour and 80% spray, although the thermodynamics of hydrogen fluoride are complex. In none of these tests was any liquid collected in the spill pond. Special facilities were provided to give a capability to increase the humidity of the ambient air. These were located upwind and consisted of a large pond and of an array of nozzles half operating on steam and half on water spray.

Trial 2 was performed at low relative humidity, the dewpoint temperature being 1.1°C. In this experiment liquid hydrogen fluoride at 115 psig and 38°C was released at a rate of 175 US gal/min (0.011 m^3/s) into the ambient air at 36°C with a wind speed of 4.2 m/s and stability category D. The crosswind elevation of the concentration contours at 300 m at 54 s and 121 s are shown in Figure 15.104(a) and (b).

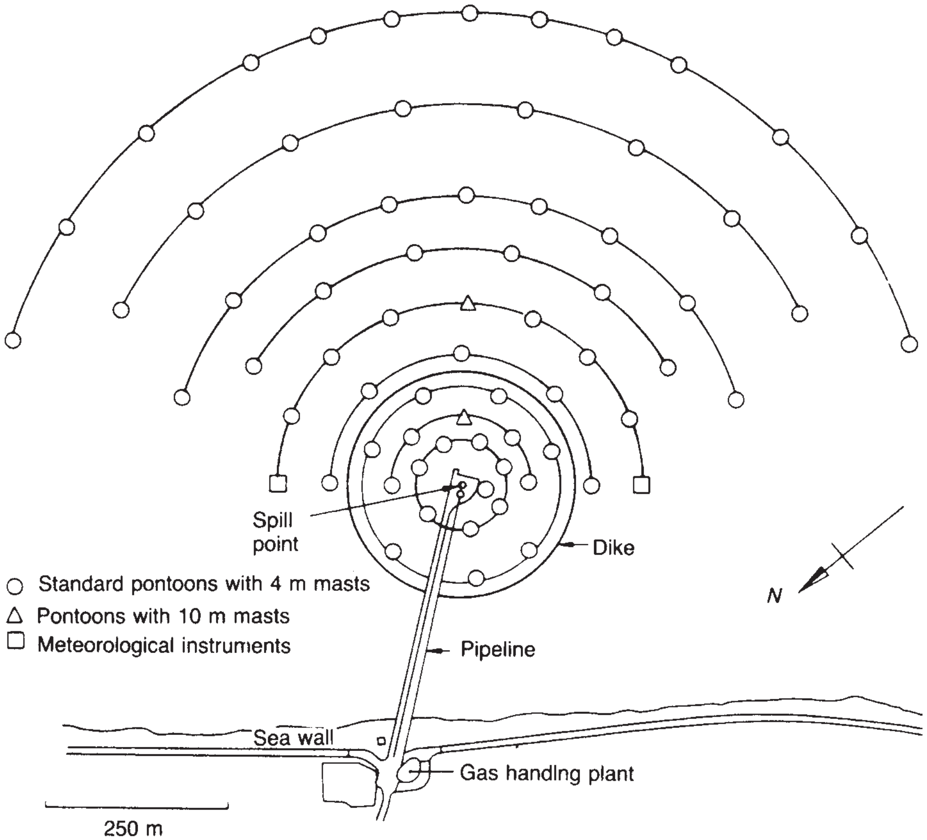

Figure 15.99 *Maplin Sands trials on dense gas dispersion – site layout (Puttock, Blackmore and Colenbrander, 1982) (Courtesy of Elsevier Science Publishers)*

Trial 3 differed in that the relative humidity was raised artificially to give a dewpoint temperature of 6.6°C. In this experiment the wind speed was 5.4 m/s and the air ambient was at 26.5°C, the other conditions being similar to those mentioned above for trial 2. The plume was visible at 400–500 m. The crosswind elevation concentration contours at 300 m at 113 and 225 s and at 1000 m at 292 and 358 s are shown in Figures 15.104(c)–(f).

The boiling point of hydrogen fluoride is 20°C. In trial 2 the temperature of the plume at 20 m downwind dropped within seconds to about −30°C below ambient temperature, then fell more gradually to about −45°C below over 350 s, whilst in trial 3 it fell sharply to about −48°C below and remained at about −45°C below again for about 350 s. In both trials the plume temperature then rose rapidly, stayed at about −10°C below until about 600 s and then rose to eliminate the temperature differential by about 700 s.

Trials 4–6 on water spray barriers are described in Section 15.53.

15.37.14 NTS trials: Hawk series

In 1988 another series of trials, the Hawk series, was carried out on hydrogen fluoride at the Nevada Test Site for the Industry Co-operative Hydrogen Fluoride Mitigation and Assessment Program (ICHMAP, or HMAP). These trials investigated not only dense gas dispersion but also the use of vapour barriers and water spray barriers. An account has been given by Diener (1991). The Goldfish trials caused some concern due to the ineffectiveness of a dike for containing a pressurized release and to the hazard ranges obtained.

The work included the development of a complete model system for emission, vaporization and dispersion of hydrogen fluoride. The HEGADAS model was selected for development as the basis of the system, HFSYSTEM, described in Section 15.31. The trials on vapour barriers and water spray barriers are described in Section 15.53.

15.38 Dispersion of Dense Gas: Thorney Island Trials

In 1982–84, the HSE organized a series of heavy gas dispersion trials (HGDTs) at Thorney Island. The trials were a major undertaking involving over a number of years the collection, processing and reconciliation of data from the trials and the comparison of the results with those from theoretical models and from physical modelling. They are described in Heavy Gas Dispersion Trials at Thorney Island (two volumes) by McQuaid (1985a, 1987).

The main trials were with instantaneous releases and were conducted in two series, Phases I and II. Phase I

involved unobstructed releases over a flat surface, Phase II releases over a flat surface with obstructions. A short series of trials with continuous releases was also performed. In addition, the Thorney Island site was subsequently used by the US Coast Guard and Department of Transportation to conduct their own series of experiments, termed the Phase III series. A summary of the Thorney Island trials is given in Table 15.52.

15.38.1 Phase I trials

An account of the Phase I trials has been given by McQuaid (1984b,c, 1985b,c). The organization of the trials has been described by A.G. Johnston (1985) and McQuaid (1985b). Other accounts cover the following aspects: systems development and operations procedures (D.R. Johnson, 1985); the site geography and meteorology (M.E. Davies and Singh, 1985b); the gas sensor system (Leek and Lowe, 1985); the meteorological data (Puttock, 1987a); the determination of the cloud area and path from visual records (Brighton, Prince and Webber, 1985; Prince *et al*., 1985 SRD R318); the determination of the cloud path from concentration measurements (Brighton, 1985 SRD R319); the computer processing of the visual records (Riethmuller, 1985); the cloud advection velocities (Wheatley and Prince, 1987); the effect of averaging time on the statistical properties of the sensor records (Nussey, Davies and Mercer, 1985); the mean concentration and variance (Cam, 1987); the area-averaged concentration, height scales and mass balances (Brighton, 1985a); the computer processing of the data for comparison with models (Pfennning and Cornwell, 1985); the presentation and availability of the data (Roebuck, 1985); and users' views of the data (N.C. Harris, 1985; Brighton, 1987). Critiques which discuss the contribution to dense gas dispersion modelling have been given by Hartwig (1985) and Puttock and Colenbrander (1985).

The aim of the Phase I trials was to obtain data which might be used to increase understanding of the mechanisms of dense gas dispersion and to validate models. The trials were designed with the needs of modellers very much in mind. Consideration was given to the requirements for the meteorological parameters and the parameters used in box and if-theory models. In particular, attention was given to the variables required to define stability and to characterize both Richardson number and Monin–Obukhov similarity, and thus in particular to wind speed, roughness length, friction velocity and sensible heat flux. These aspects are discussed by McQuaid (1985b).

The site was an airfield flat to within about 1 in 100. The layout of the site is shown in Figure 15.105. Some 250 instruments were deployed. The gas sensors were fixed to masts, the lowest level being located 0.4 m above ground and the highest levels being 4, 10 and 14.5 m in the near, mid and far fields, respectively. Photographic records were also

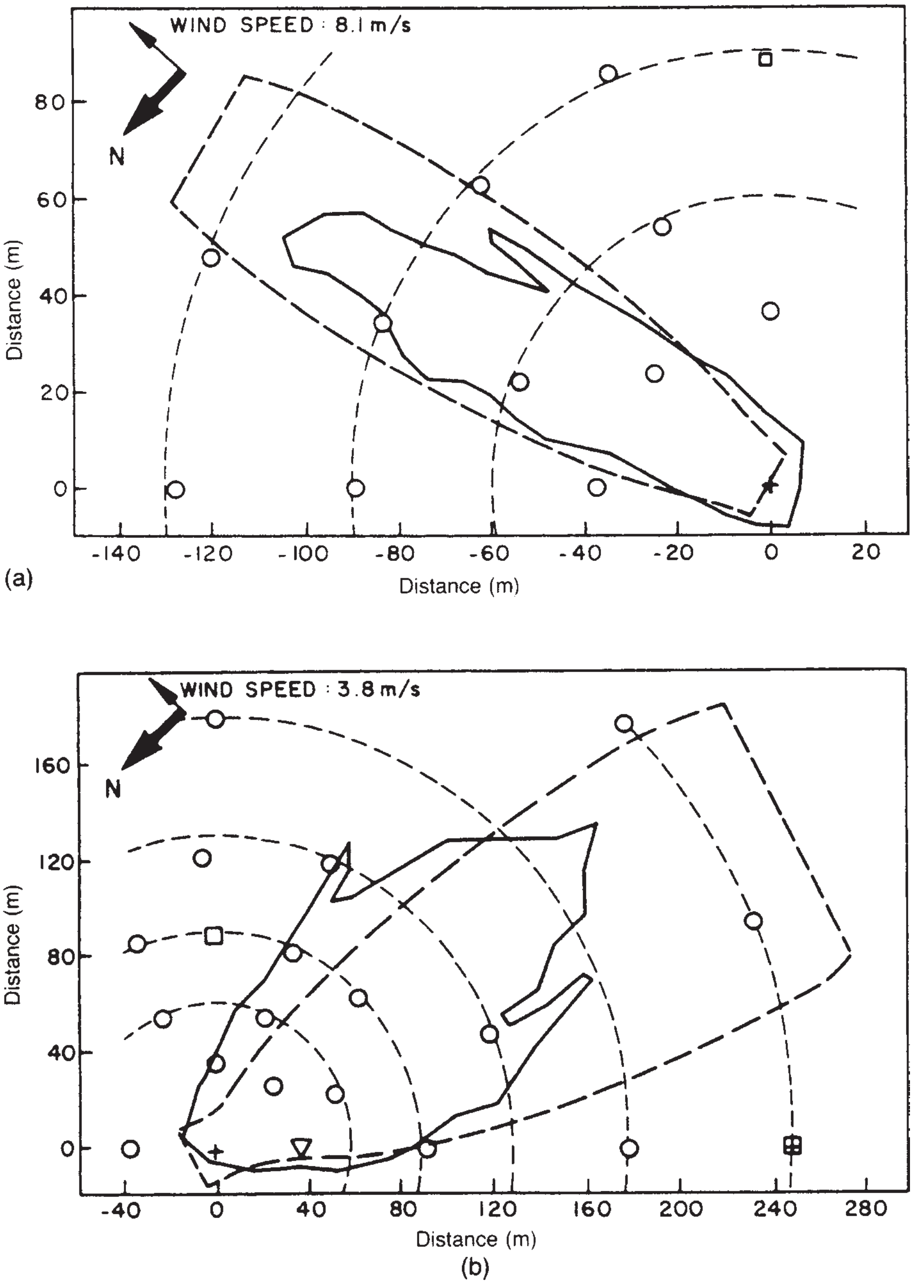

Figure 15.100 *Maplin Sands trials on dense gas dispersion – continuous spills of propane: comparison of observed plumes with limits of visible plumes predicted by HEGADAS (Puttock, Colenbrander and Blackmore, 1983). (a) Trial 46 (wind speed = 8.1 m/s); (b) trial 54 (wind speed 3.8 m/s) (Courtesy of Reidel Publishing Company)*

taken, the visibility of the cloud being enhanced by the use of cartridges of orange smoke.

The Phase I trials involved an instantaneous release of 2000 m^3 of a gas–nitrogen mixture. The gas used was Freon 12, the proportion being varied to give mixtures of different relative density up to 4.2. The container was a 12-sided container 14 m across by 13m high. The container was held up by rigging until the operation of a release mechanism which allowed it to fall to the ground.

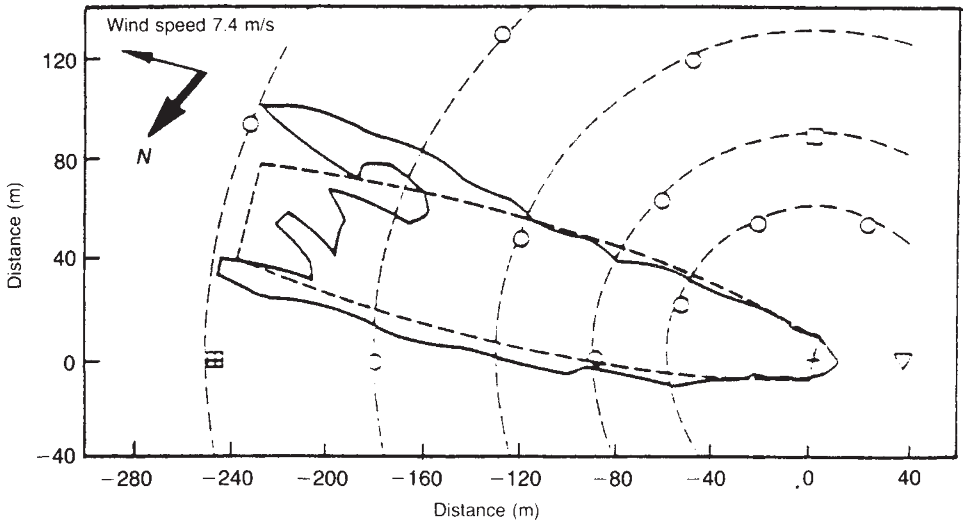

Figure 15.101 *Maplin Sands trials on dense gas dispersion – plume from continuous spill of LNG: Trial 29: comparison of observed plume with limits of visible plume predicted by HEGADAS (Puttock, Colenbrander and Blackmore, 1984) (Courtesy of the American Institute of Chemical Engineers)*

On release, the gas cloud slumped rapidly and spread out radially. There was some movement upwind until this was stopped by the wind. The cloud had a raised front and assumed the characteristic doughnut shape. It then travelled in this form for several hundred metres. Eventually a low-lying cloud formed which covered a large part of the site.

A total of 15 trials was performed, as shown in Table 15.52. In each trial measurements were taken of the concentration vs time profiles at the gas sensors within the cloud. These raw data have subsequently been processed to yield a variety of results. Plate 8 shows the development of the gas cloud in one of these trials. Figure 15.106 shows the peak concentration on the path of the cloud centroid in the Phase I trials.

15.38.2 Phase II trials

The Phase II trials have been described by M.E. Davies and Singh (1985a). The following aspects of the Phase II have been covered in other accounts: the overall properties of the clouds (Brighton and Prince, 1987); and a user's view of the data (Brighton, 1987).

The Phase II series was concerned with dense gas dispersion at obstructions. Three types of obstruction were used:

(1) solid fence;
(2) permeable screen;
(3) building cube.

Details of the Phase II trials are given in Table 15.52.

15.38.3 Phase II trials: solid fence

The solid fence consisted of tarpaulin sheets hung over scaffolding. The fence was 5 m high and was located on a 180° arc at 50 m from the source. Four trials were conducted with this configuration: trials 20–22 and 25.

In trial 25 there was complete blocking of the cloud by the fence, in trial 21 partial blocking and in trial 20 virtually no blocking. There was also appreciable blocking in trial 22 in which the cloud density was much higher.

The results of these trials were compared with Phase I trials carried out under similar conditions but without a fence. The fences affected the concentrations in the far field. Comparison of trial 20 with trial 19 exhibited a marked reduction in peak centreline concentration vs distance, with a several-fold reduction factor out to at least 500 m.

15.38.4 Phase II trials: permeable screens

The permeable screens consisted of military camouflage nets draped over scaffolding. The screens were 10 m high and were located on a 180° arc. Two trials were performed with this configuration: trial 23 with two rows of screens and trial 24 with four rows. The first row was located 50 m from the source, with the subsequent rows at intervals of 3.3 m.

The screens delayed the passage of the gas, and increased the height of the cloud, thus distributing the gas vertically, but they had little effect on peak ground level concentrations at the screens.

The screens affected the concentrations in the far field. Comparison of trial 23 with trial 19 showed a marked reduction in peak centreline concentration vs distance, with a several-fold reduction factor out to at least 500 m.

15.38.5 Phase II trials: building cube

The building cube was a single, isolated 9 m cube constructed of plastic sheets on a wooden frame. Four trials were performed with this configuration: trials 26–28 with the cube 50 m downwind of the source and trial 29 with it 27 m upwind.

6	2.0	0.123	16	5.4	C/D	Water spray (downflow) test

The effect of wind speed on the promotion of mixing by the building was examined in trials 26 and 28. In the former trial the cloud passed around the building without much sign of mixing, whilst in the latter the enhancement of mixing by the building was more obvious.

Trial 27 tested the effect of a building located upwind of the source. The gravity front moving upwind was drawn into the wake of the building but the cloud did not pass around the sides.

15.38.6 Continuous release trials

A description of the continuous release trials has been given by McQuaid (1987). Accounts have also been given of the following aspects: the mass and flux balances (Mercer and Nussey, 1987); the turbulence records (Mercer and Davies, 1987); and a user's view of the data (Brighton, 1987). The aim of the trials was essentially similar to that for the instantaneous releases, i.e. to obtain data which might be used to increase understanding of the dispersion mechanisms and to validate models.

The gas used was a mixture of air and Freon 12 with a relative density of 2.0 in all trials. The source was designed to give a release with zero vertical momentum, the gas being released through an aperture in the ground with a cap above it. The release was at a rate of 5 m^3/s maintained for 400 s. Details of the continuous trials are given in Table 15.52. Three trials were conducted: trials 45–47.

The conditions for trials 45 and 47 were similar, except that the wind speeds were 2.1 and 1.5 m/s, respectively. In trial 45 at the higher wind speed the lateral spread was less and the downwind extent was greater than in trial 47.

The concentration vs time profiles showed that at 36 m downwind a steady-state profile existed for some 360 s, whereas at 250 m no steady profile was obtained. The shape of the concentration profile at 36 m was a sharp rise followed by a slow fall, whilst at 90 m there was a nearly symmetrical concentration rise and fall. With regard to the vertical concentration profile, at 36 m the concentration exhibited intermittency. The plume was characteristically very shallow, about 2 m high, and very broad, up to 300 m wide.

15.38.7 Associated physical modelling

The programme of work associated with the Thorney Island trials included wind tunnel modelling. Preliminary wind tunnel experiments were conducted to screen the programme of trials and confirm that it was on the right lines. Following the trials comparisons were made with these simulations and with earlier ones conducted for the Porton trials. This work is described in Section 15.39.

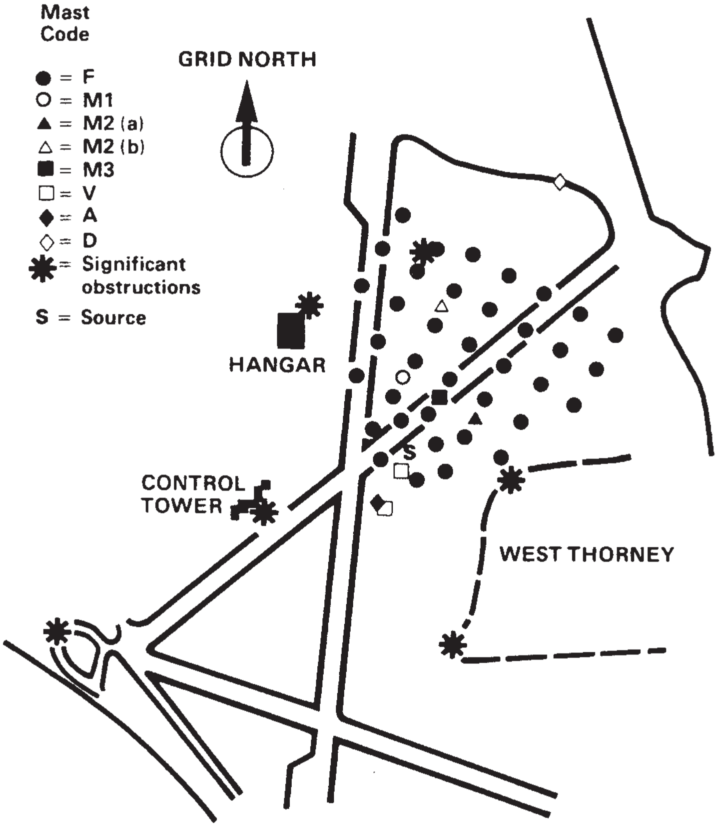

Figure 15.105 *Thorney Island trials on dense gas dispersion – site layout (McQuaid, 1985b) (Courtesy of Elsevier Science Publishers)*

15.38.8 Phase III trials

As described by M.E. Davies and Inman (1987), the Phase III trials involved releases with a 54 m × 26 m enclosure bounded by a 2.4 m vapour fence. They state that some 40 trials were performed.

15.38.9 Application to models

The Thorney Island trials, together with the analysis carried out on them, have provided a data set which has been extensively used for the determination of parameters in, and for the validation of, models. Reference to the use of these trials for both these purposes has already been made in the preceding sections. In particular, the trials have been used in the derivation of the *Workbook* correlations. The use of the Thorney Island data set in model validation is discussed further in Section 15.41.

15.39 Dispersion of Dense Gas: Physical Modelling

Another method of experimental investigation of dense gas dispersion is physical modelling, using mainly wind tunnels and water tunnels or flumes. Physical modelling makes it possible to perform dispersion experiments not only for flat unobstructed surfaces, but also with different ground slopes and other topographical features and with all kinds of obstructions, including fences and buildings, and even complete process plants, sites or terminals. It is also sufficiently economical to allow experiments to be repeated, either exactly or with minor variations.

The principal drawback is that it is not possible to scale so as to achieve complete similarity between the physical model and the scenario simulated, so that there is always a degree of distortion. However, the effects of such distortion are fairly well understood.

Accounts of physical modelling have been given by Snyder (1981), D.J. Hall, Hollis and Ishaq (1982), Meroney and Lohmeyer (1984), Meroney (1987a) and in the Workbook by Britter and McQuaid (1988).

15.39.1 Guidelines for physical modelling

Guidelines for physical modelling of dense gas dispersion have been given by Meroney (1987). They include guidance on formulation of the information to be obtained, the choice of modelling medium, the design of the experiments, the reporting of the experiments, the performance envelope within which experiments may be conducted and the scaling of the experiments.

The experiments should be matched to the information required. It may be required to determine the distance beyond which a hazardous concentration will not exist, or the distance at which the hazardous condition will occur more than a certain time with a certain probability.

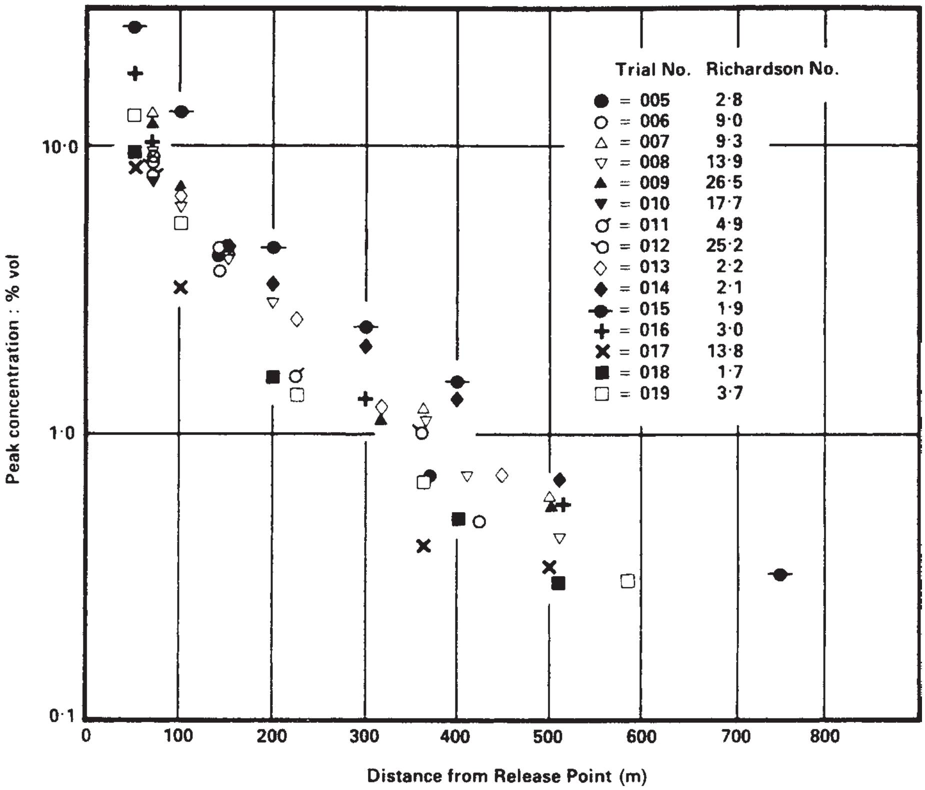

Figure 15.106 *Thorney Island trials on dense gas dispersion – peak concentrations on path of cloud centroid for instantaneous release trials (McQuaid, 1985b) (Courtesy of Elsevier Science Publishers)*

Or again, it may be required to determine the maximum concentration at a location near the source, or the concentration vs time profile at that location.

The information sought should be limited to what is really needed and overelaboration should be avoided. The data set specified should accord with what is realistically obtainable. It is useful to carry out preliminary experiments with a simple box model.

The modelling medium may be air or water. Broadly, water is often convenient for qualitative studies and visualization, but air is more often used for quantitative work. Air allows the use of a wide range of density ratios. Using heat it is comparatively easy to stratify. In theory, water should allow a Reynolds number some 16 times that of air, but in practice this advantage is not easily realized.

15.39.2 Wind tunnel facilities

A wind tunnel not only represents a major investment but also requires expertise in its use. It is therefore normal to contract work to an organization operating the wind tunnel with its own specialist team. A list of some of the principal wind tunnel facilities is given by Meroney (1987a).

15.39.3 Scaling for wind tunnel modelling

Physical modelling involves simulation of a full-scale situation by scaling down the dimensions in such a way as to retain similarity in the essential features.

Accounts of scaling for physical simulation include those given by Meroney (1979b, 1982), D.J. Hall, Hollis and Ishaq (1982), Cheah, Cleaver and Milward (1983a,b), Krogstad and Pettersen (1986), and Schatzmann, Koenig and Lohmeyer (1986) and the one given in the Workbook by Britter and McQuaid (1988).

The usual procedure is to list the relevant variables and then to derive from these the appropriate dimensionless groups. The number of dimensionless groups should be equal to the number of variables minus the number of dimensions. The lists of the variables given by different workers tends to vary slightly, in part because some list a variable only to disregard it, whilst others do not list it in the first place.

The conditions for similarity may be defined in stages. Thus, the *Workbook* defines first the requirements for the atmospheric boundary layer, then those for release of a gas with the same properties and temperature as air, and finally those for release of a dense gas. The variables commonly listed for similarity of the atmospheric boundary layer are

u characteristic velocity
L characteristic length scale
ρ density of atmosphere
μ viscosity of atmosphere
g acceleration due to gravity

The *Workbook* also includes

$\Delta\rho/\rho$	characteristic potential density difference due to atmospheric stability/instability
f	Coriolis parameter

The dimensionless groups listed by the *Workbook* are:

$$\mathrm{Re} = \frac{uL\rho}{\mu} \quad \text{Reynolds number}$$

$$\mathrm{Ri} = g\frac{\Delta\rho}{\rho}\frac{L}{u^2} \quad \text{Richardson number}$$

$$\mathrm{Ro} = \frac{u}{fL} \quad \text{Rossby number}$$

This gives only three dimensionless groups, not the four which the rule quoted above would indicate. The explanation given in the Workbook is that the Boussinescq approximation has been made, so that the effect of $\Delta\rho/\rho$ on inertia is neglected but that on buoyancy is not.

Proceeding straight to the dense gas case, the further variables introduced in the *Workbook* are:

q_o	volumetric release rate, or
Q_o	volume released
ρ_a	density of air
ρ_o	density of source gas
x, y, z	downwind, crosswind, vertical distance

The further dimensionless groups given are then:

$$\frac{q_o}{uL^2} \quad \text{source number (continuous source), or}$$

$$\frac{Q_o}{L^3} \quad \text{source number (instantaneous source)}$$

$$\frac{\rho_o}{\rho_a} \quad \text{density ratio}$$

$$\mathrm{Fr} = \frac{u^2}{gL} \quad \text{Froude number}$$

$$\frac{x}{L}, \frac{y}{L} \text{ and } \frac{z}{L} \quad \text{dimensionless downwind, crosswind and vertical distance}$$

If a degree of distortion is accepted, it is practice in modelling buoyant plumes to make the following approximations, which the *Workbook* tentatively proposes for dense plumes also. The Froude number and the density ratio may be combined using the Boussinesq approximation to give

$$\frac{u^2}{g(\Delta\rho_o/\rho_a)L} \quad \text{densimetric Froude number}$$

Similarly, the source number and density ratio may be combined to give

$$\frac{\rho_o q_o^2}{\rho_a u^2 L^4} \quad \text{source momentum ratio}$$

If the source momentum is negligible, this term may be replaced with the source number q_o/uL^2.

If the fine scale structure of the concentration field is to be preserved, the similarity of the Schmidt number Sc is relevant

$$\mathrm{Sc} = \frac{v}{D} \quad \text{Schmidt number}$$

where D is the diffusion coefficient and v is the kinematic viscosity.

This aspect may also be expressed in terms of the Peclet number Pe:

$$\mathrm{Pe} = \frac{vL}{D} \quad \text{Peclet number}$$

since

$$\mathrm{Pe} = \mathrm{Re}\cdot\mathrm{Sc}$$

If non-neutral temperature stratification is being modelled, the similarity of the Prandtl number Pr is relevant:

$$\mathrm{Pr} = \frac{v}{k} \quad \text{Prandtl number}$$

where k is the thermal conductivity.

Additional quantities mentioned by some workers include:

α	ground slope
$z_{\hat{o}}$	roughness length
u^*	friction velocity
μ_o	viscosity of source gas

and additional dimensionless groups are

$$\frac{z_o}{L} \quad \text{dimensionless roughness length}$$

$$\frac{u_*}{u} \quad \text{dimensionless friction velocity}$$

The conditions for flow to be fully aerodynamically rough depend on the group $u_* z_o/v$. In other words, for such flow the role of the kinematic viscosity v is taken over by the group $u_* z_o/v$. The *Workbook* therefore defines a more relevant Reynolds number as

$$\frac{uL}{u_* z_o} \quad \text{modified Reynolds number}$$

It may be noted that this modified Reynolds number is the product of the reciprocals of the dimensionless roughness length and friction velocity just defined.

The source volumetric flow q_o is sometimes represented by the product $u_o A_o$, where u_o is the source velocity and A_o its area.

Turning to the application of these similarity criteria to the scaling problem, it is not possible to achieve similarity of all the relevant groups. Complete similarity is not attainable and some degree of distortion has to be accepted.

Some of the groups quoted are of secondary importance, and some are frequently not mentioned by modellers. Since the full scale and model fluids are generally both air, the Prandtl number is the same. Rossby number similarity is not attainable, but a limit can be set. The *Workbook* suggests that it would be reasonable to neglect rotational effects for $\mathrm{Ro} \geq 10$, but that a value of $\mathrm{Ro} \approx 1$ should be justified.

It is not possible to obtain Reynolds number similarity. However, since the properties of turbulent flow are independent of the Reynolds number provided it is large, the approach generally taken is to make the Reynolds number as large as practical.

The *Workbook* gives a detailed discussion of the setting of the Reynolds number. The essential requirement is similarity of the mean and turbulence velocity profiles and in practice the boundary layer is adjusted until this is achieved. It suggests that the condition $u_*k/\nu > 50$ gives Reynolds number independence, though for sharp-edged elements particularly $u_*k/\nu > 5$ may suffice. Since typically $z_o \approx 0.1$, these conditions are equivalent to $u_*k/\nu > 5$ and $u_*z_o/\nu > 2$, respectively.

As far as concerns Froude number similarity, this is often difficult to achieve because it tends to involve an air velocity that is too low to give stable flow. Generally the approach taken is to combine the density ratio and Froude number into a densimetric Froude number, as described above. The *Workbook* recommends that priority be given to achieving similarity of two groups, the densimetric Froude number and the source momentum ratio.

If the fine scale structure of the concentration field needs to be modelled, and molecular diffusion effects taken into account, the Schmidt number should be similar and the Reynolds number as large as possible. Failure to achieve adequate Reynolds number results in loss of fine scale structure and is not compensated by a correct Schmidt number.

Reports of physical modelling frequently discuss aspects of scaling, either in relation to the design of the experiments or in explanation of the results, and many of those quoted below include such discussions.

15.39.4 Wind tunnel performance envelope

There are a number of practical features which set a limit to the conditions under which a wind tunnel may be operated and to the applications for which it may be used. There are problems in achieving a steady low velocity. A velocity of 1 m/s is quoted as a practical lower limit, although velocities half this or less are sometimes used. This tends to be a major constraint.

Dense gas clouds are shallow but wide, and the width of the tunnel may be a constraint. The length of the tunnel can also constrain the concentrations which can be studied; there is usually little difficulty in obtaining concentrations down to typical flammability limit levels but it may not be possible to achieve concentrations at levels of interest for some toxic gases.

The use of a very small model can cause problems of spatial resolution. There is a practical limit to the fineness of size of measurement probes.

Attainment of a Reynolds number high enough to give correct wake flows can be a difficulty, particularly for smooth structures.

The performance envelope of a wind tunnel, with particular reference to LNG dispersion experiments, has been described by Meroney and Neff (1980) and Meroney (1987a).

15.39.5 Universal plume profile

An early wind tunnel study of dense gas dispersion was that by D.J. Hall, Barrett and Ralph (1976). These workers addressed the determination of the distance for the gas concentration to fall to 2% and expressed their results in the form of a universal plume, as shown in Figure 15.107. The plume is defined by the dimension D, which for a cloud boundary concentration of 2% is given by the empirical equation

$$D\left(\frac{u}{Q}\right)^{1/2} = 107 \qquad [15.39.1]$$

where Q is the volumetric release rate and u is the wind speed. The results apply only to a fully developed plume, which may take some hours to develop.

The work illustrated the fact that a dense gas forms a wide, very shallow plume with a strong resistance to vertical dispersion and that its behaviour is quite different from that of neutral buoyancy gas. The authors present calculations which show that for stable atmospheric conditions the travel distances given by passive dispersion models considerably exceed those obtained from their model.

15.39.6 Porton Down trials

A wind tunnel investigation of some of the Porton Down trials has been carried out by D.J. Hall, Hollis and Ishaq (1982, 1984). The aim of the work was to assess the applicability of wind tunnel modelling to dense gas dispersion.

Figures 15.108 and 15.109 show some of the results obtained for the Porton trials. Figure 15.108(a)–(c) give, respectively, the cloud width, the cloud arrival and departure times and the profile of the peak ground level concentration vs downwind distance for trial 37. Figure 15.109(a)–(d) show the concentration-time profiles at four points in this trial. The figure shows the profiles of the physical model tending to lead, and to be less smoothed than, the full-scale profiles.

Figure 15.109(e) shows the variability of the concentration-time profile in repeat runs at a single point in trial 52. The figure brings out the high degree of variability between individual runs and the desirability of performing enough runs to obtain a stable characterization of the concentration. Since such repeat runs are not practical in field trials, but are so in a wind tunnel; this is an important contribution of the latter. The authors give comparative photographs for the field trials and the wind tunnel. This format for presenting results has also been used in subsequent work by the authors and others

The authors also proposed a relationship between the distance to the 2% concentration level and the Richardson number. They investigated this further in relation to the Thorney Island trials, as discussed below.

15.39.7 Thorney Island trials

At the time when the above work was being done, the Thorney Island experiments were being designed and some additional, exploratory wind tunnel work was carried out to assist in this. Following the trials, the simulations done on the Porton trials and this further work for the Thorney Island trials were revisited. Several of the simulations were sufficiently closely matched to particular Thorney Island trials to allow comparisons to be made. These have been described by D.J. Hall and Waters (1985).

Figure 15.110 shows some of the results obtained for the Thorney Island trials. Figures 15.110(a)–(c) again give the cloud width, the cloud arrival and departure times and the profile of the peak ground level concentration vs distance,

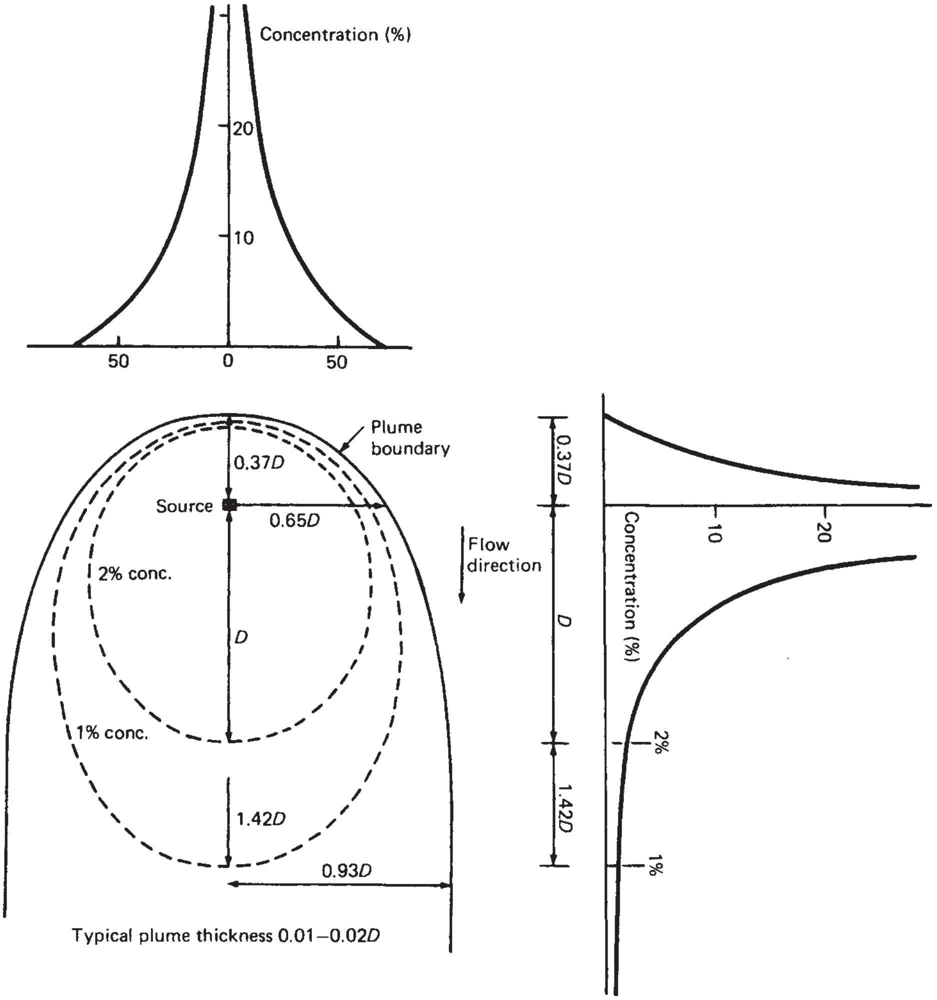

Figure 15.107 *Wind tunnel simulation of dense gas dispersion – universal plume profile (D.J. Hall, Barrett and Ralph, 1976) (Courtesy of Warren Spring Laboratory)*

respectively. Figure 15.111 shows the profile of concentration vs time at particular downwind locations. Figure 15.112 and Figure 15.113 show, respectively, plan and elevation views of the full-scale trial and of the wind tunnel model.

Figure 15.111 shows the profiles of the physical model tending in this case to lag, and to be more smooth than, the full-scale profiles. This contrasts with the results described above for Porton trial 37, where the reverse was the case. This 'persistence' of the concentration was the main discrepancy. The authors suggest that it may be explained in part by surface roughness present in the wind tunnel but not at full scale, and perhaps in part by the need to use a low wind speed of 0.4 m/s. Nevertheless, the concentrations obtained in the wind tunnel work were within a factor of 2 of those at full scale.

The authors also consider a correlation derived from their Porton simulations between the distance to a 2% concentration and the reciprocal of the Richardson number. This is shown in Figure 15.114. The distance is shown as having a maximum at $\mathrm{Ri} \approx 3 (1/\mathrm{Ri} \approx 0.3)$. For high values of Ri the cloud is advected by the wind with relatively little dispersion. For lower values atmospheric turbulence increases dispersion above that obtained from gravity-driven flow. If valid, the relationship is of some interest, but it does not appear to be supported by the Thorney Island results.

M.E. Davies and Inman (1987) describe a programme of 86 simulations of the Thorney Island trials. They give numerous sample plots, particularly concentration-time profiles, concentration-distance correlations and plan view concentration contours.

Figure 15.115 shows photographs of full scale trials and wind tunnel simulations for instantaneous and continuous releases, in both cases without and with fences. The decay

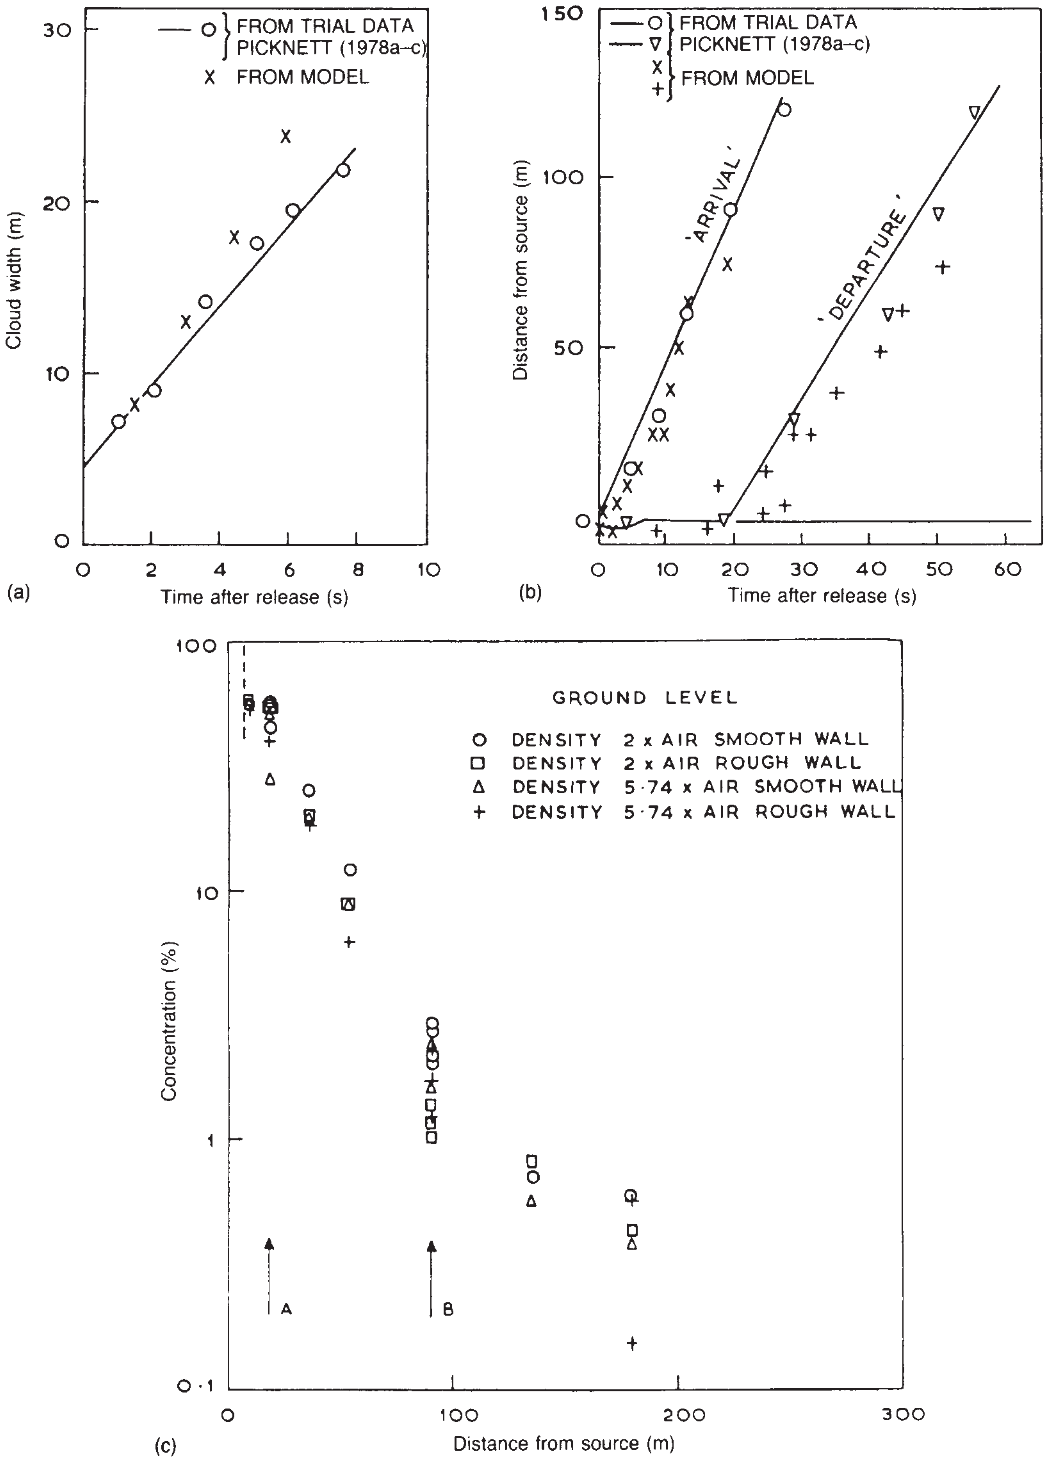

Figure 15.108 *Wind tunnel simulation of Porton Down trials on dense gas dispersion – comparison of observed and simulated features (D.J. of peak concentration with distance for the continuous releases, without and with fences, is correlated in the form shown in Figure 15.116, after Meroney and Neff (1980). A buoyancy length scale l/, is defined as

$$l_b = \frac{g'Q}{u^3} \qquad [15.39.2]$$

and the further length scale l_q as

$$l_q = \left(\frac{Q}{u}\right)^{1/2} \qquad [15.39.3]$$

where Q is the volumetric release rate.

The plot gives

$$\frac{cul_b^2}{Q} \propto \left(\frac{x}{l_b}\right)^{-2} \qquad [15.39.4]$$

and hence

$$c \propto \left(\frac{x}{l_q}\right)^{-2} \qquad [15.39.5]$$

where c is the volumetric concentration.

The distance to the 2% concentration was investigated. It was found that the ratio of this distance in the model to that at full scale fell to about unity, though with some scatter. The authors suggest that the full scale distance may be estimated with 90% confidence as lying within the range delimited by a lower limit of half the model value and an upper limit of twice that value. The peak concentrations were found to be insensitive to the value of the Richardson number.

Several other workers have performed wind tunnel simulations of the Thorney Island trials. Figure 15.117 shows a computer graphics simulation of trial 8 by S.T. Chan, Ermak and Morris (1987); the computer simulation has the appearance of a wind tunnel simulation.

Van Heugten and Duijm (1985) investigated trial 8. They obtained reasonable agreement between the full-scale trials and wind tunnel model and between both of these and the TNO model described by van den Berg (1978).

Thorney Island trial 20, with a solid fence, has been simulated in a wind tunnel by Knudsen and Krogstad (1987). Again there was a tendency for the wind tunnel concentration profile to persist longer than that for the full-scale trial. The authors state that a possible explanation is the difference in Reynolds number and thus in the wake at the fence.

15.39.8 Ground slope

Physical modelling is particularly suited to investigation of the effects of terrain, obstructions and buildings. The

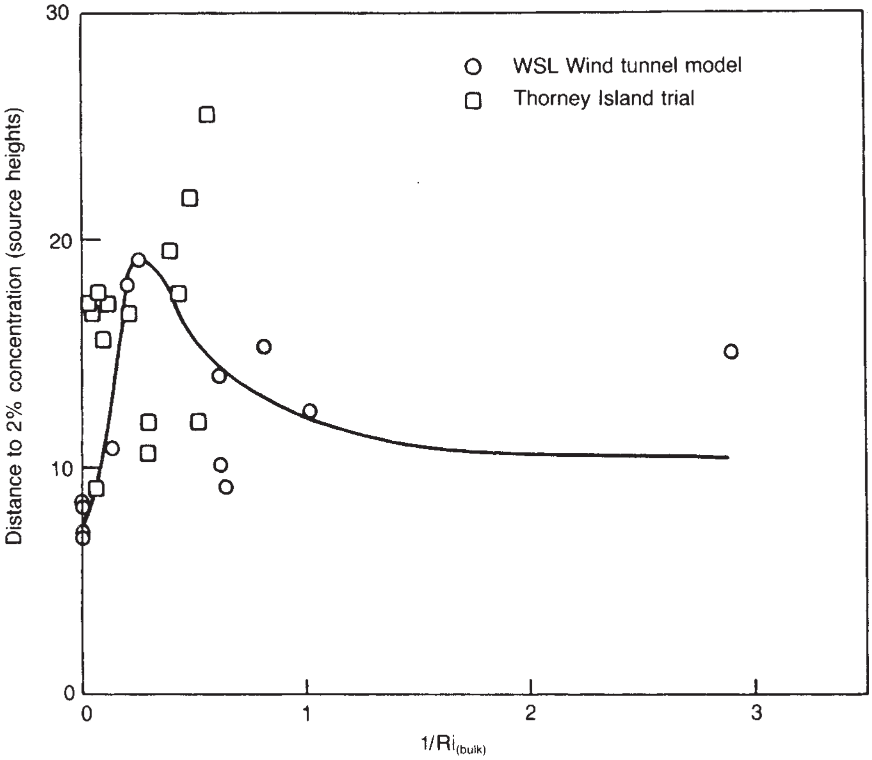

Figure 15.114 *Wind tunnel simulation of Thorney Island trials on dense gas dispersion – effect of bulk Richardson number on concentration downwind (D.J. Hall and Waters, 1985) (Courtesy of Elsevier Science Publishers)*

dispersion of dense gas on a slope was another feature investigated in the study by D.J. Hall, Barrett and Ralph (1976) already described. Some of their results for the universal profile on a slope are shown in Figure 15.118.

15.39.9 Obstructions and buildings

There have been several investigations of dense gas dispersion in the presence of obstructions and buildings. Cheah, Cleaver and Milward (1983a) have used a water tunnel to make an *ad hoc* study of the effect of a simple barrier on the dispersion of a dense gas plume. Their results give a clear illustration of the effect of the gravity-driven phase. The authors comment that Figure 15.119, which is a plot of mean concentration vs downstream distance (the distance being expressed in terms of the ratio of the distance to the source diameter and with the relative density as a parameter) shows that for the plumes of higher relative density (and Richardson number) there is an initial phase with gravity slumping but little entrainment followed by a further gravity-driven phase where entrainment does occur and that the slope of the curve in this latter phase is not the same as for passive dispersion, whilst for the plume of low relative density (and Richardson number) the slope in the second region progressively approximates that of a passive plume.

The work also indicated the effectiveness of a barrier in reducing the downstream concentration. Even with the least effective barrier distance the concentration downstream was reduced by an order of magnitude.

The dispersion of a dense gas plume around a building has been investigated by Krogstad and Pettersen (1986). The presence of the building caused a strong modification of the plume.

C.I. Bradley and Carpenter (1983) have described an assessment of physical modelling which included the comparison of results from such modelling with results from models for the dispersion of 1000 te of LNG spilled onto land at a tanker terminal and onto water at the terminal. Experiments were done using both a wind tunnel and a water flume.

They discuss the problem of scaling up in respect of the temperature of the gas. Heat transfer from the surface to the cloud has a greater influence at low wind speeds, but at higher wind speeds is less significant. They followed Neff and Meroney (1981) in taking the gas density as the source value, but restricted their study to higher wind speeds (>5 m/s).

Comparisons were made with results from the Germeles and Drake, Cox and Carpenter, Fryer and Kaiser, and ZEPHYR models. For the land spills a global roughness length of 0.2 m, corresponding to rough terrain, was used in the box models. The ZEPHYR model, being a if-theory model, modelled the effect of the structures directly.

Broadly, the distances to the extinction of the flammable plume in both the wind tunnel and water flume modelling were reduced by the presence of the terminal structures by a factor of about 2. Further, the dispersion of the land spill was dominated by the presence of the single tank from

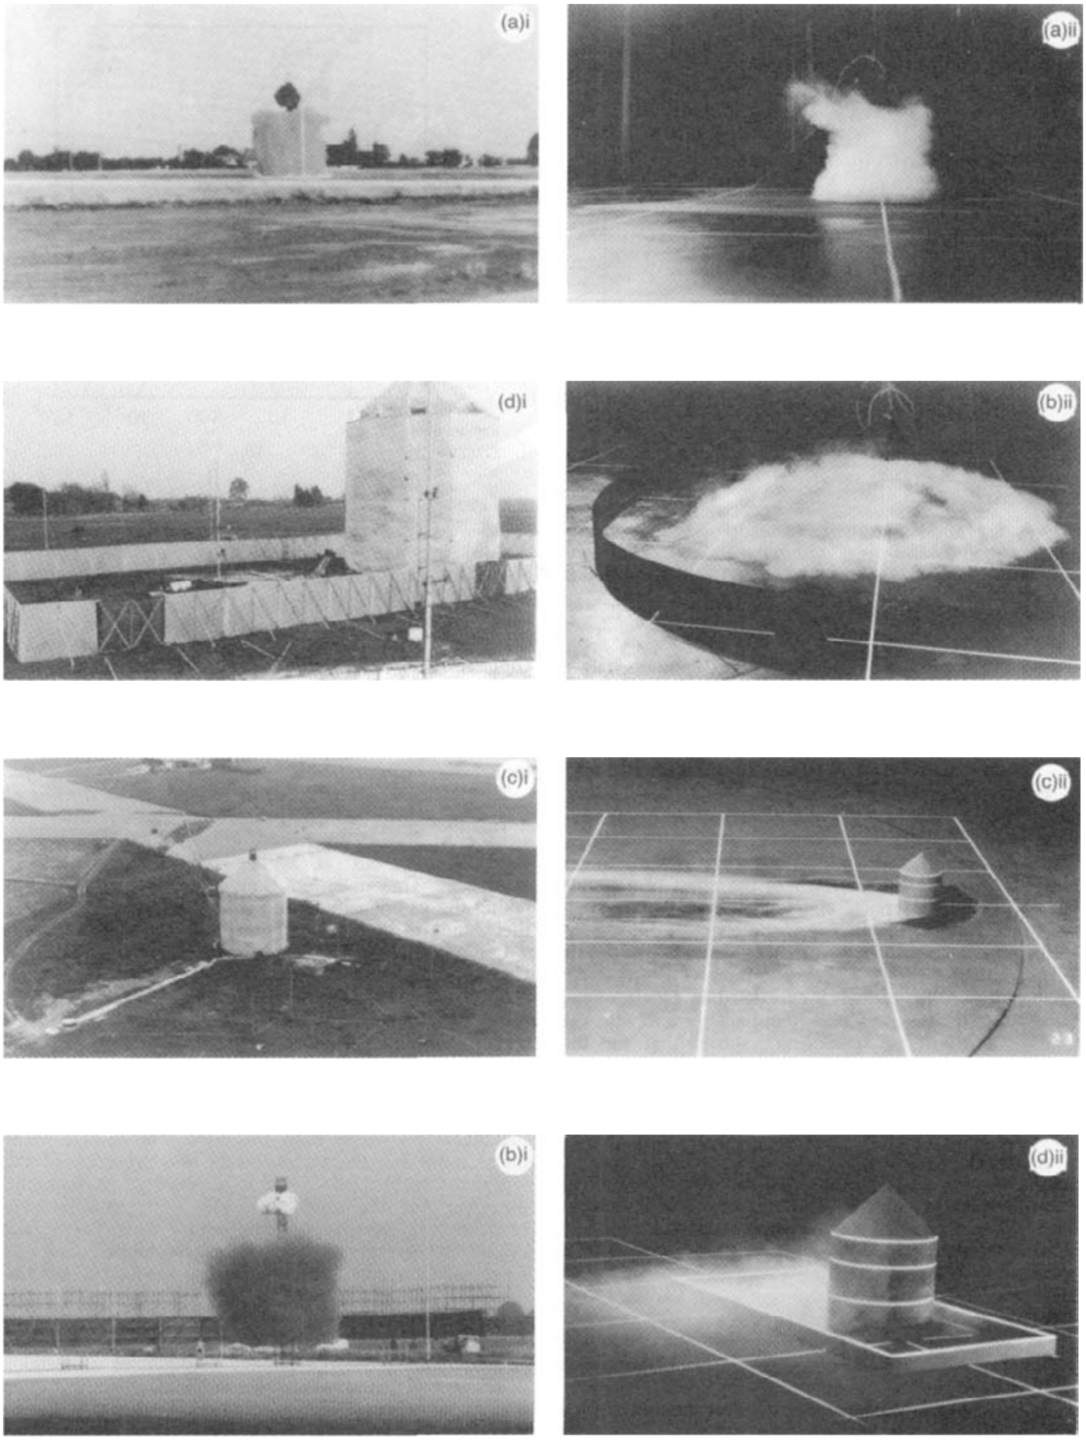

Figure 15.115 *Wind tunnel simulation of Thorney Island trials on dense gas dispersion – comparison of observed and simulated releases (M.E. Davies and Inman, 1987): (a) instantaneous release (Type 1); (b) instantaneous release with fence (Type 2); (c) continuous release (Type 3); (d) continuous release in fenced enclosure (Type 4) (Courtesy of Elsevier Science Publishers)*

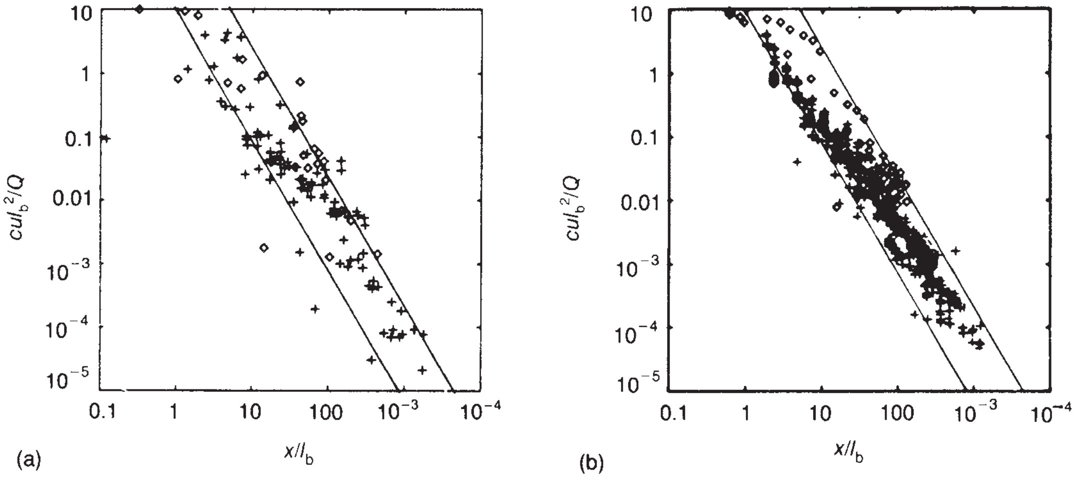

Figure 15.116 *Wind tunnel simulation of Thorney Island trials on dense gas dispersion–distance to 2% concentration (M.E. Davies and Inman, 1987): (a) observed; and (b) simulated. The solid lines represent the limits of data in the work of Meroney and Neff (1980) (Courtesy of Elsevier Science Publishers)*

which the spill originated. The models tended to give higher distances to cloud extinction than the physical modelling, but the distances generally agreed to within a factor of 2 and again showed the reduction caused by the terminal structures.

Guldemond (1986) performed wind tunnel simulations of releases of 15 ton of liquefied ammonia at release rates in the range 6.5–52 kg/s. Air entrainment was assumed such that the air/ammonia mass ratio at the source was 10 : 1 and that there was complete evaporation of the liquid spray formed. Figure 15.120(a) shows the model of the industrial site in the wind tunnel and Figure 15.120(b)–(e) show the plumes formed by a dense gas on flat terrain and on the industrial site and by neutral buoyancy gas on these two types of terrain, respectively.

On flat terrain for the neutral buoyancy gas the upwind dispersion was 10 m and the initial cloud width was 120 m. For the dense gas the values were 90 and 540 m, respectively. For the industrial site the corresponding figures for the neutral buoyancy gas were 60 and 250 m and for the dense gas 210 and 540 m.

The effect of different locations of the source within the industrial site was investigated. The location had a marked effect on the neutral buoyancy plume, which was strongly influenced by particular buildings. It had much less effect on the dense gas plume. Mixing of the dense gas plume was caused not only by atmospheric turbulence but was also strongly affected by mechanically induced turbulence due to the obstructions. The cloud tended to mix vertically up to the average height of the buildings.

The author gives concentration vs distance profiles and data on times to particular concentrations. Measurements were made at distances of 100, 400 and 450 m downwind. The concentrations at the first point were in the range 1000–3000 ppm, except for the very low release rate. Thereafter, the slope of concentration decay with distance on a log–log plot was about 1.7, which is characteristic of passive dispersion.

15.39.10 Concentration variability

As already mentioned, one of the strengths of wind tunnel modelling is that it furnishes an economical way of making a large number of repeat runs at the same nominal conditions. The variability in the concentration vs time profiles obtained in the simulation of the Porton trials by D.J. Hall, Hollis and Ishaq (1982, 1984) has already been described.

A systematic investigation of this variability in terms of the intensity of concentration fluctuations has been made by Meroney and Lohmeyer (1984). Their work is discussed in the context of concentration fluctuations in Section 15.45.

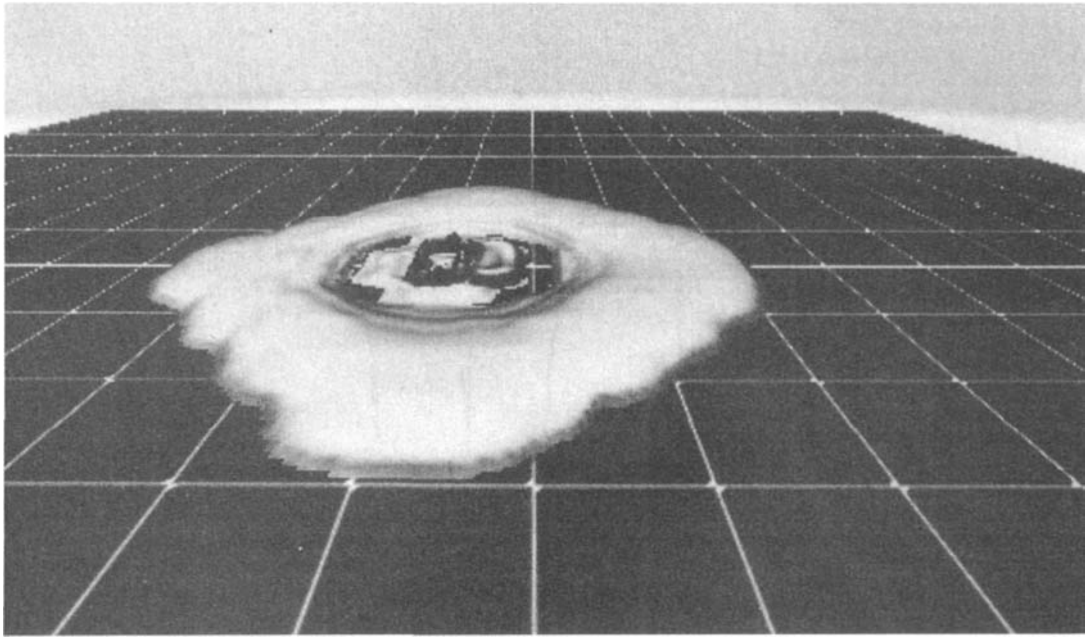
15.40 Dispersion of Dense Gas: Terrain, Obstructions and Buildings

The account of dense gas dispersion given so far has concentrated on dispersion over flat, unobstructed terrain. It is necessary now to consider more complex and obstructed terrain, including that containing buildings and obstructions. The corresponding treatment for passive dispersion is given in Section 15.17.

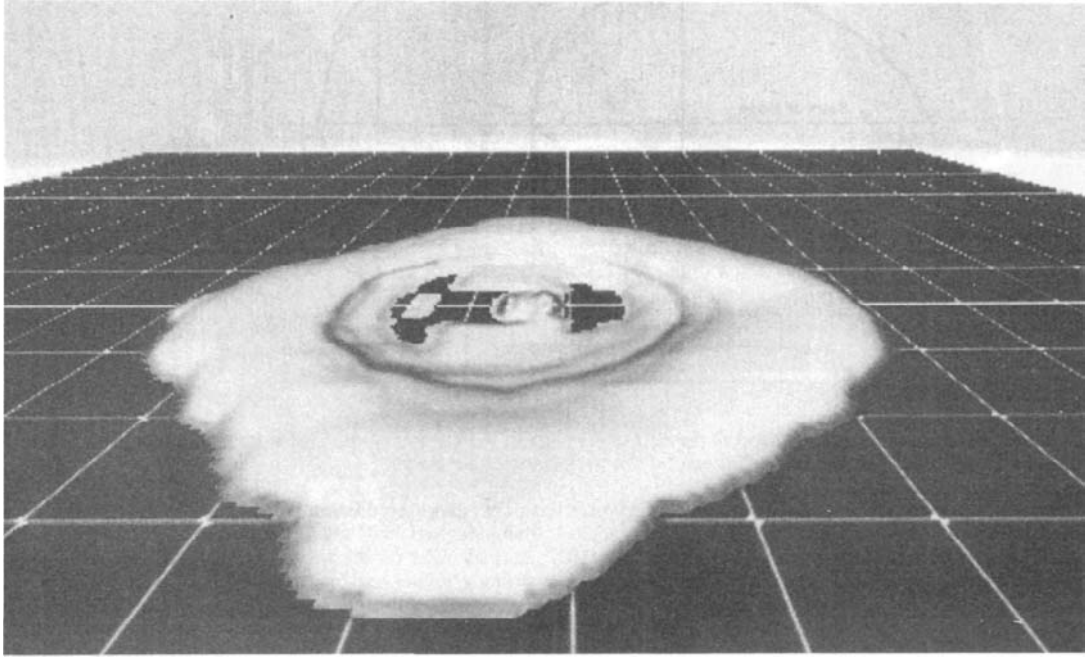
Some particular types of terrain which have been the subject of investigation include:

(1) slopes and ramps;
(2) fences and vapour barriers;
(3) water spray barrier and steam curtains;
(4) buildings – release upstream;
(5) buildings – release into wake;
(6) buildings – release inside;
(7) industrial sites;
(8) complex terrain.

The three principal approaches are the use of: (1) analytical models, (2) three-dimensional models and (3) physical modelling. The most versatile methods are three-dimensional models and physical modelling, but there is a growing body of analytical models for such features as



(a)



(b)

Figure 15.117 Wind tunnel simulation of Thorney Island trials on dense gas dispersion – simulation of trial 9 (S.T. Chan, Ermak and Morris, 1987) (a) time 20 s; (b) time 30 s (Courtesy of Elsevier Science Publishers)

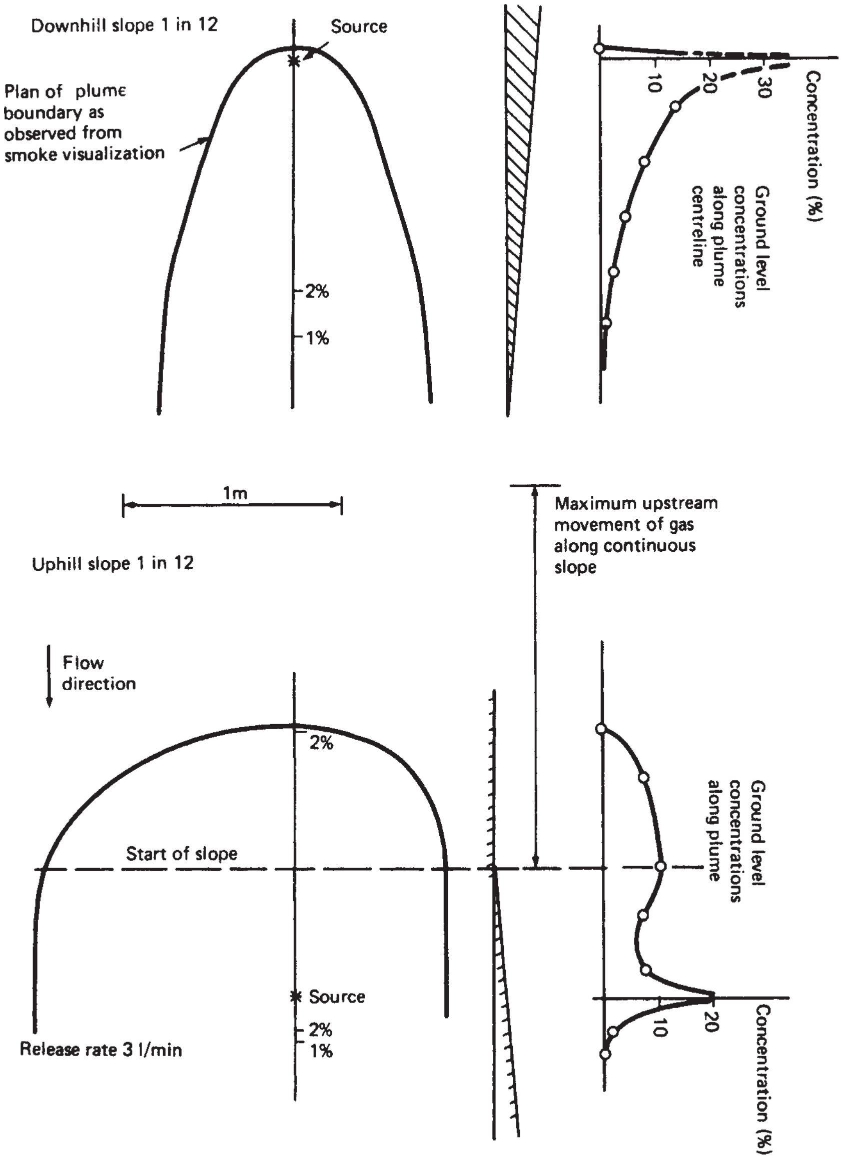


Figure 15.118 *Wind tunnel simulation of dense gas dispersion – universal plume profile for dispersion on a slope (D.J. Hall, Barrett and Ralph, 1976) (Courtesy of Warren Spring Laboratory)*

slopes and obstructions which generally draw on the theory of gravity-driven flow and which may be used alone or in combination with the other methods.

General discussions of the effect of more complex and obstructed terrain have been given by Britter and Griffiths (1982), Gunn (1984), McQuaid (1986) and Britter and McQuaid (1988).

15.40.1 Slopes and ramps

An account of the behaviour of a dense gas on a slope in the field trials at Porton Down has been given by Picknett (1978a), as described in Section 15.37. Analytical models of the dispersion of a dense gas on a slope have been given by several workers.

A gravity current flowing down a slope develops a characteristic thickening at the downhill edge, or 'head'. Ellison and Turner (1959) conducted an experimental and theoretical investigation of the gravity current on a slope. For the experiments they used salt water flowing down an inclined plane in pure water. They found that for the continuous current well behind the head the mean velocity is independent of distance, but that the thickness of the fluid layer

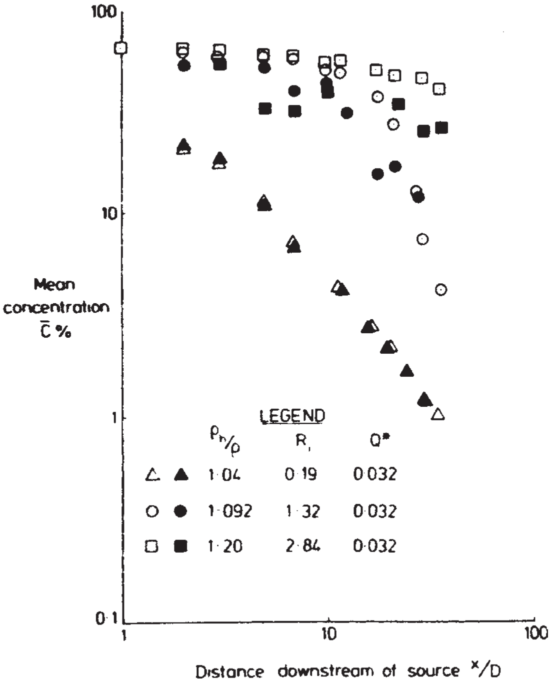

Figure 15.119 *Water tunnel simulation of dense gas dispersion at an obstacle – variation of mean concentration at ground level with distance for gas plumes of different density C̄, mean concentration; D, diameter of plume source; Q* non-dimensional plume spill rate; Ri, Richardson number; x, distance downstream of source; ρ, density of surrounding fluid; ρ_h, density of dense fluid (Cheah, Cleaver and Milward, 1983a) (Courtesy of the Institution of Chemical Engineers)*

increases at a constant rate due to entrainment. The density excess decreases, maintaining a constant buoyancy flux down the slope.

Another experimental and theoretical study is described by Britter and Linden (1980). The experiments again involved the flow of salt water in pure water down an inclined plane. These workers investigated particularly the head of the gravity current on a slope. They found that the behaviour of the head depends on the angle θ of the incline to the horizontal. For $\theta \gtrsim 5°$ the head has a constant velocity, for $\theta \lesssim 0.5°$ its velocity is strongly affected by friction and decreases with distance, whilst in the range $0.5° \lesssim \theta \lesssim 5°$ there is a perceptible but weaker frictional effect.

They also found that the velocity % of the front is proportional to the volumetric flow per unit width:

$$u_{\mathrm{f}} \propto (g'_{\mathrm{o}}Q)^{1/3} \qquad [15.40.1]$$

with

$$g'_{\mathrm{o}} = 2g\frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} \qquad [15.40.2]$$

where g'_{o} is a reduced gravity, Q is the volumetric flow per unit width, u_{f} is the velocity of the front, or head, ρ is the density and subscripts 1 and 2 denote less and more dense fluid, respectively. They obtain the relation

$$\frac{u_1}{(g'_{\mathrm{o}}Q)^{1/3}} = S_2^{1/3}\left[\frac{\cos\theta}{\alpha} + \frac{\alpha\sin\theta}{2(E + C_{\mathrm{D}})} + \frac{\sin\theta}{(E + C_{\mathrm{D}})}\right]^{-2/3} \qquad [15.40.3]$$

with

$$\alpha = u_{\mathrm{s}}/u \qquad [15.40.4]$$

$$E = \mathrm{d}h/\mathrm{d}x \qquad [15.40.5]$$

$$S_2 = \frac{\mathrm{Ri}_{\mathrm{n}}\tan\theta - C_{\mathrm{D}}}{1 + 0.5S_1\mathrm{Ri}_{\mathrm{n}}} \qquad [15.40.6]$$

$$\mathrm{Ri}_{\mathrm{n}} = \left(\frac{g'h\cos\theta}{u^2}\right)_{\mathrm{n}} \qquad [15.40.7]$$

$$g' = g\frac{\rho - \rho_1}{\rho_1} \qquad [15.40.8]$$

where C_{D} is a drag coefficient due to stress at the lower surface, E is a dimensionless rate of entraiment, or entrainment coefficient, g' is a reduced gravity, h is the height of the following flow, u is the mean velocity of the following flow, u_{s} is the velocity on a defined streamline, x is the downhill distance, S_1 and S_2 are parameters, θ is the angle of incline (°), and subscript n denotes 'normal'. The numerical values of the parameters are typically as follows: $C_{\mathrm{D}} < 0.02$; $0.1 \leq S_1 \leq 0.15$; $0.6 \leq S_2 \leq 0.9$; $\alpha \approx 1.2$. Ellison and Turner obtained typical values of $E = 0.001\theta$ and $S_2 = 0.75$.

This value of the entrainment coefficient E should be valid for dense gases also, provided the density difference is not too large. For flow of a dense gas on slope there is a significant dilution which quite quickly produces a small density difference.

Britter and Linden found that for the velocity u_{f} of the head

$$\frac{u_{\mathrm{f}}}{(g'_{\mathrm{o}}Q)^{1/3}} = 1.5 \pm 0.2 \quad \theta \geq 5° \qquad [15.40.9]$$

The authors give expressions for the mean velocity u of the following flow for limiting cases. For large slopes ($\theta \geq 30°$) they obtain with a small density excess $u_{\mathrm{f}} \approx 0.6u$ and with a large density excess $u_{\mathrm{f}} \approx u$ as $\theta \rightarrow 90°$. For small slopes they quote the results of Middleton (1966) to the effect that at very small angles $u_{\mathrm{f}} = u$ and that u_{f}/u decreases rapidly as θ increases.

De Nevers (1984a) has given a model based on a force balance in which the force in the downhill direction due to gravity, less buoyancy, is balanced by three forces acting in the uphill direction: the shear forces at ground surface and

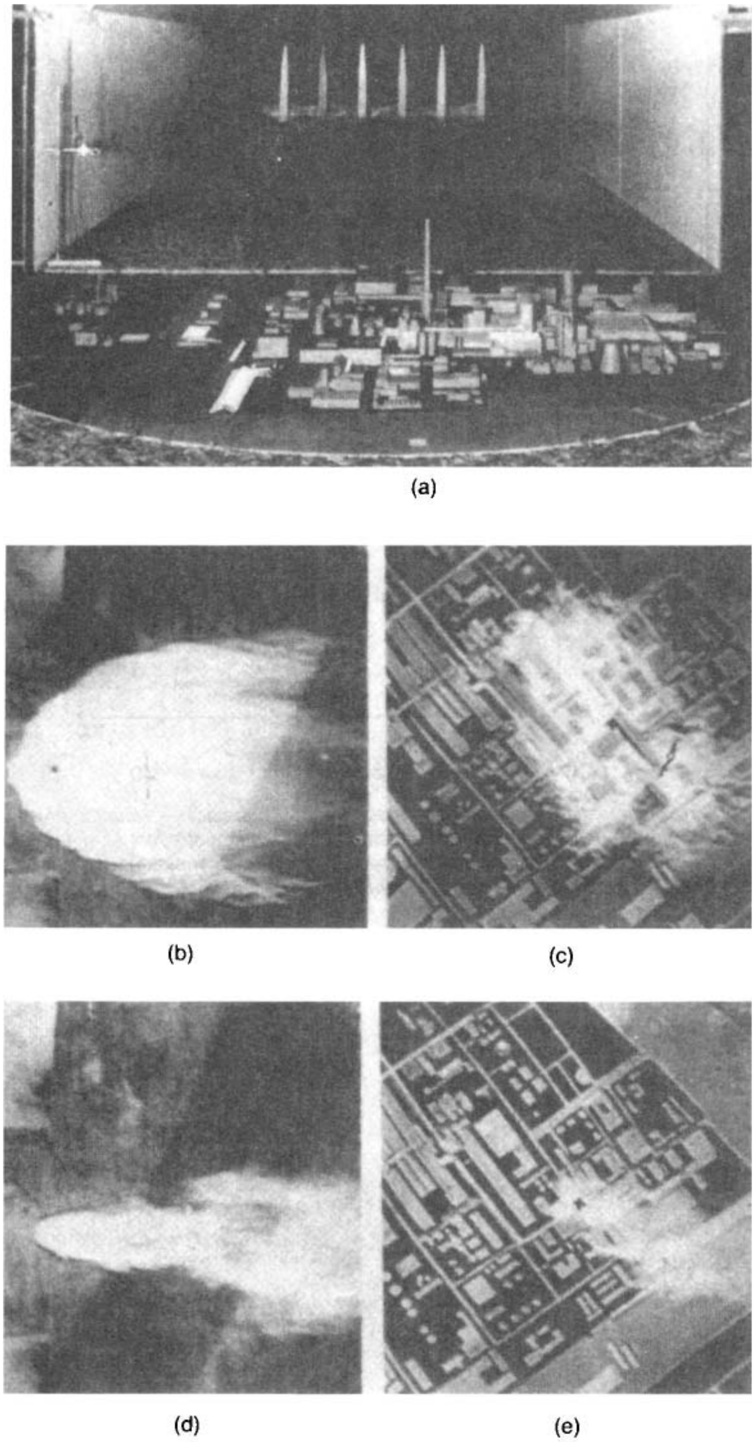

Figure 15.120 Wind tunnel simulation of dense gas dispersion over an industrial site – continuous release of ammonia (Guldemond, 1986); (a) model in wind tunnel; (b) dense gas plume on flat terrain; (c) dense gas plume on industrial site; (d) neutral buoyancy gas plume on flat terrain; (e) neutral buoyancy plume on industrial site (Courtesy of the Institution of Chemical Engineers)

at the top of the cloud, and the form force at the leading edge of the cloud. The force balance on a slope of angle θ is then

$$\pi R^2 H \rho_a g' \sin\theta = \pi R^2 \rho_g \frac{u^2}{2}(f_b + f_t) + 2RH\rho_a \frac{u^2}{2} C_D \qquad [15.40.10]$$

and hence

$$u = \left[\frac{2\sin\theta}{(\rho_g/\rho_a)(f_b + f_t) + (2HC_D)/(\pi R)}\right](g'H)^{1/2} \qquad [15.40.11]$$

where C_D is the form drag coefficient, f is the friction factor, g' is the reduced gravity, H is the height of the cloud, R is the radius of the cloud, u is the velocity downhill, ρ is the density, and subscripts a and g denote air and gas and b and t the bottom and top of the cloud, respectively.

De Nevers concludes that for even a modest slope the downhill velocity can be as large as the lateral velocity due to gravity spreading. The effect of a degree of slope in the Burro field trials has been investigated by Koopman, Ermak and Chan (1989) using FEM3, as described in Section 15.37.

The universal plume profile of a dense gas on a slope has been studied by D.J. Hall, Barrett and Ralph (1976). This work was described in Section 15.39. A model of the dispersion of a dense gas up a ramp has been given by Britter and Snyder (1988).

The effect of a slope in mitigating the dispersion of a dense gas from a source to an uphill target has been studied by Heinhold, Walker and Paine (1987) using both an analytical model and wind tunnel work. They start by quoting the work of Meroney *et al.* (1977) who carried out wind tunnel tests on the flow of dense gas on a slope with an uphill wind. After the initial gravity slumping, the flow of the gas is governed by the wind speed. There is a critical uphill wind speed below which the dense gas flows downhill and above which it flows uphill.

The authors model this situation as an energy balance between the potential energy which must be supplied to raise a plume element up the slope and the kinetic energy of the wind, and derive the relation

$$\frac{u^2}{2} = g\frac{z}{\theta}\frac{d\theta}{dz} + g_o' z \frac{A_o}{A_p} \qquad [15.40.12]$$

with

$$g_o' = \frac{\rho_p - \rho_a}{\rho_p} \qquad [15.40.13]$$

where A_o is the initial cross-plume area of the plume element, A_p is the final cross-plume area of the element, g_o' is the initial reduced gravity, u is the wind speed at ground level, z is the height from the source to the target, θ is the potential temperature, ρ is the density, and the subscript p denotes the plume. The left-hand side term is the kinetic energy. The first term on the right-hand side is the potential energy of the atmosphere, assuming constant lapse rate; this is zero for neutral conditions and a maximum for stable conditions. The second term on the right-hand side is the change in potential energy of the element. For a given density, and hence concentration, Equation 15.40.12 may be used to determine the height uphill which the plume can reach. The initial and final cross-plume areas were determined using the authors' own AIRTOX dense gas dispersion model.

Heinhold, Walker and Paine describe the application of this model to releases of liquefied ammonia, assuming complete evaporation of all liquid spray formed. Two release rates were studied, 10 and 100 kg/s. At the lower flow rate the plume became passive at 100 m. Only atmospheric stability inhibited dispersion uphill. At the higher flow rate the plume remained dense beyond 1000 m. In the latter case, the concentration at uphill locations decreased as the slope increased. For slopes of 50 : 1, 10 : 1, 5 : 1 and 2 : 1 the concentration was the following proportion of its value for flat terrain: 98, 90, 83 and 45% at 100 m; 86, 65, 35 and 20% at 200 m and 50, 28, 14 and 8% at 400 m uphill. The authors conclude that a slope can afford an appreciable degree of protection to a target uphill of a source. This is so not only for dense gas but also for passive dispersion.

Deaves (1987b) has described the treatment of the case of dense gas flowing over a river and encountering a river bank on the far side. For this use was made of the model of Rottman *et al.* (1985) for an obstacle, given below.

15.40.2 Fences and vapour barriers

One of the simplest obstacles to the dispersion of a dense gas is a fence, wall or similar barrier. This may be a feature which is already there, but in others a vapour barrier may be expressly erected to effect a reduction in downstream concentrations.

An account of the behaviour of a dense gas encountering a fence in the field trials at Thorney Island has been given by M.E. Davies and Singh (1987a), as described in Section 15.38. Field trials on dispersion of a dense gas at a fence have also been described by M. Nielsen (1991). A simple treatment of the effect of a fence has been given by Jensen (1984).

A model for the behaviour of a dense gas encountering an obstruction such as a fence or vapour barrier has been given by Rottman *et al.* (1985). The situation considered is shown in Figure 15.121(a). The model is based on the shallow water equations. At steady state, the governing equations are

$$\frac{\partial(uh)}{\partial x} = 0 \qquad [15.40.14]$$

$$u\frac{\partial u}{\partial x} + g'\frac{\partial(h_w + h)}{\partial x} = 0 \qquad [15.40.15]$$

with

$$g' = \frac{\rho - \rho_1}{\rho_1} \qquad [15.40.16]$$

where g' is the reduced gravity, h is the height of the dense fluid layer, h_w is the height of the obstacle, u is the velocity of the fluid, ρ is the density of the fluid and subscript 1

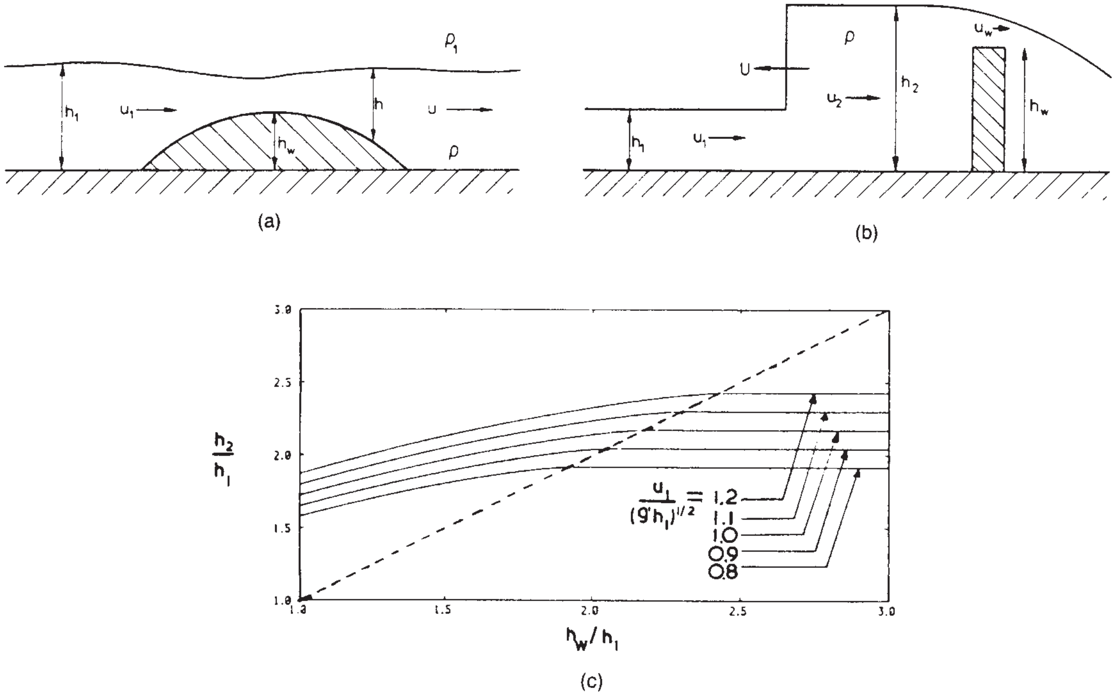

Figure 15.121 Dispersion of dense gas over an obstacle (Rottman et al., 1985): (a) shallow two-layer flow over an obstacle; (b) shallow two-layer flow over a wall; and (c) solutions of shallow water equations for depth of fluid behind the hydraulic jump as function of wall height (Courtesy of Elsevier Science Publishers)

denotes upstream. These equations are solved to give

$$uh = u_1h_1 \qquad [15.40.17]$$

$$\frac{u^2}{2g'} + h + h_w = \frac{u_1^2}{2g'} + h_1 \qquad [15.40.18]$$

The regimes of interest are those of blocked flow and partially blocked flow. The equation of the boundary between these two regimes is

$$\frac{u_1^2}{g'h_1} + 1/2(H_2 - 1)^2\left(\frac{H_w + 1}{H_w}\right) \qquad [15.40.19]$$

with

$$H_w = \frac{h_w}{h_1} \qquad [15.40.20]$$

where H_w is a ratio of heights.

If the flow is completely blocked, the gas does not disperse downwind at all. The dispersion downwind for the case of partial blockage is obtained as follows. This situation is shown in Figure 15.121(b). Conservation of mass and momentum at the jump requires the conditions

$$(u_1 - U)h_1 = (u_2 - U)h_2 \qquad [15.40.21]$$

$$(u_1 - U)^2 = \frac{1}{2}(g'h_1)\frac{h_2}{h_1}\left(1 + \frac{h_2}{h_1}\right) \qquad [15.40.22]$$

and, assuming that flow over the obstacle is critical

$$u_w = (g'h)^{1/2} \qquad [15.40.23a]$$

with

$$\Delta h = h_2 - h_w \qquad [15.40.23b]$$

where Δh is the head difference, U is the velocity of the wave travelling upstream, u_w is the velocity over the obstacle, and subscript 2 is the fluid in the space between the upstream-moving wave and the obstacle.

By mass conservation Equation 15.40.23 can be expressed in terms of u_2 to give

$$u_2^2 = (g'h_2)\left(1 - \frac{h_w}{h_2}\right)^3 \qquad \frac{h_w}{h_2} < 1 \qquad [15.40.24a]$$

$$= 0 \qquad \frac{h_w}{h_2} > 1 \qquad [15.40.24b]$$

It can be shown that Equations 15.40.21, 15.40.22 and 15.40.24 yield for $h_w/h_2 < 1$

$$u_1 - (1 - H_b)U = (g'h_1)^{1/2}\left[H_b\left(1 - \frac{H_w}{H_b}\right)\right]^{3/2} \qquad [15.40.25]$$

$$(u_1 - U)^2 = \frac{1}{2}(g'h_1)H_b(1 + H_b) \qquad [15.40.26]$$

and for $h_w/h_2 \geq 1$

$$u_1 = (1 - H_b)U \qquad [15.40.27]$$

$$U^3 = u_1U^2 - (g'h_1)^{1/2}U + 1/2(g'h_1)^{1/2}u_1 = 0 \qquad [15.40.28]$$

with

$$H_b = \frac{h_2}{h_1} \qquad [15.40.29]$$

where H_b is a ratio of heights.

Solutions of these equations are shown in Figure 15.121(c). The range $1.5 < h_2/h_1 < 2.5$ covers most cases of interest and as a rule-of-thumb $h_2/h_1 = 2$.

Release upstream of an obstacle such as a fence is one of the two main cases of more complex terrain treated in the *Workbook* by Britter and McQuaid (1988). The treatment is based on the work of Britter (1986 SRD R407). Using the Workbook notation given in Section 15.34, for a plume from a continuous release encountering a fence height H normal to the wind direction the height h of the plume in the absence of the fence is obtained from

$$C_g uh = C_o q_o^* \qquad [15.40.30]$$

where C_g is the maximum volumetric concentration at ground level, C_o is the volumetric concentration of the initial release, h is the height of the cloud, q_o^* is the volumetric release rate per unit width and u is the mean velocity at the fence.

The following regimes are distinguished. For $u/(g'_o q_o^*)^{1/3} > 5$ and $H/h \leq 30$, the plume is not blocked by the fence. In the range $4.5 \leq H/h \leq 15$ the ground level concentration is as if the plume were not dense and

$$\frac{C}{C_o}\frac{uH}{q_o^*} = 1.7 \pm 0.3 \qquad [15.40.31]$$

whilst in the range $3.5 \leq u/(g'_o q_o^*)^{1/3} \leq 5$

$$\frac{C}{C_o}\frac{uH}{q_o^*} = 2.2 \pm 0.4 \qquad [15.40.32]$$

where C is the volumetric concentration.

For $h_{0.5}/H \geq 2$ and $u/(g'_o q_o^*)^{1/3} > 3.5$, where $h_{0.5}$ is the height at which the concentration is half the ground level value, the ground level concentration is little affected by the fence.

As far as concerns plume width, the relations given for the plume widths W_f and W_{nf} with and without a fence, respectively, are as follows. The ratio W_f/W_{nf} increases with increase in fence height:

$$\frac{W_f}{W_{nf}} = 3 \qquad \frac{h}{H} \approx 0.05 \qquad [15.40.33a]$$

$$\frac{W_f}{W_{nf}} = 1.5 \qquad \frac{h}{H} \approx 0.15 \qquad [15.40.33b]$$

W_f/W_{nf} also increases weakly with $u/(g'_o q_o/W_{nf})^{1/3}$.

The following relation for concentration in terms of fence width is also given:

$$\frac{C}{C_o}\frac{uHW_1}{q_o} = 2.1 \pm 0.3 \quad 0.04 < \frac{h}{H} < 0.2; \frac{u}{(g'_o q_o/W_{nf})^{1/2}} \geq 4 \qquad [15.40.34]$$

where q_o is the volumetric rate of release.

Meroney (1991) has described the use of models for the simulation of the effects of a fence on the dispersion of a dense gas. Carissimo *et al.* (1989) have described the use of MERCURE-GL to study the effect of a fence on dense gas dispersion. The water tunnel study by Cheah, Cleaver and Milward (1983a) of dense gas dispersion at a simple barrier has been described in Section 15.39.

15.40.3 Water spray barriers and steam curtains

Work on water spray barriers and steam curtains is described in Section 15.53. Accounts of the use of HEAVYGAS to simulate the effects of the water spray barrier used in the field trials described by Moodie (1981) have been given by Deaves (1983b, 1984). This work is described in Section 15.53. In the work just mentioned on dense gas dispersion at a fence, Meroney (1991) has also treated the case of a water spray barrier.

15.40.4 Buildings: release upstream

Another well defined obstacle to the dispersion of a dense gas is a single building or a defined sequence of buildings. The effect of a building on an upstream release is well treated for passive dispersion, but not so well for dense gas dispersion.

McQuaid (1987) has given an account of the behaviour of a dense gas encountering a building in the field trials at Thorney Island, as described in Section 15.38. A review of turbulent diffusion near buildings, including a treatment of dense gas dispersion, has been given by Meroney (1982). Krogstad and Pettersen (1986) used a wind tunnel to investigate the flow of a dense gas around a rectangular building. The effect of a sequence of rectangular buildings on the dispersion of a dense gas has been studied by Deaves (1989) using an adaptation of the model by Brighton for release into a building wake, described below.

15.40.5 Buildings: release into lee

Release into the immediate lee of a building is another topic where treatments are available for passive dispersion, but where there is less guidance for dense gas dispersion. This case is relevant, however, to a number of scenarios which may arise in practice. In particular, it applies to the case where a spillage occurs from a storage tank and then evaporates in the lee of the tank.

A model for the dispersion of a dense gas in the lee of a building has been given by Brighton (1986). He takes as his starting point the models for passive dispersion in a building lee given by Vincent (1977, 1978) and Fackrell (1984b), which were described in Section 15.17. A dense gas will tend to reduce the turbulent mixing and, if the flow is large, to modify the mean wake flow, and a separate treatment is necessary.

He considers a rectangular building of height h, width w, length l and frontal area A

$$A = wh \qquad [15.40.35]$$

and a recirculation region, or wake, in the lee with height h, width w, length l_w, surface area S_w and volume V_w. The dimensionless wake length λ_w is defined as

$$\lambda_w - l_w/h \qquad [15.40.36]$$

The basis of the model is the existence of two layers, a lower and an upper layer, in the lee. It is assumed that air flows directly into the upper layer but not into the lower one:

$$F_A = \alpha_o S_w u \qquad [15.40.37]$$

where F_A is the flow of air into the wake, u is the wind speed and α_o is a constant. The concentration of contaminant C resulting from a source of strength Q in the lee is

$$C = Q/F_A \qquad [15.40.38]$$

Then from Equation 15.40.37

$$C = Q/\alpha_o S_w u \qquad [15.40.39]$$

The heights of the two layers are

$$\bar{h}_L = h_L/h \qquad [15.40.40]$$

$$\bar{h}_U = h_U/h \qquad [15.40.41]$$

$$h_L + h_U = h \qquad [15.40.42]$$

where h_L and h_U are the heights of the lower and upper layers, and $\bar{h}_L$ and $\bar{h}_U$ are the corresponding normalized values, respectively. Hence

$$\bar{h}_L + \bar{h}_U = 1 \qquad [15.40.43]$$

The treatment utilizes two main dimensionless parameters:

$$\bar{Q} = \frac{Q}{Au} \qquad [15.40.44]$$

$$B = \frac{g'_o Q}{u^3 w} \qquad [15.40.45]$$

with

$$g'_o = g\frac{\rho - \rho_a}{\rho_a} \qquad [15.40.46]$$

where B is the dimensionless buoyancy flux, g'_o is the reduced gravity at the source, $\bar{Q}$ is the dimensionless release rate, ρ is the density of the cloud and ρ_a is the density of air.

The flow from the lower to the upper layer F_{LU} is equal to that from the upper to the lower layer F_{UL} given that there is no air flow directly into the lower layer. These flows are taken as

$$F_{LU} = F_{UL} = \frac{\alpha_I \lambda_w}{\mathrm{Ri}} \qquad \mathrm{Ri} > \mathrm{Ri}_T \qquad [15.40.47a]$$

$$= \alpha_M \lambda_w \qquad \mathrm{Ri} < \mathrm{Ri}_T \qquad [15.40.47b]$$

where α_I and α_M are mixing coefficients. The Richardson number Ri is defined as

$$\mathrm{Ri} = \frac{(C_L - C_U)g'_o h}{u^2} \qquad [15.40.48]$$

which at the source becomes

$$\mathrm{Ri} = \frac{g'_o h}{u^2} \qquad [15.40.49]$$

The transition Richardson number Ri_T is

$$\mathrm{Ri}_T = \alpha_I/\alpha_M \qquad [15.40.50]$$

From analysis of the flows and concentrations in the wake, Brighton derives for one regime $\mathrm{Ri} \le \mathrm{Ri}_T$:

$$C_L = \frac{(\alpha_M\lambda_w + 0.7\bar{h}_U)\bar{Q}}{0.7\bar{h}_U\alpha_M\lambda_w + (\alpha_M\lambda_w + 0.7\bar{h}_U)\bar{Q}} \qquad [15.40.51]$$

$$C_U = \frac{\alpha_M\lambda_w C_L}{\alpha_M\lambda_w + 0.7\bar{h}_U} \qquad [15.40.52]$$

where C_L and C_U are the volumetric concentrations in the lower and upper layers, respectively. At the limit as $\bar{h}_L \to 0$ and $\bar{Q}_L \to 0$

$$\frac{C_U}{\bar{Q}} \to 1.4 \qquad [15.40.53]$$

whilst at the other limit as $\bar{h}_U \to 0$

$$C_L \to 1 \qquad [15.40.54]$$

This latter case corresponds to the situation where the source strength is so great that the gas released moves with a velocity comparable to the wind speed and occupies the whole of the wake region. For the other regime, with $\mathrm{Ri} > \mathrm{Ri}_T$:

$$C_L = 1 - \frac{\alpha_I\lambda_\omega}{B} \quad B \ge \alpha_M\lambda_w \qquad [15.40.55]$$

$$C_U = \frac{\alpha_I\lambda_w}{0.7\bar{h}_U \mathrm{Ri}_o} \qquad [15.40.56]$$

where Ri_o is the initial Richardson number before mixing.

Brighton describes the matching of this model to unpublished experimental work by Britter. He takes for λ_w a value of 2.08, as given by Fackrell $\alpha_1\lambda_w$is taken as 0.036; and α_M as unity, although the influence of this parameter is weak.

This model gives as outputs the width, height and concentration at the end of the wake region. The inputs required for a dense gas dispersion model are these parameters plus the velocity. Brighton suggests matching may be achieved by retaining the width and concentration given by his wake model, but adjusting the height to give mass conservation. This will generally involve a reduction in the height; the plume contracts as it accelerates up to the wind speed.

If the buoyancy flux is large with $B \gg 1$, there is a tendency for the cloud at the source to spread upwind and sideways. For this condition Brighton quotes the relations obtained by Britter (1980):

$$S_{\mathrm{U}} = \frac{1}{2}D + 2L_{\mathrm{B}} \qquad [15.40.57]$$

$$S_{\mathrm{L}} = \frac{1}{2}D + 4L_{\mathrm{B}} \qquad [15.40.58]$$

with

$$L_{\mathrm{B}} = \frac{g_{\mathrm{o}}'Q}{u^3} \qquad [15.40.59]$$

where D is the diameter of the source orifice, L_{B} is the buoyancy length scale, S_{L} is the lateral spread of the cloud and S_{U} is the upwind spread of the cloud. This model has been used by Deaves (1987b, 1989), as described above, in modelling for safety cases.

Release into the lee of a building is the other main case treated by Britter and McQuaid (1988) in the Workbook. The treatment for a continuous release is based on the work of Britter (1982, 1986 SRD R407) on a square flat plate of side H normal to the direction of flow.

For the concentrations in the immediate lee, the following regions or limits are distinguished:

Region 1 $\quad \dfrac{g_{\mathrm{o}}'q_{\mathrm{o}}}{u^3H} < 4 \times 10^{-3}$

Region 2 $\quad 4 \times 10^{-3} < \dfrac{g_{\mathrm{o}}'q_{\mathrm{o}}}{u^3H} < 4 \times 10^{-2}$

Limit 3 $\quad \dfrac{g_{\mathrm{o}}'q_{\mathrm{o}}}{u^3H} > 2 \times 10^{-1}$

Limit 4 $\quad \dfrac{g_{\mathrm{o}}'q_{\mathrm{o}}}{u^3H} > 1$

where g_{o}' is the reduced gravity at the source, H is the height of the obstacle, q_{o} is the volumetric rate of release of material and u is the mean velocity at the obstacle height.

In region 1, the release rate is so low that the density of the release has virtually no effect on the concentration. In region 2, the lateral width of the plume is maintained within the recirculation zone in the immediate lee. At limit 3, there is some enhanced dilution in the immediate lee but the effect is weak. By limit 4, the effect of the obstacle has become negligible.

In both regions 1 and 2 by a distance of $x/H = 2$ the concentration is given by the relation

$$\frac{C}{C_{\mathrm{o}}}\frac{uH^2}{q_{\mathrm{o}}} \approx 1.5 \qquad [15.40.60]$$

where C is time mean ground level volumetric concentration and C_{o} is the volumetric concentration at the source.

These results apply for the condition (q_{o}/uH^2) or (q_{o}/uH^2) less than about 0.1, where q_{o}' is the volumetric rate of release per unit length. Further downwind, the effect of the density difference is liable to reassert itself. For concentrations further downwind, one approach is to work in terms of a new source with values of q_{o} and g_{o}' determined from the value of C.

15.40.6 Buildings: release inside

A release of gas may occur inside a building and then escape into the atmosphere. A study of this scenario has been made by Brighton (1986, 1989 SRD R468). The particular case of interest was a release of liquefied chlorine.

For a continuous release of gas into a space ventilated by air, the molar flow of gas is

$$\frac{q_{\mathrm{G}}}{M_{\mathrm{G}}} = \frac{N_{\mathrm{G}}Q}{V} \qquad [15.40.61]$$

and that of air is

$$\frac{Q_{\mathrm{A}}\rho_{\mathrm{A}}}{M_{\mathrm{A}}} = \frac{N_{\mathrm{G}}Q}{V} \qquad [15.40.62]$$

where M is the molecular weight, N is the number of moles, Q is the volumetric flow, V is the volume of space, ρ is the density, and subscripts A and G denote air and gas, respectively. The variables Q and ρ without a subscript refer to the gas-air mixture.

The natural ventilation flow Q_{A} is given by the ventilation equation

$$Q_{\mathrm{A}} = bA(\Delta P/\rho_{\mathrm{A}})^{1/2} \qquad [15.40.63]$$

where A is the area of the opening, ΔP is the pressure difference between the outside and the inside, and b is a constant. Equation 15.40.63 is an application of Bernouilli's equation and is a standard relation given in various ventilation codes such as BS 5925: 1980. The value of constant b is taken by Brighton as 0.88. The pressure drop is a function of the wind speed u:

$$P = \frac{1}{2}C\rho_{\mathrm{A}}u^2 \qquad [15.40.64]$$

where C is a pressure coefficient. Values of C for cuboid buildings are tabulated in BS 5925: 1980. They are in the range 0.7–0.8 for an upwind face, –0.8 to –0.5 for the sides, and –0.4 to –0.1 for the lee.

The cases considered are (1) release under gravity alone and (2) release under the combined influence of gravity and wind. For the first case, Equation 15.40.63 is used for the air flow; Equation 15.40.64 is not used. For this case, the gas–air mixture flows out through an area at the bottom of the space and air flows in through an area at height h at the top of the space. The hydrostatic pressure is

$$= (\rho - \rho_{\mathrm{A}})gh \qquad [15.40.65]$$

where ρ is the density of the gas–air mixture and ρ_{A} is the density of air. The pressure at the top openings is

$$= P_{\mathrm{o}} - P' \qquad [15.40.66]$$

and that at the bottom opening is the sum of these

$$= P_o - P' + (\rho - \rho_A)gh \qquad [15.40.67]$$

where P is the pressure difference between atmospheric pressure and the internal pressure and P_o is the atmospheric pressure. Applying Equation 15.40.63 to the two areas, the inflow of air is

$$Q_A = bA_i(P'/\rho_A)^{1/2} \qquad [15.40.68]$$

and the outflow of gas–air mixture is

$$Q = bA_o\left(-P'/\rho + \frac{\rho - \rho_o}{\rho}gh\right)^{1/2} \qquad [15.40.69]$$

where A_i is the area for inflow and A_o is the area for outflow.

Eliminating P from Equations 15.40.68 and 15.40.69 and then utilizing Equations 15.40.61 and 15.40.62 yields

$$\tilde{q}_G = \tilde{N}_G\left(\frac{\rho/\rho_A - 1}{n^2\tilde{N}_G^2 + a^2\rho/\rho_A}\right)^{1/2} \qquad [15.40.70]$$

with

$$\tilde{q}_G = \left(\frac{M_A q_G}{bM_G\rho_A A_i(gh)^{1/2}}\right) \qquad [15.40.71]$$

$$\tilde{N}_G = \frac{N_G R T_A}{P_o V} \qquad [15.40.72]$$

$$a = A_i/A_o \qquad [15.40.73]$$

$$n = N_A/N_G \qquad [15.40.74]$$

where a is the ratio of areas, n is the ratio of molar flows, $\tilde{N}_G$ is a dimensionless quantity, q_G is the flow of gas, $\tilde{q}_G$ is the dimensionless flow of gas, R is the universal gas constant and T_A is the absolute temperature of the air.

Treating the contents of the space as a mixture of perfect gases or a two-phase mixture with vapour fraction f

$$\tilde{N}_G = \frac{1}{1+f}\,\frac{T_A}{T} \qquad [15.40.75]$$

where f is the vapour fraction and T is the absolute temperature of the gas–air mixture.

The time τ for the concentration of the gas to reach steady state if outflow is neglected is

$$\tau = \frac{M_G N_G}{q_G} \qquad [15.40.76]$$

$$\frac{\bar{\tau} V}{bA_i(gh)^{1/2}} \qquad [15.40.77]$$

with

$$\bar{\tau} = \frac{\tilde{N}_G}{\tilde{q}_G} \qquad [15.40.78]$$

For this case n and $\bar{\tau}$ are shown in Figures 15.122(a) and (b), respectively.

For the second case, that of release under the combined influence of gravity and wind, use is made of both Equations 15.40.63 and 15.40.64. For this case, it is necessary to consider several different situations since, depending on the configuration, the ventilation flow may assist or oppose the gravity flow. This is illustrated in Figure 15.123. For Case (a) in Figure 15.123, the inlet opening is high up on the upwind face and above the outlet opening and hence the ventilation effect always assists the gravity effect. For Cases (b) and (c) the inlet opening is low down on the upwind face and below the outlet opening and hence the ventilation effect opposes the gravity effect. In Case (b) the ventilation effect is strong enough to overcome the gravity effect, whilst in Case (c) it is not. Case (a) is termed the 'co-operative combined' mode, whilst Cases (b) and (c) are termed the 'opposing combined' mode.

A Richardson number is defined as

$$\mathrm{Ri} = \frac{2gh}{(C_i - C_o)u^2} \qquad [15.40.79]$$

where C_i is the pressure coefficient for the inflow opening and C_o is that for the outflow opening.

The point at which gravitational and wind effects are of equal importance is given by

$$\mathrm{Ri}^{-1} = \rho/\rho_A - 1 \qquad [15.40.80]$$

Then, incorporating the additional pressure term from Equation 15.40.64 and proceeding as before yields

$$\tilde{q}_G = \tilde{N}_G\left(\frac{1 - \rho/\rho_A + \mathrm{Ri}^{-1}}{n^2\tilde{N}_G^2 + a^2\rho/\rho_A}\right)^{1/2} \quad \mathrm{Ri} < (\rho/\rho_A - 1)^{-1} \quad \text{(Case (b))} \qquad [15.40.81a]$$

$$\tilde{q}_G = \tilde{N}_G\left[\frac{\rho/\rho_A - 1 - \mathrm{Ri}^{-1}}{n^2\tilde{N}_G^2 + (1/a^2)\rho/\rho_A}\right]^{1/2} \quad \mathrm{Ri} > (\rho/\rho_A - 1)^{-1} \quad \text{(Case (c))} \qquad [15.40.81b]$$

For this case, n and $\bar{\tau}$ are shown in Figures 15.124(a) and (b), respectively. The plots have a rather peculiar shape. At values of $\tilde{q}_G$ below a critical value, there are three steady-state solutions, of which one is unstable. For the case of a space containing originally zero concentration of the gas, it is the higher value of η in Figure 15.124(a) which represents the eventual steady state. At values of $\tilde{q}_G$ above the critical value there is only one steady state.

Accounts of the use of this work in the modelling of dense gas dispersion for safety cases have been given by Deaves (1987b, 1989).

15.40.7 Industrial sites

There have been several studies of the effect on the behaviour of a dense gas when it disperses over an industrial site containing features such as process plants, storages or terminals.

C.I. Bradley and Carpenter (1983) have conducted an investigation of dense gas dispersion at a storage and

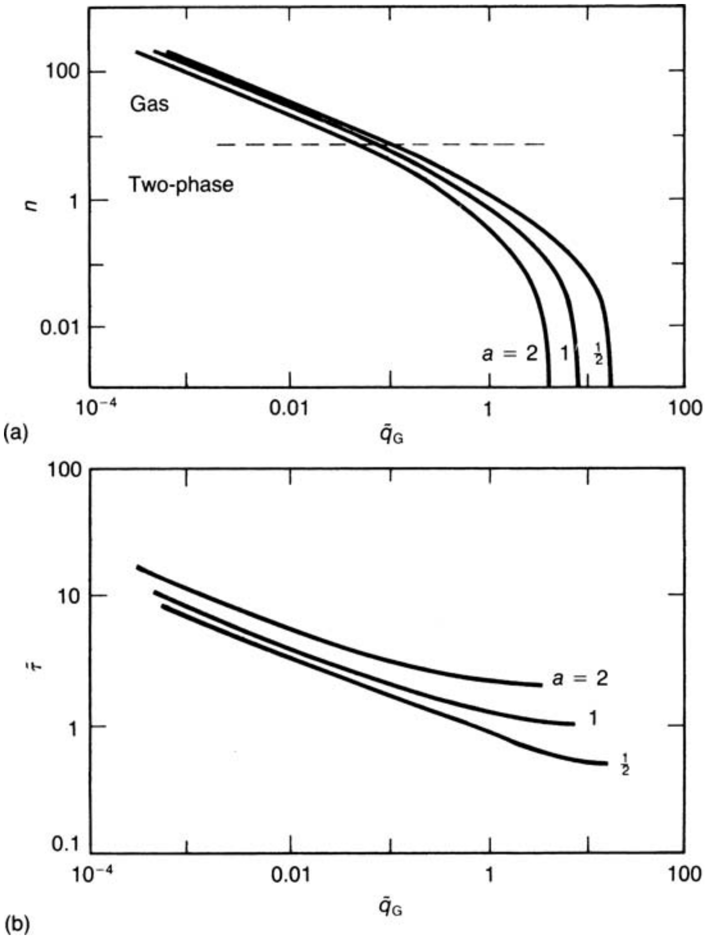

Figure 15.122 *Brighton model of release of gas inside a building – continuous release of chlorine under gravity alone (Brighton 1989, 3RD R468): (a) air/chlorine molar flow ratio; (b) dimensionless time (Courtesy of the UKAEA Safety and Reliability Directorate)*

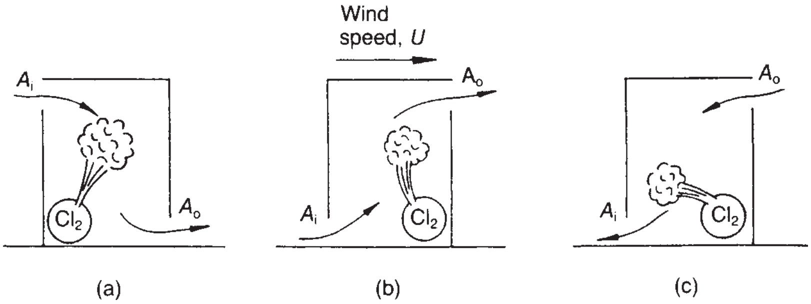

Figure 15.123 *Brighton model of release of gas inside a building – modes of release (Brighton 1989 SRD R468): (a) cooperative combined mode; (b) opposing combined mode Ri* $< (\rho/\rho_o - 1)^{-1}$; *(c) opposing combined mode Ri* $> (\rho/\rho_o - 1)^{-1}$ *(Courtesy of the UKAEA Safety and Reliability Directorate)*

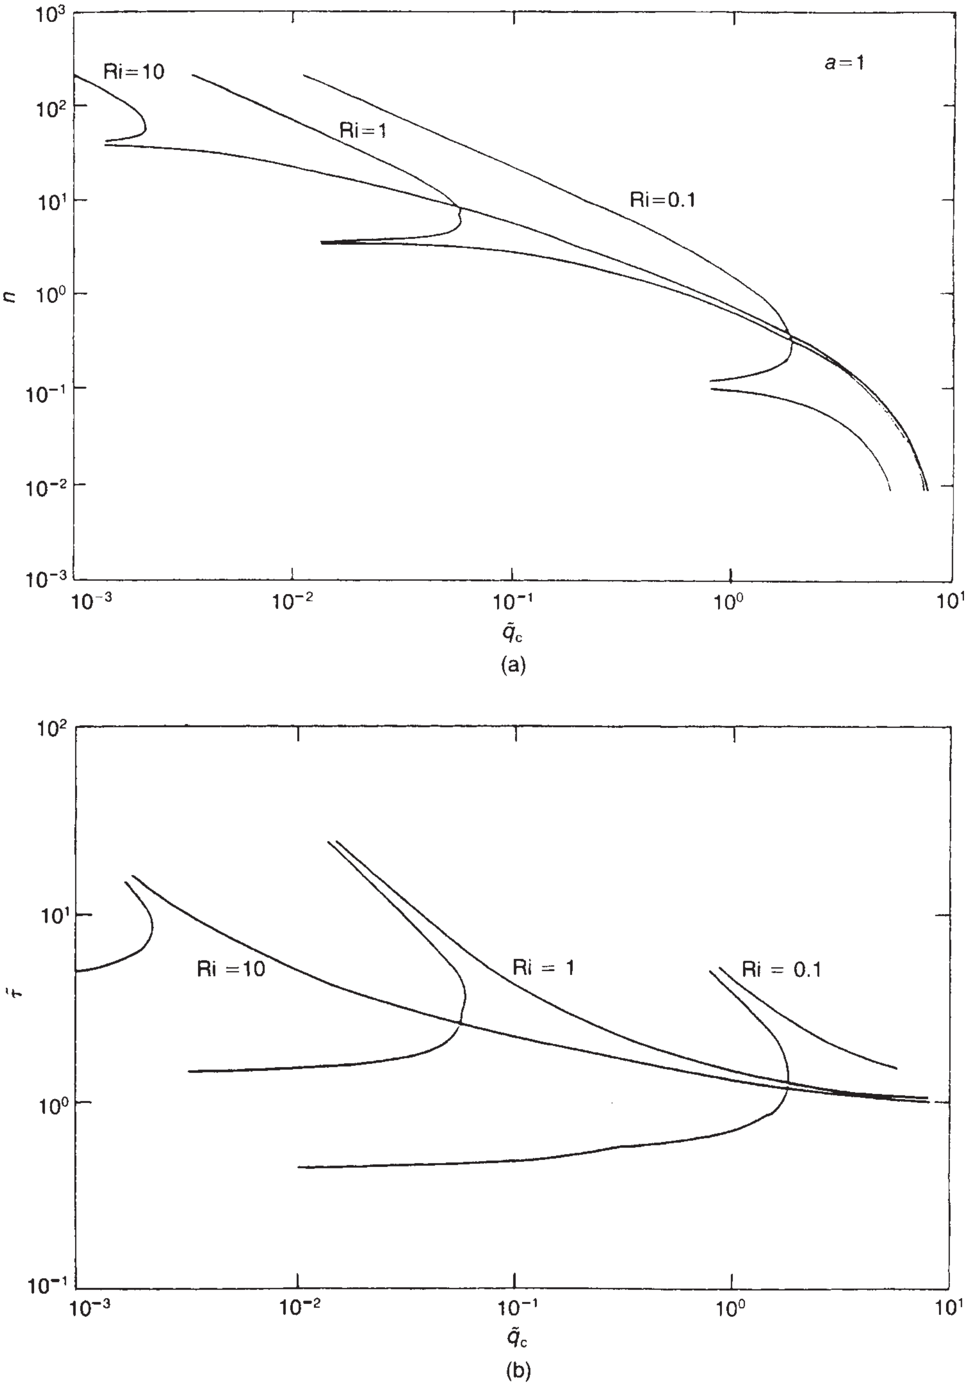

Figure 15.124 *Brighton model of release of gas inside a building – continuous release of chlorine in opposing combined mode with a = 1 (Brighton, 1989 3RD R468): (a) air/chlorine molar flow ratio n; and (b) dimensionless time (Courtesy of the UKAEA Safety and Reliability Directorate)*

terminal site using both ZEPHYR and wind tunnel modelling. This work is described in Section 15.39. An account is also given in the same section of the work of Guldemond (1986) on a wind tunnel study of dispersion of ammonia on an industrial site.

Deaves (1989), in the work on safety cases already mentioned, used HEAVYGAS to study dense gas dispersion over a works site. An account of this study is given in Section 15.33.

Both in the work of Bradley and Carpenter and in that of Deaves the presence of the industrial site caused a reduction in the hazard range compared with unobstructed ground. This reduction was typically of the order of 2, although this value should be regarded as no more than a pointer.

15.40.8 Complex terrain

Complex terrain such as hills and valleys appears not to have been investigated to any great extent in relation to dense gas dispersion. Such terrain is of practical importance for passive dispersion of pollutant gases where the contamination distances are typically some kilometres, but of less concern for dense gas dispersion where the hazard ranges tend to be shorter. Likewise, coastal regions and urban areas have not received much attention as far as dense gas dispersion is concerned.

15.41 Dispersion of Dense Gas: Validation and Comparison

In the account given so far of dense gas dispersion, the various models have been presented, often with some mention of comparisons made with experimental work, and physical modelling has been described, much of it simulating field trials.

The degree of scale-up between laboratory experiments (or even field trials) and incident scenarios, the differences in the definitions of concentration used and the variability of concentration between different realizations of an ensemble of experiments, the large number of models and the appreciable differences in the predictions which they give, and the variety of outputs which may be of interest, all underline the need for methods of evaluating models.

Model evaluation has been a live issue for passive dispersion, as described in Section 15.15. Approaches to validation of models of dense gas dispersion have been described by Fay (1980), Wheatley and Webber (1984 CEC EUR 9542 EN), Brighton (1987) and Mercer (1988).

15.41.1 Degree of scale-up

The degree of scale-up which is involved in going from even the largest field trials to the scenario of a major incident can be very large. For example, the Thorney Island trials involved 2000 m^3 of gas. The LNG spill studied by Havens (1978) involved 25,000 m^3 of LNG, equivalent to 6×10^6 m^3 of gas; this is a scale-up of over three orders of magnitude.

15.41.2 Differences between models

At the start of the Thorney Island trials the organizers invited modellers to submit for defined conditions and releases the profile of concentration with downwind distance which their models predict for a particular scenario. The results of this exercise are illustrated in Figure 15.125. The figure shows a high degree of variability between the models.

15.41.3 Differences in model outputs

There is large variety of outputs which have been used by authors of models in making comparisons with

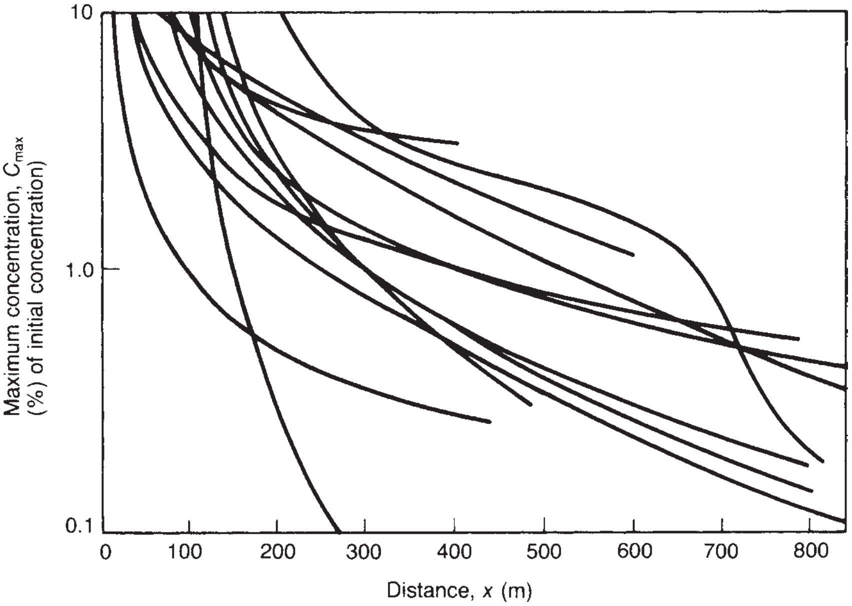

Figure 15.125 *Evaluation of models for dense gas dispersion – predictions of different models prior to the Thorney Island trials (McQuaid, 1984b) (Courtesy of Springer Verlag)*

experimental results. A review of these outputs has been given by Mercer. They include the concentrations

(1) bulk concentration as function of distance or time;
(2) peak concentration as function of distance or time;
(3) concentration at a given distance and time;

and

(4) cloud radius or height as a function of distance or time;
(5) location of cloud centre, leading edge or trailing edge, peak concentration as a function of time;
(6) maximum downwind extent of the lower flammability limit (LFL) or (1/2) LFL

Mercer gives details of comparisons made, showing there is little uniformity in the choice of outputs used for comparison.

15.41.4 Definition and determination of concentration

In large part, the problem of evaluation centres around that of defining the experimental concentrations and then obtaining experimentally stable values for these. One problem is that the values of the concentration obtained in a single trial vary with the sampling time. It is necessary that the sampling time be clearly defined both for the model and for the experiment.

Frequently, experimental results are reported using some kind of average concentration at a fixed location. Usually, for the plume from a continuous release the concentration used is a long-time average, whilst for the cloud from an instantaneous release it is a short-time average. Likewise, a model should include adequate definitions of the concentration to which the predictions are intended to apply. Such definitions are exemplified by those given in the Workbook. For a continuous release the correlations are for a concentration averaged over 10 min, whilst for a instantaneous release they are for the ensemble average of the maximum of 0.6 s mean concentrations.

A second problem is that there is a high degree of variability between the values of a concentration measured in experiments under the same nominal conditions. In principle, it is necessary to perform sufficient experiments to obtain a stable ensemble value. However, this is impractical with large field trials. Yet it is highly desirable that the predictions of models be compared with large-scale experiments.

A third problem is that the maximum concentration of a plume occurs on the centre line, but in relation to a fixed location this centre line may be continuously displaced due to plume meander. An alternative approach described by Puttock, Blackmore and Colenbrander (1982) is therefore to reconstruct from experimental measurements the variation of the location of the centre line with time and to utilize for comparison the concentrations on this reconstructed centre line.

A more detailed discussion of concentration is given in Section 15.45. The work described there, particularly that of Chatwin and co-workers, points to a fundamental approach in which the concentration is defined in terms of concentration probability contours.

15.41.5 Methods of evaluation

Some of the methods available for checking a model are described by Mercer. The predictions of the model may be compared with experimental work, either by the authors or by others. The data may also be compared with those from other models. The sensitivity of the predictions may be investigated. The variables and the dimensionless quantities used in the model may be examined. The constants in the submodels may be optimized by comparison with observation.

15.41.6 Comparison between models and experiments

Most authors of models have presented some comparison of predictions from their model with results of experimental work, ranging from laboratory-scale experiments to field trials. However, as just described, the problem of evaluation is a complex one, and such comparisons are frequently pointers rather than full validations.

A review of comparisons between models and experiments has been given by Mercer (1988). He defines a number of variables which are commonly compared (as described above), tabulates those which have been used in particular comparative studies and lists the data sets used in these studies. He comments that there is little commonality in the variables chosen for comparison and little justification given for the choice of experiments with which to make the comparison.

15.41.7 Comparison between models and experiments: some studies

Some mention of comparisons made between models and experiments has been made above in the accounts given of the individual models. In most cases, these are comparisons made by the authors themselves. There have also been a number of comparative studies involving a number of models and trial series. Reviews of studies involving comparison of models with experiments have been given by Blackmore, Herman and Woodward (1982) and the CCPS (1987/2).

The CCPS (1987/2) describes evaluation studies by a number of workers. Quantities compared include: cloud dimensions; concentration contours, both in plan and crosswind elevation views; concentration vs distance; and mean relative error.

J.L. Woodward *et al.* (1982, 1983) have compared the Germeles and Drake model, the Eidsvik model, HEGADAS, ZEPHYR and MARIAH with the Dutch Freon, Matagordo Bay and Porton Down trials. Quantities compared include cloud height, cloud concentration contour (for LFL), and the concentration vs time profile at a fixed point.

A comparison has been given by Havens, Spicer and Schreurs (1987a) of SIGMET-N, ZEPHYR, MARIAH-II and FEM3 with the Burro trials, the quantity compared being concentration vs distance.

Koopman, Ermak and Chan (1989) have described a comparison of the Gaussian model, SLAB, FEM3 and HEGADAS and the proprietary model CHARM with the Burro, Coyote, Desert Tortoise, Eagle, Goldfish, Falcon, Maplin Sands and Thorney Island trials. Quantities compared include: concentration contours, both in plan and crosswind elevation views; concentration vs distance; and cloud temperature vs distance.

S.R. Hanna, Strimaitis and Chang (1991b) have compared the Gaussian model, INPUFF, HEGADAS, DEGADIS and the Workbook model and the propriety models AIRTOX and CHARM with the results of the Burro, Coyote, Desert Tortoise, Goldfish, Porton Down, Maplin Sands and Thorney Island trials and also with the passive dispersion

Hanford and Prairie Grass trials. The quantities compared were the fractional bias and the normalized mean square error, evidently for the concentrations at different distances.

Touma *et al.* (1991) have compared SLAB, HEGADAS and DEGADIS and also AIRTOX and CHARM with the results of the Burro, Desert Tortoise and Goldfish trials, the quantity compared being concentration vs distance.

In some cases (e.g. CCPS, 1987/2) investigators have found the performance of the Gaussian model to be virtually as good as that of dense gas dispersion models, though this finding should be treated with caution.

15.41.8 Comparison between models and experiments: some problems

The use of data from field trials to validate models involves a number of problems. An account of these in the context of the Thorney Island trials has been given by Brighton (1987). He describes in detail the sources of error in the data obtained from such trials.

The data required depend on the type of model. The data yielded by a trial are a set of measurements of profiles of concentration vs time at each sensor within the cloud together with the parameters.

For a three-dimensional model the outputs are again concentration vs time profiles and thus comparison is relatively straightforward. A problem can arise, however, if the experimental measurements are taken very close to the ground. The grid size in the three-dimensional model may be too coarse to give an accurate prediction of these concentrations.

The comparison is more difficult for a box model. It is not a simple matter to extract from the experimental data the quantities required by modellers. The extent of the processing necessary to convert the Thorney Island results into a data set that conforms with the requirements of modellers was indicated in Section 15.38.

Quantities required are those such as mean concentration, cloud dimensions and advection velocity. Brighton gives examples of the differences in the estimates of these quantities given by different workers.

In view of the work involved in establishing the data sets required to conduct model evaluations, it is valuable, where the data permit it, to have an archive of data in standard format. S.R. Hanna, Strimaitis and Chang (1991b) describe the creation of such a modeller's data archive (MDA).

15.41.9 Comparison between different models: some studies

In addition to comparisons between predictions of models and results of experiments made by the authors of the particular model, comparisons have also been made between a number of models. A series of studies of the performance of available models has been carried out by Havens, starting with the LNG spill studies described in Section 15.22. Mention of some of the other comparisons made between models has been made in the accounts of the various models.

The CCPS Workbook of Test Coses for Vapor Cloud Source Dispersion Models (CCPS, 1990/8) gives results from a number of models, principally the Gaussian dispersion model, SPILLS, SLAB and DEGADIS, and thus gives a comparison of models in a set of typical hazard assessment applications.

15.41.10 Measures for evaluation

There have been, therefore, quite a large number of model evaluation studies. Most of these studies have relied on essentially *ad hoc* criteria of evaluation. One problem in developing evaluation criteria is to identify those parameters which are the best discriminators. Thus, for example, one of the main features which a model should predict is the degree of air entrainment. The cloud radius tends not to be a good discriminator for this. It is the height which is much more strongly affected by entrainment.

Another problem is the formulation of criteria which allow comparisons to be made between models. Here criteria such as cloud dimensions or concentration profiles may be abandoned in favour of statistical measures. There is no generally accepted set of measures for validating models, but several authors have developed particular methods.

Fay (1980) has utilized a scatter diagram technique in which for the variable of interest the experimental value is plotted against the model value. By normalizing the variable, the method can be extended to allow comparisons to be made between the experimental value and the values predicted by different models. One of the plots using a normalized variable given by Fay is shown in Figure 15.126.

Work on goodness-of-fit measures (GFMs) between area-averaged concentrations obtained in experiments and concentrations given by box models has been described by Wheatley, Prince and Brighton (1985).

S.R. Hanna, Strimaitis and Chang (1991b) have utilized two statistical measures: the fractional bias (FB) and the normalized mean square error (NMSE). They give a series of plots of FB vs NMSE, each showing the performance of a number of models for a particular series of trials.

In wind tunnel work there is evidence of a degree of uniformity in comparing results of field experiments and of physical modelling, in that several workers have adopted the practice of D.J. Hall, Hollis and Ishaq (1982, 1984) in utilizing cloud width, arrival and departure times, and concentration vs time profiles.

15.41.11 Extent of validation attainable

For gas dispersion modelling generally, it has to be recognized that there may be limits to the degree of agreement which can be expected between model predictions and experimental results. A discussion of the problem is given by Mercer (1988). In large part, it centres on the variability of concentrations just described. Mercer quotes the following statement by Lamb (1984) made in the context of air pollution and its regulation:

> The predictions even of a perfect model cannot be expected to agree with observations at all locations. Consequently, the goal of 'model validation' should be one of determining whether observed concentrations fall within the interval indicated by the model with the frequency indicated, and if not, whether the failure is attributable to sampling fluctuations or is due to failure of the hypotheses on which the model is based. From the standpoint of regulatory needs the utility of a model is measured partly by the width of the interval in which a majority of observations can be expected to fall.

For heavy gas dispersion specifically, the high degree of inertia of the cloud results in some reduction in the variability which would otherwise occur. Mercer suggests that

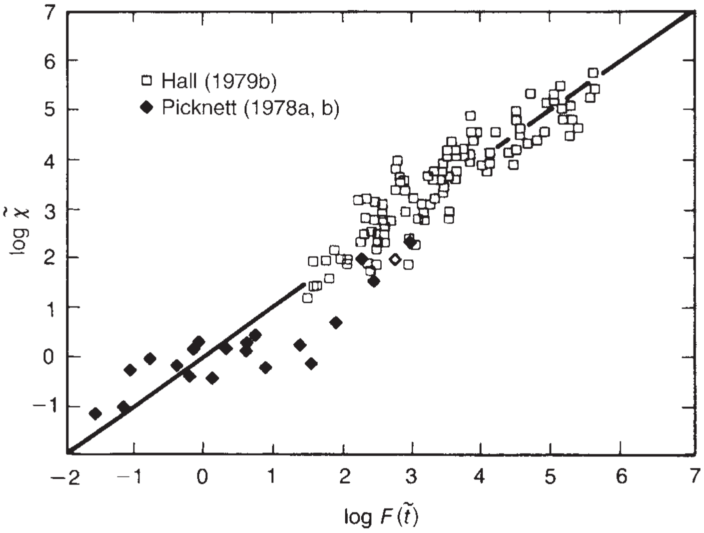

Figure 15.126 *Evaluation of models for dense gas dispersion – comparison of observed peak concentrations with those predicted by models τ, time of passage of peak concentration; $\tilde{\chi}$ peak cloud concentration. (Fay and Ranck, 1983) (Courtesy of Pergamon Press)*

a realistic expectation for a model may be that its predictions be accurate within a factor of 2–3.

In order to reduce the degree of uncertainty, the experimental work should cover a wide range of conditions and scales and should include repeat experiments, which may most conveniently be obtained by physical modelling.

15.41.12 Validation of models against Thorney Island trials: Phase I

Mention has already been made of the exercise carried out before the Thorney Island trials in which modellers were invited to submit predictions from their models. A large number of comparisons have been presented between the results of the Thorney Island Phase I trials and those from model simulations. Some of these comparisons are listed in Table 15.53.

15.41.13 Validation of models against Thorney Island trials: Phase II

The number of models which are capable of simulating dense gas dispersion over other than flat, unobstructed terrain is limited, and the number of comparisons between the results of the Thorney Island Phase II trials and those from model simulations is correspondingly smaller. Such comparisons have been given for SLUMP and HEAVYGAS by Deaves (1985, 1987a,b).

15.41.14 Comparison of physical models with Thorney Island trials

Comparisons have also been presented between the results of the Thorney Island trials and those from physical modelling, predominantly in wind tunnels. Mention has already been made of the exploratory work done by D.J. Hall, Hollis and Ishaq (1982, 1984) using a wind tunnel to assist in the design of the trials. Some of the trials conducted were sufficiently close to these pre-trial experiments to allow comparison to be made. These comparisons have been reported for trials 7, 11, 13, 15 and 18 by D.J. Hall and Waters (1985). Further comparisons include those for trial 8 by van Heugten and Duijm (1985) and for trial 20 by Knudsen and Krogstad (1987). A programme of wind tunnel simulations for all the Thorney Island trials has been described by M.E. Davies and Inman (1987).

15.42 Dispersion of Dense Gas: Particular Gases

So far the account given of dense gas dispersion has been a general one. It is now necessary to consider some gases of industrial interest for which the dense gas behaviour is governed by the specific characteristics of the gas. The gases considered are:

(1) propane;
(2) LNG;
(3) chlorine;
(4) ammonia;
(5) hydrogen fluoride.

The source terms for some of these gases are considered in Section 15.23. The validation of models against experimental work on, and the application of these models to simulations for, these gases are treated in the sections on the individual models, Sections 15.25–15.36. Mitigation of releases of the gases is dealt with in Sections 15.53 and 15.54.

The account in this section deals with the effect on the density of the gas cloud of the following factors:

(1) molecular weight;
(2) boiling point;
(3) chemical behaviour;
(4) atmospheric humidity;
(5) surface heat transfer;
(6) liquid spray.

Table 15.53 Some comparisons made between results of Thorney Island Phase I trials and results of model simulations

The modelling of the dispersion of these materials raises two questions: whether the gas cloud is dense immediately following the initial release; and, if so, how the cloud changes in density and whether it becomes buoyant. The main interest is in the behaviour of the gas cloud from release of a liquefied gas.

15.42.1 Propane

Propane has a molecular weight of 44. It is dense by virtue of its molecular weight. This is so whether the release is one of propane gas or liquefied propane.

The normal boiling point of propane is −42°C. If the release is one of liquefied propane, the low temperature makes the gas cloud initially somewhat more dense. In principle, heating up of the gas will render it less dense. However, the initial temperature difference between the gas at its boiling point, and the ambient features, the ground or water surface and the atmosphere, is not great and heat transfer to the gas does not play a major role. Any density changes due to temperature changes tend to be small.

The density of the gas cloud will also be affected by atmospheric humidity and by any liquid present as spray. The effect of these factors on the density of propane gas clouds does not appear to have been much studied, but some indication may be obtained from their effect on clouds of the other gases, as described below. Propane is generally modelled as a 'simple' dense gas.

15.42.2 LNG

The characteristics of the gas cloud from a release of LNG, mainly methane, have been described by Puttock (1987c). Broadly, LNG releases normally give rise to dense gas clouds. However, under conditions of very high atmospheric humidity the initial cloud may be buoyant, whilst in other cases the cloud, initially dense, may become buoyant with time due to surface heat transfer.

LNG is mainly liquefied methane and, as such, has a molecular weight of 16 and a normal boiling point of −161°C. Insofar as it behaves as a dense gas, it does so by virtue of factors other than its molecular weight. Of these the principal factor is temperature. The gas is sufficiently cold that on release it is dense.

The temperature difference between the cold gas and the ambient features is significant. Heat transfer from the atmosphere and from the surface is appreciable and can have a significant effect on the density. The gas may be heated up sufficiently that it becomes buoyant.

Another factor which affects the density of the gas cloud is the humidity. The cold gas causes condensation, and also freezing, to occur and the heat release consequent on these phase changes causes heating of the cloud. If the humidity is high, this can just cause the cloud to become buoyant.

Figure 15.127, from Puttock, gives relative density vs concentration curves for mixing of methane at its boiling point with air with relative humidity (RH) as parameter. They show that with dry air (RH = 0%) the gas cloud remains dense at all concentrations, whereas with wet air (RH = 100%) the cloud is slightly buoyant at lower concentrations.

The effect of the above variables is illustrated in the modelling work done on the Maplin Sands trials, described by Puttock. Using a version of the HEGADAS model in which surface heat transfer and atmospheric humidity were neglected gave downwind distances to the LFL which were large and exceeded those observed, whilst inclusion of these effects in the model reduced the distances appreciably and brought them closer to the observed values. This is illustrated in Figure 15.128 for trial 29, for which the wind speed was quite high (7.4 m/s). Comparative results for this and other trials are tabulated by Puttock.

Some accounts of work on mathematical modelling and physical modelling of LNG dispersion suggest that surface heat transfer can be neglected, except for low wind speed conditions. These results of Puttock indicate that failure to take it into account can lead to appreciable error.

The density of an LNG cloud will also be affected by any liquid spray which may be present. The source invariably considered for an LNG cloud is a spillage of the refrigerated liquid followed by evaporation of the liquid pool. By comparison with the quantity of spray generated by a typical flashing liquid jet, the quantity entrained in the vapour evolved will be small; it may be expected to be rather greater from a spillage on sea than from one on land. In any event, accounts of the density of gas clouds from LNG spillages tend to disregard the effect of liquid spray.

15.42.3 Chlorine

As a dense gas, chlorine has some of the features of propane. The molecular weight of chlorine is 71 so that it is dense by virtue of its molecular weight. This is so whether the release is one of chlorine gas or liquefied chlorine.

The normal boiling point of chlorine is −34°C. If the release is one of liquefied chlorine, the low temperature makes the gas somewhat more dense so that, in principle, heating up of the gas will render it less dense, but in practice heat transfer to the gas does not play a major role and any density changes due to temperature changes tend to be small.

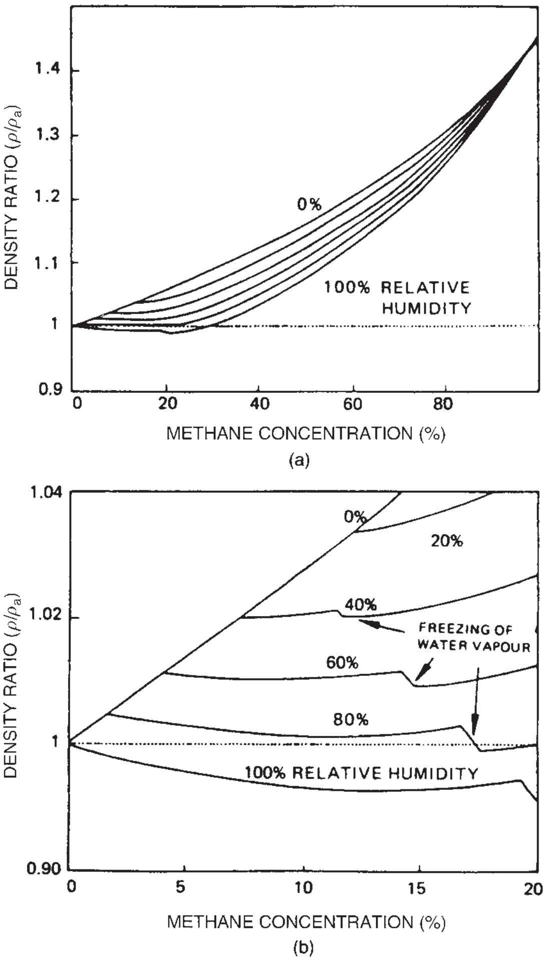

Figure 15.127 *Density of a methane–air mixture formed by release of LNG into the atmosphere (Puttock, 1987c): (a) main plot; and (b) enlargement of lower left-hand section of (a) (Courtesy of the American Institute of Chemical Engineers)*

With regard to atmospheric humidity and liquid spray, the points made above in relation to propane apply also to chlorine. Chlorine is another gas which tends to be modelled as a 'simple' dense gas.

15.42.4 Ammonia

The characteristics of the gas cloud from a release of anhydrous liquefied ammonia have been described by Haddock and Williams (1978 SRD R103, 1979) and Blanken (1980). Broadly, a release of liquid anhydrous ammonia normally gives rise to a dense gas cloud. The cloud will tend to be dense if the atmospheric humidity is low and/or the fraction of liquid spray is high. A cloud with little or no liquid spray in air with high humidity may be buoyant.

The molecular weight of ammonia is 17 and its normal boiling point is −33°C. Thus the molecular weight is not responsible for any dense gas behaviour. A systematic investigation of the factors governing the density of clouds of ammonia in air has been made by Haddock and Williams (1978 SRD R103, 1979). They consider chemical interactions, atmospheric humidity and liquid spray.

Possible chemical interactions with atmospheric air would appear to be formation of ammonium hydroxide (NH_4OH), ammonium bicarbonate (NH_4HCO_3) and ammonium carbonate ($(NH_4)_2CO_3$). The authors conclude that formation of these compounds directly from ammonia vapour, water vapour and carbon dioxide would be negligible, but that there would be dissolution of ammonia into water droplets formed due to cooling of the air by the cold ammonia gas and dissolution of carbon dioxide in these droplets. The effect of these processes on the density and temperature of the cloud would be minimal, but the effect on toxicity could be appreciable. Thus the volume of air required to convert a cloud of pure ammonia to one with an ammonia concentration of 2000 ppm contains enough carbon dioxide to reduce the concentration of free ammonia to about 1400 ppm.

A model of the thermodynamics of the NH_3–H_2O–air system is used to derive plots of the density and temperature of a cloud formed from the mixing of ammonia and air, as shown in Figure 15.129, whilst Figure 15.129(a) shows the temperature for the dry air case. Figure 15.129(b) shows a plot of the density vs the air/ammonia mass ratio with the liquid fraction f as the parameter, for ammonia initially at its boiling point, for dry air ($RH = 0\%$) and Figure 15.129(c) that for wet air ($RH = 100\%$).

The work showed that if there is no liquid spray, the density of the cloud, for dry or wet air, rises asymptotically to that of air, and therefore never exceeds that of air. If liquid spray is present, the cloud may be denser than air. There are limits to the liquid fraction below which the cloud density will not exceed that of air, the limits being different for dry and wet air. For dry air, this limit on the liquid fraction is about 8% and for wet air it is about 12%.

For wet air with liquid fractions of 12–16% the cloud is denser than air at low dilutions but less dense than air at high dilutions, whilst with liquid fractions of 16–20% it is denser than air at low dilutions and remains denser throughout the dilution process.

Haddock and Williams consider the behaviour of the ammonia droplets. Ammonia will evaporate from the droplets, causing their temperature to fall. Evaporation becomes mass and heat transfer limited. The presence of water vapour will not greatly affect this process. For droplets up to the upper limit of interest, about 100 μm the time scale for evaporation remains short relative to that for precipitation.

As far as concerns the behaviour of the droplets during the initial gravity slumping of the cloud, ammonia-air mixtures with mass ratios greater than 10 will not be significantly depleted of ammonia by precipitation of ammonia droplets. This applies even where the cloud height after slumping is quite low.

The broader aspects of an ammonia release, particularly dispersion, have been treated by Kaiser and Walker (1978), Griffiths and Kaiser (1979 SRD R154) and Kaiser and Griffiths (1982).

15.42.5 Hydrogen fluoride

The gas cloud characteristics for a release of liquefied anhydrous hydrogen fluoride (HF) have been described by Puttock *et al.* (1991). Broadly, releases of liquid HF may give

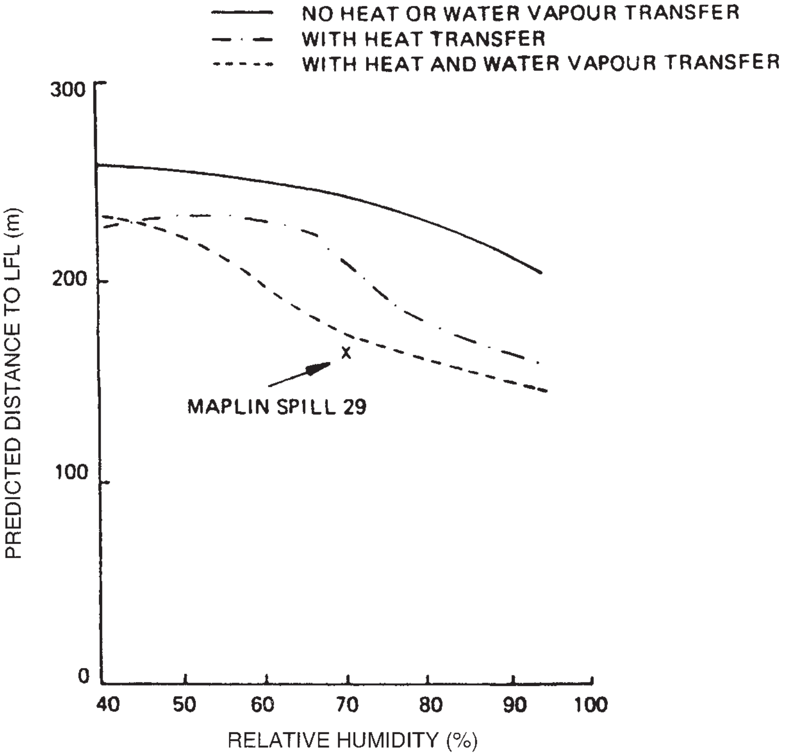

Figure 15.128 *Effect of heat transfer from surface on dense gas dispersion – predictions of HEGADAS for distance to the LFL for the Maplin Sands LNG spill trial 29 under three different assumptions (Puttock, 1987c) (Courtesy of the American Institute of Chemical Engineers)*

rise to gas clouds which are dense or buoyant; a large proportion will be dense. The cloud will tend to be dense if the atmospheric humidity is low and/or the fraction of liquid spray is high. A cloud with little or no liquid spray in air with high humidity may be buoyant.

The molecular weight of HF is 20 (as monomer) and its normal boiling point is 20°C. Dense gas behaviour is therefore attributable to factors other than molecular weight of the monomer.

HF differs from the other gases considered here in that it is subject to self-association and tends to form polymers of the general formula $(HF)_n$. Treatments of this feature in the context of dense gas dispersion have been given by Chikhliwala and Hague (1987), Clough, Grist and Wheatley (1987) and Schotte (1987).

Saturated vapour of HF has an apparent molecular weight of 78.2 at its normal boiling point. At 100°C, HF has a molecular weight of 49.1; at 300°C it is virtually monomolecular. Dilution of the gas cloud with air also results in a decrease in its apparent molecular weight. This associative behaviour, or oligomerization, of HF has been studied by a number of workers and various schemes have been proposed. For example, MacLean *et al.* (1962) give a monomer–dimer–hexamer model, and Beckerdite, Powell and Adams (1968) give a monomer–trimer–hexamer model.

Thus, in order to have a complete description of the behaviour of an HF cloud it is necessary to take account of self-association, atmospheric humidity and liquid fraction.

A model of HF fog formation is that proposed, and revised, by Schotte (1987, 1988). The model treats the self-association of HF and the formation of HF fog, or liquid $HF–H_2O$ droplets.

Another model of HF which takes into account self-association and atmospheric humidity has been described by Clough, Grist and Wheatley (1987); the model is entitled WETAFH. It comprises for self-association the monomer–dimer–hexamer model of MacLean *et al.*, which includes the chemical equilibrium relations, and a model for the equilibrium and thermodynamic relations of the HF–air–water system. The model shows that in moist air an $HF–H_2O$ liquid phase will generally form and that in some cases as much as 50% of the HF will be in this liquid phase. It is assumed that the liquid will be in the form of an aerosol. The density of the aerosol would be low, of the order of 0.05 kg/m^3. Provided the droplet size is not too large (<20 μm), the aerosol would be expected to persist for several hours. The authors give plots of cloud density and temperature vs concentration of HF, with relative humidity of the air as parameter.

A model which yields similar information and which is incorporated in HFSYSTEM has been described by Puttock, MacFarlane, Prothero, Roberts *et al.* (1991). The model is based on that of Schotte. Plots from this model are shown in Figure 15.130. This figure gives relative density and temperature curves with relative humidity as parameter for the mixing of HF and air, both initially at 25°C, thus close to the boiling point of HF. They show that with dry air (RH = 0%) the gas cloud remains dense at all concentrations, whereas with saturated air (RH = 100%) the cloud is slightly buoyant at lower concentrations.

The effect of liquid present as spray is treated in the model given by Chikhliwala and Hague (1987). The authors refer to the method of Haddock and Williams for ammonia, and adopt a somewhat similar approach. They use the self-association model of Beckerdite, Powell and Adams and a model for the equilibrium and thermodynamic relations of the HF vapour-HF liquid system in dry air. Figure 15.131 gives plots of density and temperature vs the air/HF mass ratio with the liquid fraction as the parameter for the mixing of HF and air, the initial temperatures of the HF and of the air being 292.7 and 293 K, respectively.

Figure 15.132 gives the parameters for the condition where the liquid fraction just evaporates: the density D^*, the temperature T^* and the air/HF mass ratio R^*.

15.43 Dispersion of Dense Gas: Plumes from Elevated Sources

The treatment of dense gas dispersion given so far has been largely confined to releases from sources at ground level. It is now necessary to consider elevated releases. A review of work on the dispersion of an elevated plume of dense gas has been given by Ooms and Duijm (1984).

In this and the following section an account is given of some of the principal models for the dispersion of an elevated

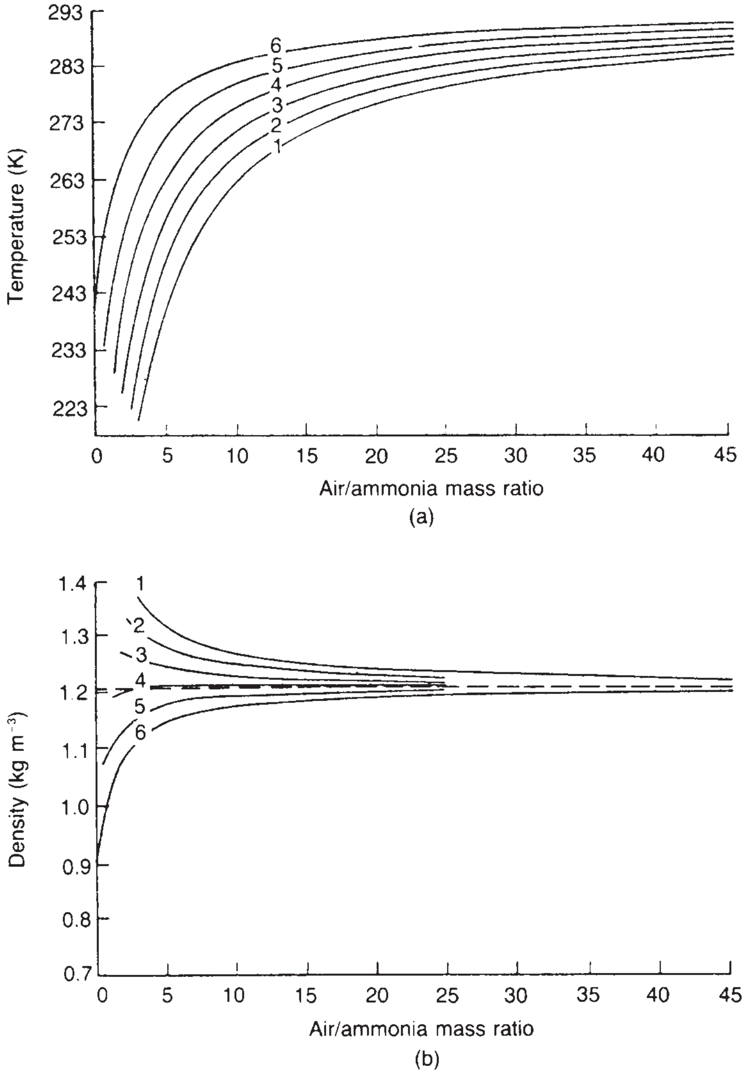

Figure 15.129 *continued*

(1) f = 20%; (2) f = 16%; (3) f = 12%; (4) f = 8%; (5) f = 4%; (6) f = 0, in all three plots (Courtesy of the UKAEA Safety and Reliability Directorate)*

release of a dense gas. A further discussion related to safe dispersion from reliefs and vents is given in Section 15.48.

15.43.1 Experimental work

Experimental work on dispersion of dense gas from an elevated source has been mainly by physical modelling. Bodurtha (1961, 1980, 1988), Hoehne and Luce (1970), Hoot, Meroney and Peterka (1973), Giesbrecht, Seifert and Leuckel (1983), Li Xiao Yun, Leidens and Ooms (1986) and Schatzmann, Snyder and Lawson (1993) used a wind tunnel; Holly and Grace (1972), J.L. Anderson, Parker and Benedict (1973), Chu (1975) and Badr (1984) used a water flume.

Bodurtha (1961) carried out wind tunnel experiments in which a photographic record was taken of a Freon 114–air mixture made visible with oil-fog smoke released from a stack. Measurements taken from the photographs include the maximum initial plume rise, distance to touchdown, velocity of plume descent and plume radius. Figure 15.133 shows the effect of the specific gravity of the gas on the behaviour of the plume.

The wind tunnel work of Hoot, Meroney and Peterka (1973) yielded data on, and correlations of, the maximum initial plume rise, distance to touchdown, and maximum concentrations, including those at maximum rise and at touchdown.

Work in the field has been reviewed by Schatzmann, Snyder and Lawson (1993). The main data sets are those of Bodurtha (1961) and Hoot, Meroney and Peterka (1973). The authors comment that the data of Bodurtha do not lend themselves to generalization and that those of Hoot, Meroney and Peterka are regarded as the most reliable and complete. However, the latter set has certain limitations. The experiments were performed in a laminar crossflow, whereas the real atmosphere is turbulent. The densimetric Froude numbers investigated did not cover the whole range of interest. The data of Bodurtha (1961) and Li Xiao Yun, Leidens and Ooms (1986) are also for laminar crossflow and low-to-medium Froude numbers. The work of Giesbrecht, Seifert and Leuckel (1983) does cover larger Froude numbers, but for quiescent atmospheres. The investigation which the authors report extends to a turbulent atmosphere and to higher Froude numbers.

Schatzmann, Snyder and Lawson found that a dense gas jet released into a turbulent atmosphere tended, by comparison with one released into a laminar atmosphere, to have a reduced rise height and an increased touchdown distance with lower concentrations both at the point of maximum rise and at touchdown.

The concentration of interest for a toxic release is generally much lower than that for a flammable release. The relative effect of atmospheric turbulence increases with distance from the release point. The authors suggest that, whereas it may not be overly conservative to neglect this factor for concentrations of interest in respect of their flammability, it appears essential to take it into account if a realistic estimate is to be obtained for toxic concentrations.

15.43.2 Ooms model

A model for dispersion of a dense gas plume from an elevated source which has been widely used is that described by Ooms (1972) and Ooms, Mahieu and Zelis (1974). Whereas previous models were based on the assumptions that the gas is of neutral density and that the plume velocity is equal to the wind speed, the Ooms model does not rely on these assumptions but gives a more realistic description of entrainment into and drag on the plume.

The model consists of a set of equations for conservation of mass, momentum and energy and for air entrainment of the general form

$$\frac{d}{ds}\int_0^{\sqrt{2}.b} \phi_i(r) 2\pi r \, dr = \psi_i \qquad [15.43.1]$$

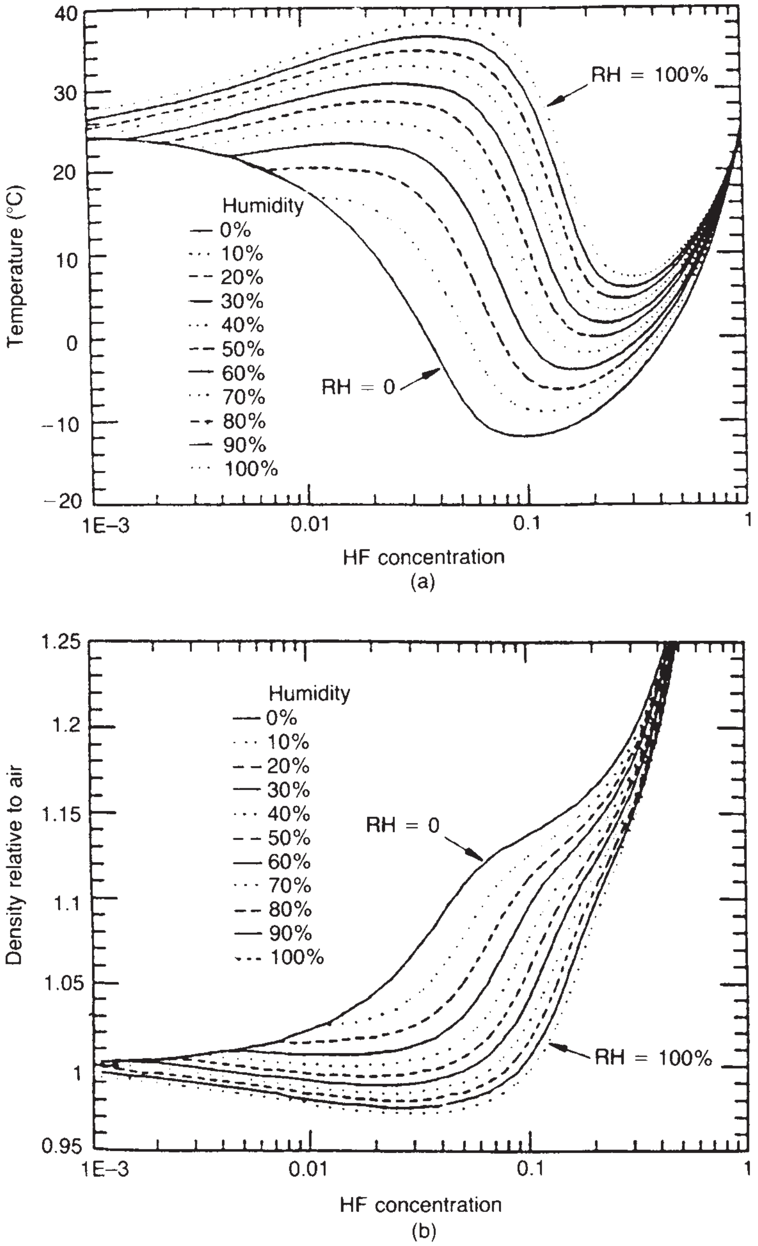

Figure 15.130 *Temperature and density of a hydrogen fluoride–air mixture formed by release of hydrogen fluoride into the atmosphere (Puttock, MacFarlane, Prothero, Roberts et al., 1991): (a) temperature for release into air of varying humidity; and (b) density for release into air of varying humidity (Courtesy of the American Institute of Chemical Engineers)*

where b is a characteristic width of the plume, r is the radius of the plume, s is the distance along the axis of the plume, π_i is a set of functions and ψ_i is a further set of functions.

The functions ϕ_i is given by the following relations for conservation of total mass, mass of contaminant, momentum in the horizontal direction, momentum in the vertical direction and energy, respectively:

$$\phi_i(r) = \rho u \qquad [15.43.2a]$$

$$= cu \qquad [15.43.2b]$$

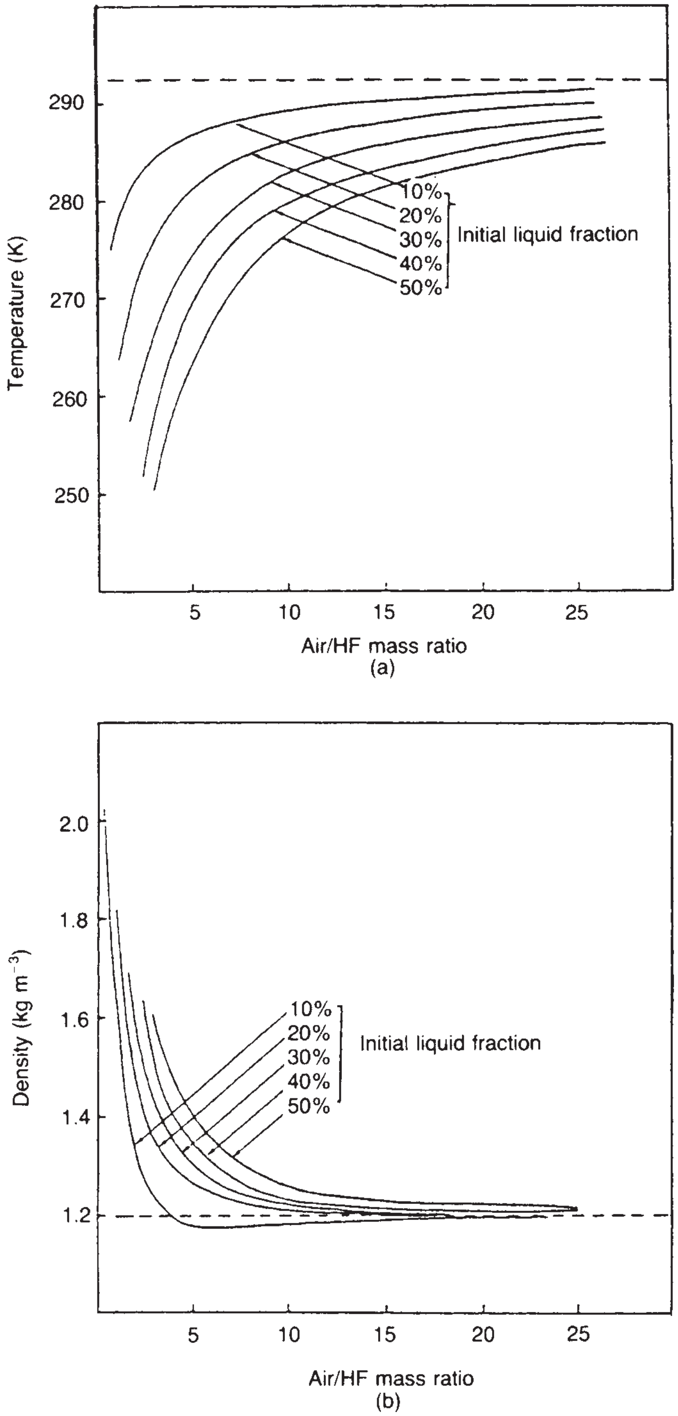

Figure 15.131 *Temperature and density of a hydrogen fluoride–air mixture formed by release of hydrogen fluoride into the atmosphere – 1 (Chikhliwala and Hague, 1987): (a) temperature for release with different liquid fractions; (b) density for release with different liquid fractions (Courtesy of the American Institute of Chemical Engineers)*

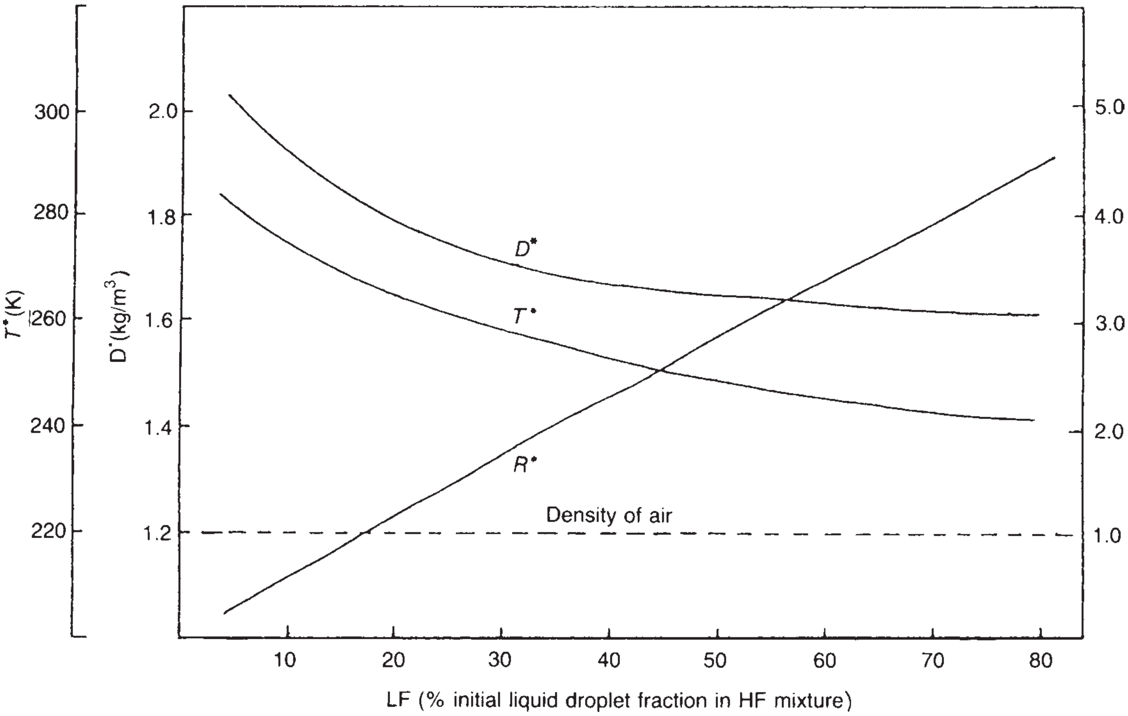

Figure 15.132 *Temperature and density of a hydrogen fluoride–air mixture formed by release of hydrogen fluoride into the atmosphere – 2 (Chikhliwala and Hague, 1987): parameters for condition where liquid fraction (LF) just evaporates. D* density; T, temperature and Ft*, air/HF mass ratio (Courtesy of the American Institute of Chemical Engineers)*

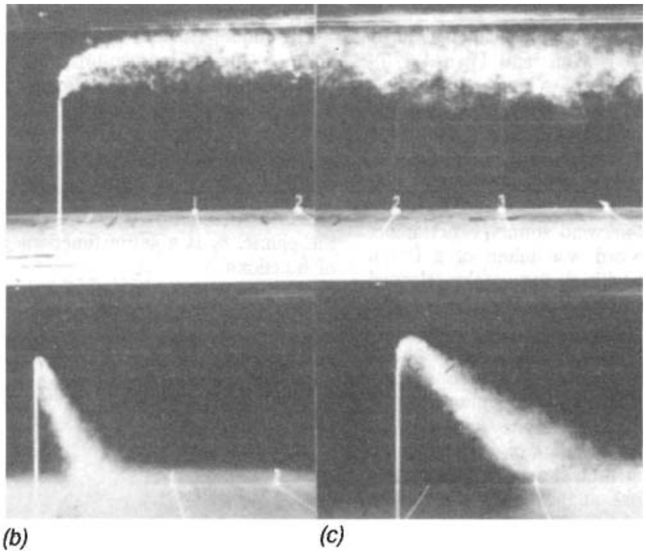

Figure 15.133 *Dispersion of dense gas from an elevated relief: wind tunnel tests (Bodurtha, 1961): Full scale conditions: stack diameter 610 mm, stack height 30.5 m, wind velocity 1.34 m/s, gas exit velocity 6.1 m/s: (a) gas specific gravity 1 (air); (b) gas specific gravity 5.15 and (c) gas specific gravity 1.52 (Courtesy of the Air Pollution Control Association)*

$$= \rho u^2 \cos\theta \qquad [15.43.2c]$$

$$= \rho u^2 \sin\theta \qquad [15.43.2d]$$

$$= \rho u\left(\frac{1}{\rho} - \frac{1}{\rho_{\mathrm{ao}}}\right) \qquad [15.43.2e]$$

where c is the concentration of the contaminant, u is the velocity along the axis of the plume, θ is the angle between the plume axis and the horizontal, ρ is the density of the plume and ρ_{ao} is the density of the atmosphere at the stack outlet.

The functions ψ_i are functions primarily of velocity and density.

For example, the relation used for the conservation of mass draws on the work of Albertson *et al.* (1950) and Abraham (n.d.) for entrainment into a turbulent jet and of Abraham (1970) for entrainment into a plume and is

$$\frac{\mathrm{d}}{\mathrm{d}s}\int_0^{\sqrt{2}.b} \rho u 2\pi r\,\mathrm{d}r = 2\pi b \rho_{\mathrm{a}}[\alpha_1 |u_*(s)| + \alpha_2 U_{\mathrm{a}} |\sin\theta| \cos\theta + \alpha_3 u'] \qquad [15.43.3]$$

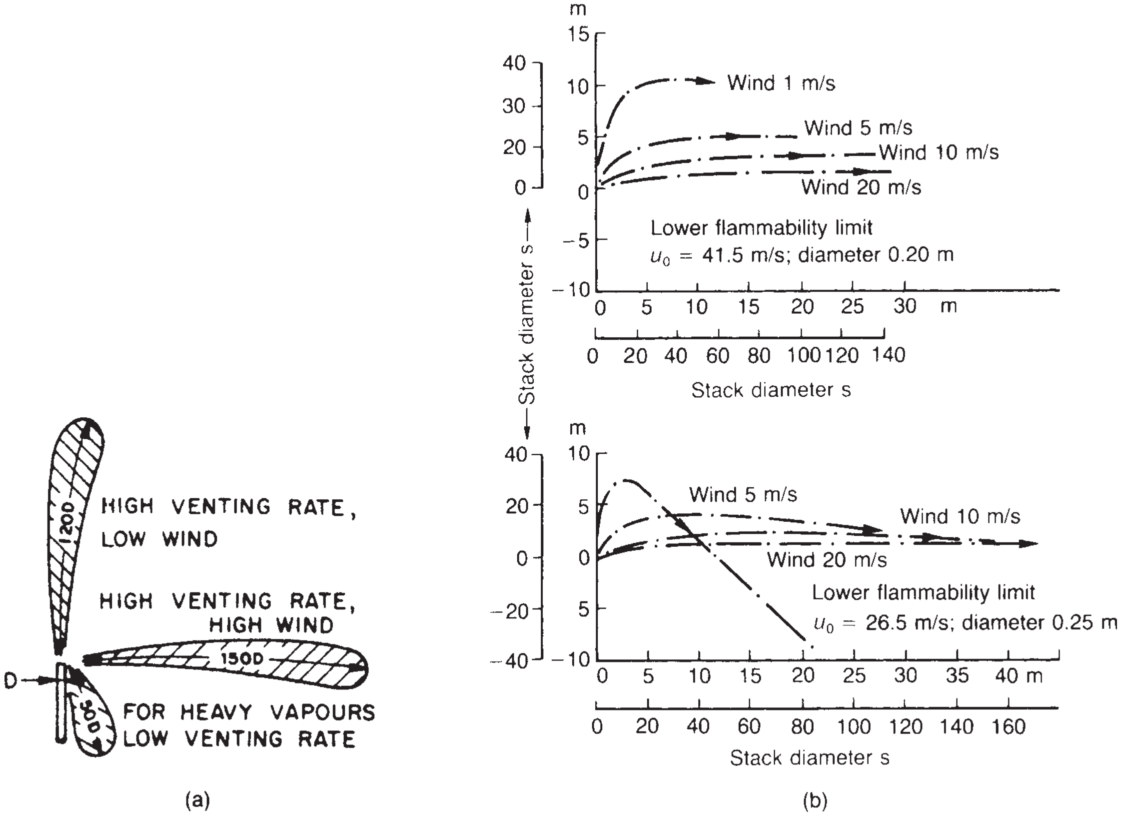
where u' is the entrainment velocity due to atmospheric turbulence, U_{a} is the mean wind velocity, ρ_{a} is the density of the air and α_1, α_2 and α_3 are the entrainment coefficients for a free jet, a line thermal and due to turbulence, respectively. The values taken for the constants α_1, α_2 and α_3 are 0.057, 0.5 and 1.0, respectively. The set of equations represented by Equation 15.43.1 is integrated with respect to 5 numerically.

The model has been compared with various sets of experimental results and gives good agreement for the position of the plume axis. The Ooms model has been encoded for the US Coast Guard in the computer code ONDEK. For determination of the distances within which vented hydrocarbon releases may be assumed for design purposes to have fallen below the lower flammability limit, Ooms, Mahieu and Zelis give the relations shown in Figure 15.134(a).

They also give the illustrative example shown in Figure 15.134(b) for the discharge of butane from two different sized vents, one giving an exit velocity of 26.5 m/s and the other one of 41.5 m/s. For this heavy gas the lower outlet velocity leads to a much more rapid descent to ground level than does the higher velocity.

15.43.3 Hoot, Meroney and Peterka model

Another model is that given by Hoot, Meroney and Peterka (1973) (HMP model). This model too has found widespread



(a) (b)

Figure 15.134 *Dispersion of dense gas from an elevated relief: (a) approximate distances for dispersion of hydrocarbons; (b) dispersion of butane vapour (Ooms, Mahieu and Zelis, 1974) (Courtesy of Elsevier Science Publishers)* use. The basic equations of the model are those of conservation of mass, of horizontal and vertical momentum and of entrainment, and are as follows:

$$\frac{\mathrm{d}(R^2\rho_\mathrm{o}u_\mathrm{s})}{\mathrm{d}s} = \rho_\mathrm{a}\frac{\mathrm{d}(R^2u_\mathrm{s})}{\mathrm{d}s} \qquad [15.43.4]$$

$$\frac{\mathrm{d}(R^2\rho_\mathrm{o}u_\mathrm{s}^2\cos\theta)}{\mathrm{d}s} = \rho_\mathrm{a}u\frac{\mathrm{d}(R^2u_\mathrm{s})}{\mathrm{d}s} \qquad [15.43.5]$$

$$\frac{\mathrm{d}(R^2\rho_\mathrm{o}u_\mathrm{s}^2\sin\theta)}{\mathrm{d}s} = (\rho_\mathrm{a}-\rho_\mathrm{o})R^2g \qquad [15.43.6]$$

$$\frac{\mathrm{d}(R^2u_\mathrm{s})}{\mathrm{d}s} = \alpha_1R|u_\mathrm{s}-u\cos\theta| + \alpha_2Ru|\sin\theta| \qquad [15.43.7]$$

where R is radius of the plume, s is the distance along the plume axis, u_s is the velocity along the plume axis, θ is the angle of the plume axis to the horizontal, ρ is the density of the plume, ρ_a is the density of the air, ρ_o is the density of the outlet gas and α_1 and α_2 are the entrainment coefficients. Values of α_1 and α_2 from wind tunnel work are 0.09 and 0.9, respectively.

The authors divide the plume path into three regions and solve the model Equations 15.43.4–15.43.7 analytically in each region. The HMP model is then as follows. For the initial plume rise

$$\frac{\Delta h}{2R_\mathrm{o}} = 1.32\left(\frac{w_\mathrm{o}}{u}\right)^{1/3}\left(\frac{\rho_\mathrm{o}}{\rho_\mathrm{a}}\right)^{1/3}\left[\frac{w_\mathrm{o}^2}{2R_\mathrm{o}g(\rho_\mathrm{o}-\rho_\mathrm{a})/\rho_\mathrm{o}}\right]^{1/3} \qquad [15.43.8]$$

for the touchdown distance

$$\frac{x_\mathrm{td}}{2R_\mathrm{o}} = \left[\frac{w_\mathrm{o}u}{2R_\mathrm{o}g(\rho_\mathrm{o}-\rho_\mathrm{a})/\rho_\mathrm{o}}\right] + 0.56\left\{\left(\frac{\Delta h}{2R_\mathrm{o}}\right)^3\left[\left(\frac{2+h_\mathrm{s}}{\Delta h}\right)^3 - 1\right]\right\}^{1/2} \times \left\{u^3/[2R_\mathrm{o}w_\mathrm{o}(\rho_\mathrm{o}-\rho_\mathrm{a})/\rho_\mathrm{a}]\right\}^{1/2} \qquad [15.43.9]$$

and for the maximum concentration on the plume axis

$$\frac{C}{C_\mathrm{o}} = 2.43\left(\frac{w_\mathrm{o}}{u}\right)\left(\frac{h_\mathrm{s}+2\Delta h}{2R_\mathrm{o}}\right)^{-1.95} \qquad [15.43.10]$$

where C is the concentration, h_s is the height of the stack, Δh is the maximum initial plume rise, u is the wind speed, w is the velocity of the plume, x is the downwind distance, ρ is the density of the plume and subscripts a, m, o and td denote air, maximum, initial and touchdown, respectively.

The HMP model is one of the models given in the CCPS *Vapor Cloud Dispersion Model Guidelines* and is selected for use in the associated *Workbook*. As an illustration, consider the following example given in the *Workbook*. Butane is released from a stack internal diameter 0.75 m and height 5 m such that $h_\mathrm{s} = 5$ m, $R_\mathrm{o} = 0.375$ m, $u = 5$ m/s, $w_\mathrm{o} = 12.7$ m/s, $\rho_\mathrm{a} = 1.16$ kg/m^3 and $\rho_\mathrm{o} = 2.67$ kg/m^3. The resultant values of the initial plume rise, the touchdown distance and the concentration ratio at the touchdown distance are, respectively, $\Delta h = 6$ m, $x_\mathrm{td} = 57$ m and $C/C_{\hat{\mathrm{o}}} = 0.014$.

15.43.4 Jagger and Edmondson model

An alternative approach to the modelling of a heavy gas plume is that of Jagger and Edmondson (1984), who have developed from the basic conservation equations a set of asymptotic solutions. The model utilizes the following length scales

$$t_\mathrm{Q} = \frac{Q}{M^{1/2}} \qquad [15.43.11]$$

$$l_\mathrm{m} = \frac{M^{3/4}}{B^{1/2}} \qquad [15.43.12]$$

$$z_\mathrm{m} = \frac{M^{1/2}}{U} \qquad [15.43.13]$$

$$z_\mathrm{B} = \frac{B}{U^3} \qquad [15.43.14]$$

with

$$M = Qu_\mathrm{o} \qquad [15.43.15]$$

$$B = Qg' \qquad [15.43.16]$$

$$g' = \frac{\rho-\rho_\mathrm{a}}{\rho_\mathrm{a}}g \qquad [15.43.17]$$

where B is the initial buoyancy flux (m^4/s^3), g is the acceleration due to gravity (m/s^2), g' is the reduced gravity (m/s^2), M is the initial momentum flux (m^4/s^2), Q is the initial volumetric flow (m^3/s), u_o is the outlet velocity (m/s) and U is the wind speed (m/s).

The length l_Q is a function of the source and only influences flow near the source. l_m indicates the point of transition from momentum to buoyancy control. z_m and z_B indicate the influence of crossflow. For large values of z_m and z_B the jet is essentially vertical, while for small values it is bent over.

The method allows the calculation of the trajectory of the vertical co-ordinate z_s of the jet or plume axis and, in particular, of heights for the jet–plume transition and for the virtual source of the resultant effective plume.

For a vertical jet the relations given include:

$$\frac{\mathrm{d}z_\mathrm{s}}{\mathrm{d}x} = \frac{w_\mathrm{cl}}{u} \qquad [15.43.18]$$

$$\frac{w_\mathrm{cl}}{u} \approx \frac{z_\mathrm{m}}{z_\mathrm{s}} \qquad [15.43.19]$$

where *x, y* and *z* are the distances in the downwind, crosswind and vertical directions (m), *u, v* and *w* are the components of the release velocity in the *x, y* and *z* directions (m), z_s is the coordinate of the jet axis (m) and the subscript cl denotes the centre line.

Then from Equations 15.43.18 and 15.43.19 the authors derive the following relation for the vertical coordinate of the axis:

$$\frac{z_\mathrm{s}}{z_\mathrm{m}} = A_1\left(\frac{x}{z_\mathrm{m}}\right)^{1/2} \qquad [15.43.20]$$

where A_1 is a constant. The value given for the constant A_1 is 2.0.

For the gas density the authors give

$$\theta = C_1 \frac{UBz_m}{Mgz_s} \qquad [15.43.21]$$

with

$$\theta = \frac{\rho_a - \rho}{\rho_o} \qquad [15.43.22]$$

where θ is a relative density difference, ρ is the density, C_1 is a constant and subscripts a and o denote atmosphere and initial gas, respectively. The value given for the constant C_1 is 2.4. The complete set of asymptotic formulae, and the corresponding values of the constants, given by Jagger and Edmondson are shown in Table 15.54.

The model is completed by the following additional relations. The maximum rise of the plume with weak crossflow is:

$$z_{max} = A_5 \frac{M^{3/4}}{B^{1/2}} \quad \frac{M^{1/2}}{B} U \ll 1 \qquad [15.43.23]$$

and in strong crossflow conditions

$$z_{max} = A_6 \left(\frac{M^2}{BU}\right)^{1/3} \quad \frac{M^{1/2}}{B} U \gg 1 \qquad [15.43.24]$$

where z_{max} is the maximum rise and A_5 and A_6 are constants. The value given for constants A_5 ands A_6 is about 2.0 for each.

It is convenient from this point for the purposes of exposition to introduce several quantities additional to those given in the original paper and to use a modified notation.

The distance of the virtual source of the jet below the stack outlet is given by

$$z_{vs} = \frac{d_o}{2\alpha} \qquad [15.43.25]$$

where d_o is the diameter of the stack outlet (m), z_{vs} is the distance of the jet virtual source below the stack outlet (m) and α is an entrainment coefficient. The value given for α is 0.15.

The model also utilizes a second virtual source, that of the plume falling to earth. Use is made of two sets of coordinates. The first set is the horizontal and vertical coordinates (x_{je}, z_{je}) of the jet end point. The second set is the horizontal and vertical coordinates (x_{veff}, z_{veff}) of the plume virtual source. The second set of coordinates is obtained from the first by applying the distance corrections (Δx_v, Δz_v). The following equations apply:

$$z_{je} = h_s - z_{vs} + z_{max} \qquad [15.43.26a]$$

$$x_{veff} = x_{je} + x_v \qquad [15.43.26b]$$

$$z_{veff} = z_{je} + z_v \qquad [15.43.26c]$$

$$x_{td} = \phi x'_{td} + x_{veff} \qquad [15.43.27]$$

$$c = f(\theta) \qquad [15.43.28]$$

where c is the concentration of the plume at touchdown (v/v), h_s is the height of the stack (m), x_{je} is the horizontal coordinate of the jet end point (m), x_{td} is the horizontal distance from the base of the stack at which touchdown occurs, or the touchdown distance (m), x'_{td} is an uncorrected touchdown distance (m), Δx_v, is the horizontal distance between the jet end point and the plume virtual source (m), x_{veff} is the horizontal coordinate of the plume virtual source (m), z_{je} is the vertical coordinate of the jet end point (m), Δz_v is the vertical distance between the jet end point and the plume virtual source (m), z_{veff} is the vertical coordinate of the plume virtual source (m) and ϕ is a correction factor. The coordinates (x_{je}, x_{veff}, z_{je}, z_{veff} are measured from the base of the stack. x_{veff} may assume a negative value.

The correction factor ϕ is introduced to allow for the fact that the prior calculation applies to the centre line of the plume, whereas the touchdown distance at which a significant concentration occurs is that of the edge of the plume nearest the base of the stack. An empirical value of 0.85 is assigned to ϕ.

The application of the model to the case where there is wind is to determine by repeated use of the asymptotic formulae given in Table 15.54 first the coordinates of the jet end point, then those of the plume virtual source and finally the touchdown distance and concentration. The procedure is illustrated in the example given below.

Table 15.54 *Formulae and constants for asymptotic plume model (after Jagger and Edmondson, 1984) (Courtesy of the Institution of Chemical Engineers)*

A Formulae

Flow type	*Range of validity*	*(A)* w_{cl}	*(B)* z_s/z_m	*(C)* z_s/z_B	*(D)* $Mg\theta/UB$
Vertical jet	$z_s \ll z_m$	$\approx z_m/z_s$	$A_1(x/z_m)^{1/2}$		$C_1(z_m/z_s)^2$
Bent-over jet	$z_s \gg z_m$	$\approx (z_m/z_s)^2$	$A_2(x/z_m)^{1/3}$		$C_2(z_m/z_s)^2$
Vertical plume	$z_s \ll z_B$	$\approx (z_B/z_s)^{1/3}$	–	$A_3(x/z_B)^{3/4}$	$C_3(z_B/z_s)^{5/3}(z_m/z_B)^2$
Bent-over plume	$z_s \gg z_B$	$\approx (z_B/z_s)^{1/2}$	–	$A_4(x/z_B)^{2/3}$	$C_3(z_B/z_s)^2(z_m/z_B)^2$

B Constants

A_1	A_2	A_3	A_4	C_i	C_2	C_3	C_4
2.0	2.0	1.6	2.0	2.4	2.4	2.4	3.1

There is a separate treatment for calm conditions, or zero wind. For this case the method is to determine first the maximum rise of the plume. The plume is then envisioned as falling from this point to earth so that the plume fall distance is

$$z_{\mathrm{pf}} = h_{\mathrm{s}} - z_{\mathrm{vs}} - z_{\max} \qquad [15.43.29]$$

where z_{pf} is the plume fall distance (m). The falling plume has a radius b and downward velocity w given by

$$b = \frac{6\alpha z}{5} \qquad [15.43.30]$$

$$w = \frac{5}{6\alpha}\left(\frac{9\alpha B}{10\pi}\right)^{1/3} z^{-1/3} \qquad [15.43.31]$$

and covers an area A_{pgr} and has a volumetric flow V_{pgr}, which are

$$A_{\mathrm{pgr}} = \frac{\pi}{4} b^2 \qquad [15.43.32a]$$

$$V_{\mathrm{pgr}} = w A_{\mathrm{pgr}} \qquad [15.43.32b]$$

where A_{pgr} is the ground area centring on the base of the stack covered by the falling plume (m^2), b is the radius of the plume (m), V_{pgr} is the volumetric flow of the plume at ground level (m^3/s) and w is the vertical downwards velocity of the plume (m/s). The concentration is then obtained from

$$c = Q/V_{\mathrm{pgr}} \qquad [15.43.33]$$

The application of the model where there is a wind is as follows. The fluxes M and B, the wind speed U and the length scales l_{m}, l_{Q}, z_{B} and z_{m} are determined. The maximum height of the plume $z_{\max}$ is then obtained from Equation 15.43.24. The distance z_{vs} of the jet virtual source below the outlet is calculated from Equation 15.43.25.

The procedure involves first the determination of coordinates (x_{je}, z_{je}). The coordinate z_{je} is obtained from Equation 15.43.26a and the coordinate x_{je} from the relation given in Table 15.54 for a bent-over jet $z_{\mathrm{s}}/z_{\mathrm{m}} = A_2(x/z_{\mathrm{m}})^{1/3}$, setting $z_{\mathrm{s}} = z_{\max}$ and $x = x_{\mathrm{je}}$. Next, an estimate is made of the distances (Δx_{v}, Δz_{v}). The first step is to obtain from the relation given in Table 15.54 for a bent-over jet the group $Mg\theta/UB = (z_{\mathrm{m}}/z_{\mathrm{s}})^2$, setting $z_{\mathrm{s}} = z_{\max}$. Then the distance Δz_{v} is determined from the relation in Table 15.54 for a bent-over jet $Mg\theta/UB = C_4(z_{\mathrm{B}}/z_{\mathrm{s}})^2(z_{\mathrm{m}}/z_{\mathrm{B}})^2$, setting $z_{\mathrm{s}} = \Delta z_{\mathrm{v}}$. The distance Δx_{v} is calculated from the relation in Table 15.54 for a bent-over plume $z_{\mathrm{s}}/z_{\mathrm{B}} = A_4(x/z_{\mathrm{B}})^{2/3}$ setting $z_{\mathrm{s}} = \Delta z_{\mathrm{v}}$ and $x = \Delta x_{\mathrm{v}}$. The coordinates ($x_{\mathrm{veff}}$, z_{veff}) are then obtained from Equations 15.43.26b and 15.43.26c.

For the touchdown conditions, the uncorrected touchdown distance x'_{td} is obtained from the relation in Table 15.54 for a bent-over plume $z_{\mathrm{s}}/z_{\mathrm{B}} = A_4(x/z_{\mathrm{B}})^{2/3}$, setting $z_{\mathrm{s}} = z_{\mathrm{veff}}$ and $x = x'_{\mathrm{td}}$. The corrected touchdown distance x_{td} is then calculated from Equation 15.43.27. The touchdown concentration is obtained from the relation in Table 15.54 for a bent-over plume $Mg\theta/UB = C_4(z_{\mathrm{B}}/z_{\mathrm{s}})^2(z_{\mathrm{m}}/z_{\mathrm{B}})^2$, setting $z_{\mathrm{s}} = \mathrm{veff}$, which gives the relative density difference θ. For low concentrations the relation between the relative density difference θ and the volumetric concentration c is $c \approx [\theta(\rho_{\mathrm{o}} - \rho_{\mathrm{a}})\rho_{\mathrm{a}}]$.

For the case of calm conditions the model is applied as follows. The maximum rise of the plume $z_{\max}$ is obtained from Equation 15.43.23 and the plume fall distance from Equation 15.43.29. The touchdown radius b, velocity w, ground area A_{pgr}, volumetric flow V_{pgr} and concentration c are then determined from Equations 15.32.30–15.43.33.

Jagger and Edmondson give a set of illustrative examples of their method, in which they determine the touchdown distances and concentrations for a release of butane from an elevated pressure relief valve. The base conditions are

Height of vent $h_{\mathrm{s}} = 30\,\mathrm{m}$
Diameter of outlet $d_{\mathrm{o}} = 0.2\,\mathrm{m}$
Mass flow of butane $= 7.1\,\mathrm{kg/s}$
Density of butane $= 2.54\,\mathrm{kg/m}^3$

Hence

Volumetric flow of butane $Q = 2.8\,\mathrm{m}^3/\mathrm{s}$
Initial momentum flux $M = 255.6\,\mathrm{m}^4/s^2$
Initial buoyancy flux $B = 27.8\,\mathrm{m}^4/s^3$
Distance below outlet of jet virtual source $z_{\mathrm{vs}} = 0.7\,\mathrm{m}$

Cases considered are calm conditions and wind speeds of 2 and 4 m/s. For these cases:

	Wind speed (m/s)		
	0	2	4
l_{Q}	0.18	0.18	0.18
l_{B}	12.1	12.1	12.1
z_{m}		8.0	4.0
z_{B}		3.5	0.4

For the case of a wind speed of 2 m/s, the method described yields

$z_{\max} = 20.6\,\mathrm{m}$
$x_{\mathrm{je}} = 17.1\,\mathrm{m}$; $z_{\mathrm{je}} = 49.9\,\mathrm{m}$
$Mg\theta/UB = 0.36$
$\Delta x_{\mathrm{v}} = 21.5\,\mathrm{m}$; $\Delta z_{\mathrm{v}} = 23.5\,\mathrm{m}$
$x_{\mathrm{veff}} = -4.4\,\mathrm{m}$; $z_{\mathrm{veff}} = 73.4\,\mathrm{m}$
$x_{\mathrm{td}} = 118.8\,\mathrm{m}$; $x_{\mathrm{td}} = 96.6\,\mathrm{m}$
$\theta = 8.2 \times 10^{-4}$
$c(\approx 2\theta) = 0.00164\mathrm{v/v} = 0.164\%\,\mathrm{v/v}$

For the case of calm conditions

$z_{\max} = 24.4\,\mathrm{m}$
$z_{\mathrm{pf}} = 53.7\,\mathrm{m}$
$b = 9.7\,\mathrm{m}$; $A_{\mathrm{pgr}} = 296\,\mathrm{m}^2$
$w = 1.56\,\mathrm{m/s}$; $V = 462\,\mathrm{m}^3/\mathrm{s}$
$c = 0.0061\,\mathrm{v/v} = 0.061\%\,\mathrm{v/v}$

The touchdown conditions obtained for all three cases are:

	Wind speed (m/s)		
	0	2	4
Touchdown distance (from stack base) (m)	0	96.6	239
Touchdown concentration (v/v)	0.0061	0.0016	0.0011

(These values differ from those given in the original paper but have been checked with one of the authors (S.F.J.)).

15.43.5 Emerson models

Another model is that given by Emerson (1986a). The model is a modification of the Ooms model already described. The Emerson model differs from the Ooms model in several ways. One is that, whereas in the Ooms model the vertical component of the axial velocity tends to a constant value, in the Emerson model it is multiplied by the Gaussian term and therefore tends to zero. This obviates the need for the use of 2½*b* as the limit of integration. Another difference is in the selection of a more appropriate mass flow. This avoids problems with situations where the jet emission is in the upwind direction. The Emerson model is the basis of the computer code TECJET (Technica, 1987).

Emerson (1986b, 1989) has also given a further, separate model for a jet of dense gas undergoing transition to, and then dispersing as, a dense gas cloud. As already described, models for dense gas dispersion are sensitive to the source term used. It is the object of this model to provide an improved source term where the release occurs due to a jet, which is the usual situation.

The dispersion of the gas is assumed to occur in three phases, as shown in Figure 15.135. The first phase is a momentum jet, the second phase is a hybrid one in which slumping and transition occur and the third phase is a dense gas cloud. A box model approach is used in which the dimensions of the gas cloud are calculated and concentration within this envelope is assumed to be constant.

For the momentum jet phase Emerson quotes the work of Ricou and Spalding for the entrainment of air with distance along the jet axis and gives for a jet in still conditions the relation

$$Q_a = k_1(\rho_a I_o)^{1/2} \qquad [15.43.34]$$

where I_o is the momentum flux, Q_a is the entrainment flow and k_1 is a constant. The value of the constant k_1 is 0.282. Equation 15.43.34 is equivalent to Equation 15.20.13a of Ricou and Spalding.

Then, for a jet in windy conditions, Emerson assumes that Equation 15.43.34 can be modified to read

$$Q_a = k_1(\rho_a I_o)^{1/2}\,\frac{w - u_o}{v} \qquad [15.43.35]$$

where I_o is now the excess momentum flux, u_w is the wind speed and v is the velocity of the gas in the jet.

The jet is assumed to have a square cross-section. The rate of lateral growth is determined solely by the entrainment of air into the cloud. Transition to the second phase occurs when this rate of spreading falls below that which would occur due to gravitational slumping.

The second, hybrid phase combines features of both the preceding and the succeeding phases. It is assumed that the rate of air entrainment is as in the previous stage, but the rate of lateral spreading is based on dense gas behaviour. The relation used is

$$\frac{\mathrm{d}R}{\mathrm{d}t} = (k_2 g H \rho/\rho)^{1/2} \qquad [15.43.36]$$

where H is the height of the cloud, R is the half-width of the cloud, ρ is the density of the cloud, $\Delta\rho$ is the density difference between the cloud and the air and k_2 is a constant. The value of the constant k_2 is approximately unity. The height of the cloud in this second phase is obtained from the mass of air entrained in the jet and the resulting necessary cross-section.

In the third phase the dispersion is that of a dense gas cloud. This is described using the model of R.A. Cox and Carpenter (1980).

15.43.6 Woodward model

J.L. Woodward (1989a) has given a model for a release from an elevated source of a two-phase flashing fluid of pressurized liquefied gas, forming a jet of vapour and liquid droplets. The model is derived from that of Ooms, Mahieu and Zelis. The model is the basis of the computer code EJET.

15.43.7 Other models

There are several other models for dispersion of an elevated release of a dense gas. The Environmental Protection Agency (EPA) (1989a) has developed a relief valve screening model. Other models include those by Giesbrecht, Seifert and Leuckel (1983) and Havens and Spicer (1985).

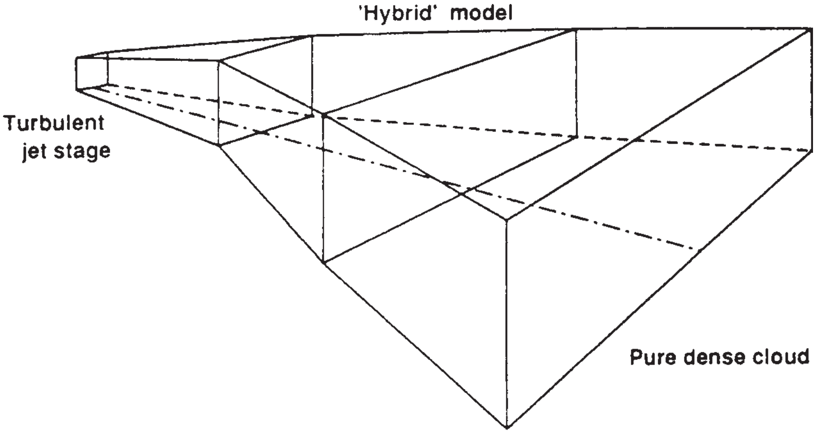


Figure 15.135 *Emerson model for dispersion of dense gas from elevated jets and plumes – idealized cloud shape (Emerson, 1986a) (Courtesy of the Clarendon Press)*

15.43.8 Criterion for dense gas dispersion

A criterion for deciding whether a dense gas treatment is necessary has been given by Fay and Zemba (1986) as follows:

$$\mathrm{Ri_o} \gg 1$$

with

$$\mathrm{Ri_o} = \frac{w_o D_o}{(u_*^3)} g = \frac{\rho_o - \rho_a}{\rho_a} \qquad [15.43.37]$$

where D is the diameter, w is the velocity of the plume, ρ is the density of the plume and the subscripts a and o denote air and initial, respectively. This criterion is adopted in the CCPS *Vapor Cloud Dispersion Model Guidelines*.

15.44 Dispersion of Dense Gas: Plumes from Elevated Sources – PLUME

A model for dispersion from a jet or plume has been developed by Shell as part of the HGSYSTEM package. This model, PLUME, is one of the front-end models for the main dispersion model, HEGADAS. It has been described by McFarlane (1991). PLUME is a generalization of a more specific model HFPLUME developed for the dispersion of hydrogen fluoride.

15.44.1 Plume development

The scenario modelled is that of a jet or plume issuing along the direction of the wind at an inclination to the horizontal. The plume is treated as passing through three stages:

(1) airborne plume;
(2) touchdown plume;
(3) slumping plume.

The plume geometry, coordinate system and control volume are shown in Figure 15.136.

The cross-section of the airborne plume is assumed to be circular. The touchdown regime starts when the circumference of the airborne plume touches the ground and it ends when the cross-section of the plume has become semi-circular. The slumping regime then begins and the cross-section becomes elliptical.

The coordinate system used is as follows. For the airborne plume the angle of inclination of the axis is ϕ, and the distance along the axis s and a point on the cross-section of that plume is given by the polar coordinates r and θ. For the plume in all regimes the centroid of the plume is located at distances x and z from the sources in the horizontal, vertical directions. For the touchdown and slumped plumes the height of the centre of the plume is z_c.

The core of the model is a complex set of integral equations which are then simplified to the sets of equations for the three regimes given below.

15.44.2 Airborne plume

The model for the airborne plume consists of the following set of six differential equations:

$$\frac{d\dot{m}}{ds} = \mathrm{Entr} \qquad [15.44.1]$$

$$\frac{d\dot{P}_x}{ds} = \mathbf{Drag} \cdot \mathbf{e}_x + \mathrm{Shear} \qquad [15.44.2]$$

$$\frac{d\dot{P}_z}{ds} = \mathbf{Drag} \cdot \mathbf{e}_z + \mathrm{Buoy} \qquad [15.44.3]$$

$$\frac{d\dot{E}_x}{ds} = \mathrm{Ener} \qquad [15.44.4]$$

$$\frac{dx}{ds} = \cos\phi \qquad [15.44.5]$$

$$\frac{dz}{ds} = \sin\phi \qquad [15.44.6]$$

where $\mathbf{e}_x$ is a unit vector in the horizontal, wind aligned direction, $\mathbf{e}_z$ is a unit vector in the vertical direction, $\dot{E}$ is the excess energy flux, $\dot{m}$ is the mass flux, $\dot{P}_x$ is the excess horizontal momentum flux, $\dot{P}_z$ is the excess vertical momentum flux and s is the distance along the axis of the plume.

The term 'Buoy' is the section averaged buoyancy force in the plume; '**Drag**' is the drag force acting on the plume as a result of vortex formation in the plume wake; 'Ener' is the change in energy in the plume resulting from vertical gradients of temperature and wind speed; 'Entr' is the entrainment rate for unit distance along the plume axis; and 'Shear' is the shear force associated with the vertical gradient of wind speed. Supplementary equations used are

$$A = \frac{\pi}{4} D^2 \qquad [15.44.7]$$

$$\dot{m} = A\rho u \qquad [15.44.8]$$

$$\dot{m}_g = Acu \qquad [15.44.9]$$

$$\dot{P}_x = \dot{m}(u\cos\phi - u_\infty) \qquad [15.44.10]$$

$$\dot{P}_z = \dot{m}\, u \sin\phi \qquad [15.44.11]$$

$$\dot{E} = \dot{m}\left[\left(h + \frac{1}{2}u^2\right) - \left(h_\infty + \frac{1}{2}u_\infty^2\right)\right] \qquad [15.44.12]$$

where A is the cross-sectional area of the plume, c is the concentration (mass per unit volume), D is the diameter of the plume, h is the specific enthalpy, ρ is the density, u is the mean flow velocity and subscripts g and ∞ denote material released and ambient conditions at centroid height, respectively.

15.44.3 Touchdown plume

Touchdown occurs when the plume envelope first touches the ground. The plume cross-section is then modelled as a circular segment, the centroid of which falls until the cross-section becomes a semi-circle, at which point the touchdown regime ends.

The model for the touchdown plume also consists of a set of six differential equations. These are Equations 15.44.1, 15.44.2 and 15.44.4–15.44.6 with:

$$\frac{d\dot{P}_z}{ds} = \mathbf{Drag} \cdot \mathbf{e}_z + \mathrm{Buoy} + \mathrm{Foot} \qquad [15.44.13]$$

where 'Foot' is a reactive pressure force function.

Supplementary equations used are Equations 15.44.8–15.44.12 and

$$A = \frac{D^2}{4}\left[\cos^{-1}(-\eta_c)(1 - \eta_c)^{1/2}\right] \qquad [15.44.14]$$

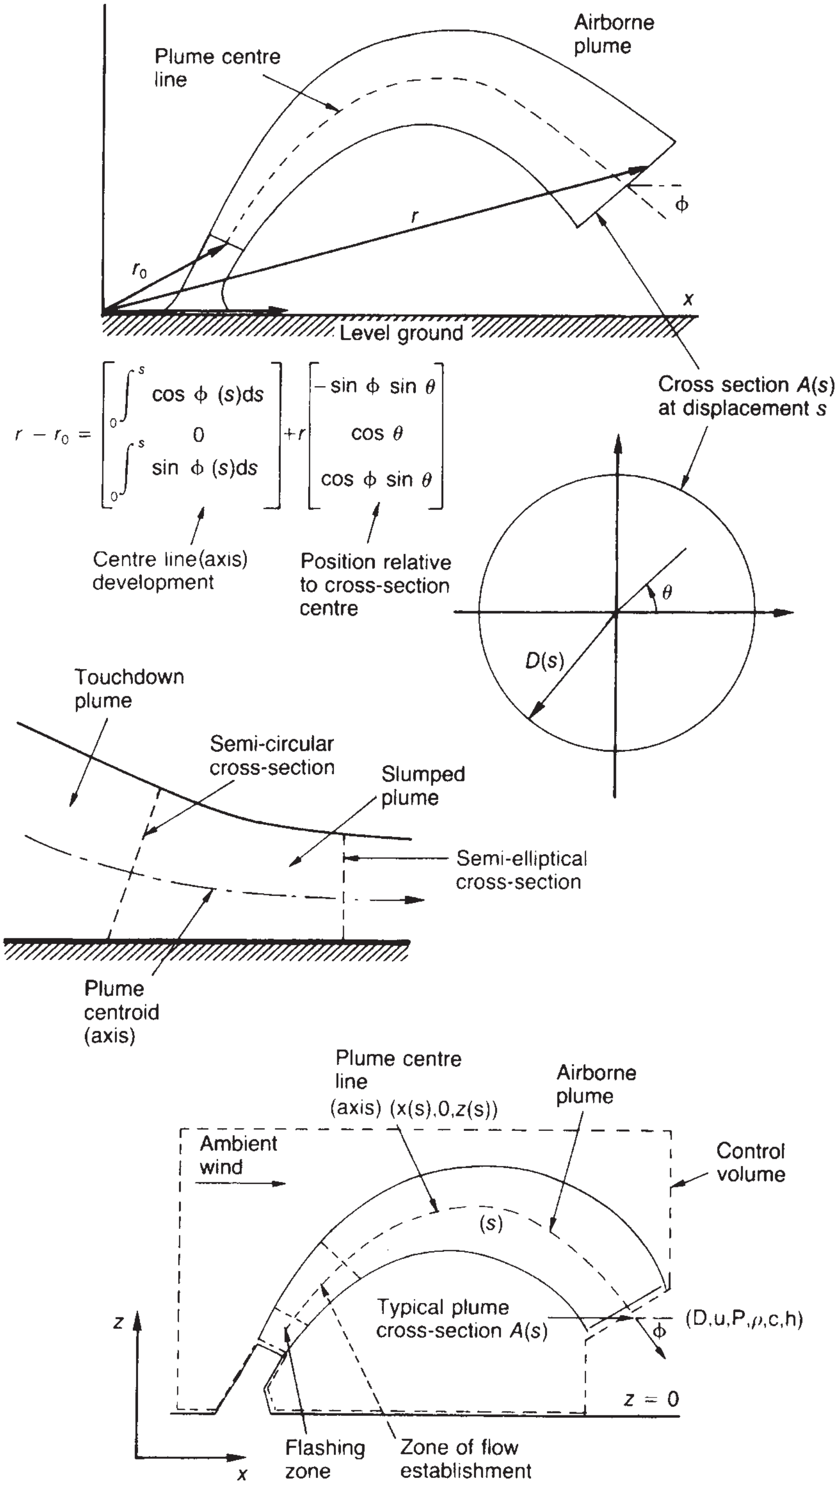

Figure 15.136 *PLUME model for dispersion of dense gas from elevated jets and plumes: plume geometry, coordinate system and control volume (McFarlane, 1991) (Courtesy of the American Institute of Chemical Engineers)*

$$\eta_{\mathrm{c}} = \frac{\eta}{2\left(1 + \left\{1 - 2/\left(3\left[\eta^2(1-\eta^2)(1-\eta^2)^{1/2}\right]\right)\right\}^{1/2}\right.} \qquad [15.44.15]$$

$$\eta = \frac{2z}{D|\cos\phi|} \qquad [15.44.16]$$

$$\eta_{\mathrm{c}} = \frac{2z_{\mathrm{c}}}{D|\cos\phi|} \qquad [15.44.17]$$

where η is a parameter and subscript c denotes centre.

15.44.4 Slumped plume

The model for the slumped plume consists of the same set of six differential equations as for the touchdown plume. Supplementary equations used are Equations 15.44.8–15.44.12 and

$$A = \frac{e\pi}{8}D^2 \qquad [15.44.18]$$

$$e = \frac{3\pi}{2}\frac{(z/D)}{|\cos\phi|} \qquad [15.44.19]$$

where D is the length of the major axis of the ellipse and e is the eccentricity of the ellipse.

15.44.5 Buoyancy, shear and energy functions

For the airborne plume the buoyancy function 'Buoy' is

$$\mathrm{Buoy} = A(\rho - \rho_{\mathrm{g}})g \qquad [15.44.20]$$

This relation is valid, for expansion about the plume centroid, for the touchdown and slumped plume regimes also. The shear function 'Shear' is

$$\mathrm{Shear} = \dot{m}\sin\phi\frac{\mathrm{d}u_\infty}{\mathrm{d}z} \qquad [15.44.21]$$

for all three regimes. The energy function 'Ener' is

$$\mathrm{Ener} = \dot{m}\sin\phi\frac{\mathrm{d}\left(h_\infty + 1/2u_\infty^2 + gz\right)}{\mathrm{d}z} \qquad [15.44.22]$$

15.44.6 Drag and pressure force functions

For the airborne plume the drag is airborne drag, which is not considered significant, and the drag function '**Drag**' is taken as zero. For the touchdown and for the slumped plume there is a ground surface drag, which is significant. For these latter regimes the drag function '**Drag**' is

$$\mathbf{Drag} = l\rho_\infty u_*^2\left[(\rho/\rho_\infty)^{1/2}(u/u_\infty)\cos\phi - 1\right] \times \left[(\rho/\rho_\infty)^{1/2}(u/u_\infty)\cos\phi + 1\right] \qquad [15.44.23]$$

where l is the width of the 'footprint' of the plume and u_* is the friction velocity.

The value of the pressure force function 'Foot' is governed by the behaviour of the gravity current. At some point in the slumping regime the gravity current collapses. Before the point of collapse the spreading rate and the corresponding value of 'Foot' are

$$\frac{1}{2}\frac{\mathrm{d}D}{\mathrm{d}s} = (k/u)[gh(1 - \rho_\infty/\rho)]^{1/2} \qquad [15.44.24]$$

$$\mathrm{Foot} = \left(\frac{3\pi^2}{32}\right)^3\frac{1}{k^2}l\rho u^2\left(\frac{1}{2}\frac{\mathrm{d}D}{\mathrm{d}s}\right)^2 \qquad [15.44.25]$$

where k is the slumping coefficient. The value of k is taken as 1.15.

The criterion of collapse and the spreading rate after collapse are

$$(\rho_\infty/\rho)^{1/2}(D/h) > \frac{16}{3\kappa(\mathrm{Ri}_*)^{1/2}\Phi(\mathrm{Ri}_*)} \qquad [15.44.26]$$

$$\frac{1}{2}\frac{\mathrm{d}D}{\mathrm{d}s} = \frac{\rho_\infty u_* h}{3\kappa C_{\mathrm{D}}uD\mathrm{Ri}_*\Phi(\mathrm{Ri}_*)} \qquad [15.44.27]$$

with

$$\Phi(\mathrm{Ri}_*) = \frac{1}{(1 - 3\mathrm{Ri}_*/5)^{1/2}} \qquad \mathrm{Ri}_* < 0 \qquad [15.44.28a]$$

$$= 1 \qquad 0 \le \mathrm{Ri}_* < 189/80 \qquad [15.44.28b]$$

$$= (10/17)\max\left[\mathrm{Ri}_*/7, (1 + 4\mathrm{Ri}_*/5)^{1/2}\right] \qquad \mathrm{Ri}_* > 189/80 \qquad [15.44.28c]$$

$$\mathrm{Ri}_* = \frac{gh(\rho/\rho_\infty - 1)}{u_*^2} \qquad [15.44.29]$$

where h is the plume height, Ri_* is a bulk Richardson number, κ is the von Karman constant and $\Phi(\mathrm{Ri}_*)$ is a heavy gas entrainment function. The value of 'Foot' after collapse is

$$\mathrm{Foot} = \left(\frac{3\pi^2}{64}\right)^3\frac{3\kappa C_{\mathrm{D}}}{\psi(\mathrm{Ri}_*)}l_{lruu*}(D/z)\frac{\mathrm{d}D}{\mathrm{d}s} \qquad [15.44.30]$$

for

$$(\rho_\infty/\rho)^{1/2}(D/z) > \frac{1024}{(9\pi^2)(\mathrm{Ri}_*)^{1/2}\Phi(\mathrm{Ri}_*)} \qquad [15.44.31]$$

with

$$\mathrm{Ri}_* = \frac{2gz(\rho/\rho_\infty - 1)}{u_*^2} \qquad [15.44.32]$$

where C_{D} is an empirical spreading coefficient. The value of C_{D} is taken as 5.0.

15.44.7 Entrainment function

The entrainment function Entr is, in principle, the sum of the following entrainment mechanisms: jet entrainment, crosswind entrainment, gravity slumping entrainment, passive entrainment and heavy gas entrainment. The jet entrainment function $\mathrm{Entr}_{\mathrm{jet}}$ is

$$\mathrm{Entr}_{\mathrm{jet}} = e_{\mathrm{jet}}\eta_\rho L_{\mathrm{fs}}\rho_\infty|u - u_\infty\cos\phi| \qquad [15.44.33]$$

with

$$\eta_\rho = \frac{1 + (4/3)(\rho/\rho_\infty - 1)}{1 + (5/3)(\rho/\rho_\infty - 1)} \qquad [15.44.34]$$

where e_{jet} is an entrainment coefficient and L_{fs} is the Monin–Obukhov length for a free surface, this latter being the surface not bounded by the ground. The value of e_{jet} is taken as 0.08.

The crosswind entrainment function $\mathrm{Entr}_{\mathrm{cw}}$ is

$$\mathrm{Entr} = e_{\mathrm{u,cr}}\eta L_{\mathrm{fs}}\rho_\infty u_\infty (u_\infty/u)^{1/2}|\sin\phi| \qquad [15.44.35a]$$

with

$$\eta_\rho = 1 + e_{\rho,\mathrm{cr}}\max[0,(\rho/\rho_\infty - 1)\sin\phi] \qquad [15.44.35b]$$

where $e_{\mathrm{u,cr}}$ and are $e_{\rho,\mathrm{cr}}$ coefficients and η_ρ is a parameter. The values of $e_{\mathrm{u,cr}}$ and $e_{\rho,\mathrm{cr}}$ are 0.6 and 7.5, respectively.

The gravity slumping entrainment function $\mathrm{Entr}_{\mathrm{gs}}$ is, for the touchdown plume

$$\mathrm{Entr}_{\mathrm{gs}} = \left[1 - \frac{2z_{\mathrm{c}}}{D|\cos\phi|}\right] e_{\mathrm{gs}}\rho_\infty z u|\cos\phi|\frac{\mathrm{d}D}{\mathrm{d}s} \qquad [15.44.36]$$

and for the slumped plume

$$\mathrm{Entr}_{\mathrm{gs}} = e_{\mathrm{gs}}\rho_\infty z u|\cos\phi|\frac{\mathrm{d}D}{\mathrm{d}s} \qquad [15.44.37]$$

where e_{gs} is a coefficient. A value of 0.85 is given for e_{gs}, but with some qualification.

The passive entrainment $\mathrm{Entr}_{\mathrm{at}}$ due to atmospheric turbulence is

$$\mathrm{Entr}_{\mathrm{at}} = (1 - 1/D)\pi e_{\mathrm{at}}\rho_\infty \in^{1/3}\left(l_y^{4/3} + l_z^{4/3}\right) \qquad [15.44.38]$$

with

$$l_y = \min[D/2, 0.88(z+z_{\mathrm{o}})(1 - 7.4\kappa\zeta/(1-5k\zeta)] \quad \text{Stability categories A–C} \qquad [15.44.39a]$$

$$= \min[D/2, 0.88(z+z_{\mathrm{o}})] \quad \text{Stability category D} \qquad [15.44.39b]$$

$$= \min[D/2, 0.88(z+z_{\mathrm{o}})(1+0.1\zeta)] \quad \text{Stability categories E and F} \qquad [15.44.39c]$$

$$l_z = \min[D/2, 0.88(z+z_{\mathrm{o}})(1 - 7.4\kappa\zeta/(1-5\kappa\zeta)] \quad \text{Stability categories A–C} \qquad [15.44.40a]$$

$$= \min[D/2, 0.88(z+z_{\mathrm{o}})] \quad \text{Stability category D} \qquad [15.44.40b]$$

$$= \min[D/2, 0.88(z+z_{\mathrm{o}})/(1+4\zeta)] \quad \text{Stability categories E and F} \qquad [15.44.40c]$$

$$\epsilon = (1-5\kappa\zeta)u_*^3/[\kappa(z+z_{\mathrm{o}})] \quad \text{Stability categories A–C}$$

$$= u_*^3/[\kappa(z+z_{\mathrm{o}})] \quad \text{Stability category D} \qquad [15.44.41b]$$

$$= (1+4\kappa)u_*^3/[\kappa(z+z_{\mathrm{o}})] \quad \text{Stability categories E and F} \qquad [15.44.41c]$$

$$\zeta = \frac{z+z_{\mathrm{o}}}{L} \qquad [15.44.42]$$

$$L = \frac{u_*^3}{\kappa(g/T_{\mathrm{gr}}/u_* T^*)} \qquad [15.44.43]$$

where e_{at} is a coefficient, l_y and l_z are the turbulent length scales in the horizontal and vertical directions, L is the Monin–Obukhov length, T_{gr} is the temperature of the ground, $u_* T^*$ is the ground–air heat flux, ϵ is the dissipation rate of turbulent kinetic energy and is a parameter. The value of e_{at} is 1.0. The heavy gas entrainment $\mathrm{Entr}_{\mathrm{hg}}$ is

$$\mathrm{Entr}_{\mathrm{hg}} = \frac{1}{\Phi(\mathrm{Ri}_*)}L_{\mathrm{fs}}\kappa\rho_\infty u_* \qquad [15.44.44]$$

with $\Phi(\mathrm{Ri}_*)$ given by Equations 15.44.28 and 15.44.29, but with z substituted for h in the latter.

The jet entrainment and heavy gas entrainment each modify the level of turbulence and are not independent mechanisms. The combined contribution of these two effects is taken as the greater of the each of the two effects considered separately. Further, the contribution of each of the two effects is taken as proportional to the value of that effect divided by the sum of the values of the two effects. The passive entrainment and gravity slumping entrainment constitute another pair which interact and which are treated in a similar manner.

15.44.8 Atmospheric model

The plume behaviour is a function of the atmospheric conditions, and an atmospheric model is defined which includes the wind speed and temperature profiles and the Monin–Obukhov length. The wind speed profile is

$$= \frac{\kappa(z+z_{\mathrm{o}})}{u_*}\frac{\mathrm{d}u_\infty}{\mathrm{d}z} = \psi_{\mathrm{u}}(\zeta) \qquad [15.44.45]$$

with

$$\psi_{\mathrm{u}}(\zeta) = (1-22\zeta)^{-1/4} \quad \zeta < 0 \qquad [15.44.46a]$$

$$= 1 + 6.9\zeta \quad \zeta \geq 0 \qquad [15.44.46b]$$

The temperature profile is

$$\frac{\kappa(z+z_{\mathrm{o}})}{T^*}\frac{\mathrm{d}T_{\infty\mathrm{pot}}}{\mathrm{d}z} = \psi_{\mathrm{T}}(\zeta) \qquad [15.44.47]$$

with

$$\psi_{\mathrm{T}}(\zeta) = (1-13\zeta)^{1/2} \quad \zeta < 0 \qquad [15.44.48a]$$

$$= 1 + 9.2\zeta \quad \zeta \geq 0 \qquad [15.44.48b]$$

where the subscript pot denotes potential. The Monin–Obukhov length is

$$L = -10.99 z_{\mathrm{o}}^{0.0993} \quad \text{Stability category A} \qquad [15.44.49a]$$

$$= -13.44 z_{\mathrm{o}}^{0.1631} \quad \text{Stability category B} \qquad [15.44.49b]$$

$$= -113.5 z_{\mathrm{o}}^{0.2946} \quad \text{Stability category C} \qquad [15.44.49c]$$

$$= \infty \quad \text{Stability category D} \qquad [15.44.49d]$$

$$= 125 z_{\mathrm{o}}^{0.3090} \quad \text{Stability category E} \qquad [15.44.49e]$$

$$= 26.12 z_{\mathrm{o}}^{0.1667} \quad \text{Stability category F} \qquad [15.44.49f]$$

15.45 Concentration and Concentration Fluctuations

The account of gas dispersion given so far has touched only lightly on the question of concentration and concentration fluctuations and has dealt mainly with average concentration. It is now necessary to go into this more deeply.

Concentration fluctuations are relevant both to flammable and toxic gas releases. For flammable gas clouds, fluctuations may cause the gas concentration equivalent to the lower flammability limit to reach further than the boundary given by the mean value. For a toxic gas cloud, fluctuations may result in toxic effects associated with concentrations higher than the mean value.

Accounts of concentration fluctuations have been given by a number of authors, including Gosline (1952), Gifford (1960b), Long (1963), Slade (1968), Barry (1971), Ramsdell and Hinds (1971), Csanady (1973), Chatwin (1982b), C.D. Jones (1983), S.R. Hanna (1984), Ride (1984a,b) and J.K.W. Davies (1987, 1989).

It is convenient to deal primarily with the concentration in a plume from a continuous release, but that in a cloud from an instantaneous release is also considered.

15.45.1 Experimental studies and empirical features

It has been shown in experiments on plumes from a continuous point source by a number of workers that the instantaneous concentration measured at a fixed point fluctuates about the mean value and that the ratio of the maximum instantaneous value to the time mean value, or peak-to-mean ratio, can be quite large.

An account of experimental work on the peak-to-mean (P/M) ratio has been given by Gifford (1960b). He describes the results obtained by six previous workers. The ratio of the peak concentration P to the mean concentration M, or P/M, is a function of the ratio of the corresponding sampling times t_p and t_m from which these concentrations are derived. As shown in Figure 15.137 the P/M ratio tends to increase with increase in t_m/t_p, or decrease in t_p/t_m.

As Figure 15.137 indicates, the P/M ratio measured at ground level is appreciably greater for an elevated source than for one at ground level. This is illustrated also in Figure 15.138, which gives P/M as a function of distance. Gifford states that for measurements at ground level P/M can be expected to be about 1–5 for a ground level source but as much as 50–100 for an elevated source. Work by Ramsdell and Hinds (1971) has shown that the P/M ratio tends to be greater off the centre line.

Other workers have measured the proportion of time for which the concentration at a point is zero, or the intermittency. Work on concentrations in a plume by C.D. Jones (1983) has shown that the levels of intermittency can be very high, some 80–90%, with P/M ratios in the range 30–150.

Physical modelling using wind tunnels makes it possible to perform repeated experiments at the same nominal conditions. Figure 15.109(e) shows an ensemble of 21 concentration vs time profiles obtained by D.J. Hall, Hollis and Ishaq (1982) in wind tunnel work at Warren Spring Laboratory (WSL). The variability from one run to another is pronounced.

The intensity of the concentration fluctuations, defined below, is another widely used measure. An intensity value of zero corresponds to zero fluctuation. Figure 15.139 shows intensities obtained in wind tunnel work by Meroney and Lohmeyer (1984).

Such concentration fluctuations are not limited to gas clouds. Birch, Brown and Dodson (1980, 1981) have found large fluctuations in jets.

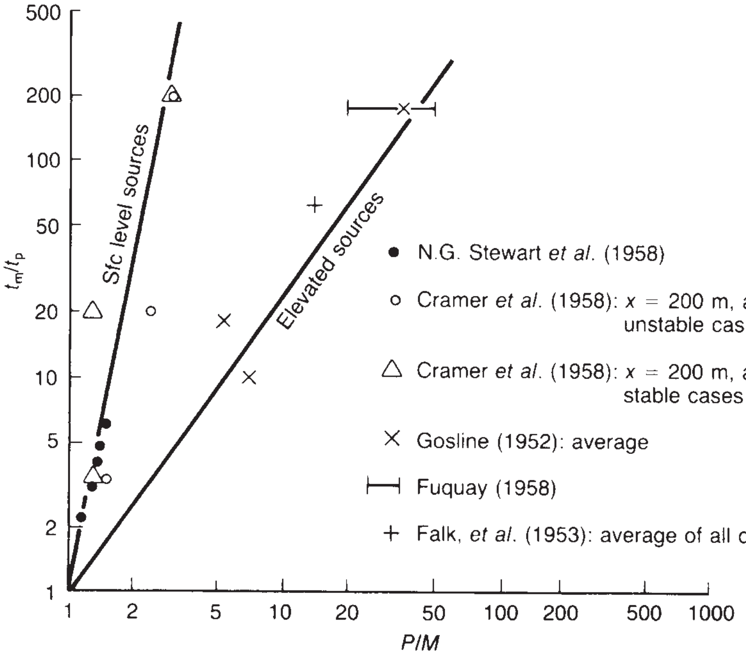

Figure 15.137 *Concentration fluctuations in a meandering plume: effect of mean sampling time t_m and peak sampling time t_p on the peak-to-mean concentration (Gifford, 1960b) (Courtesy of Pergamon Press)*

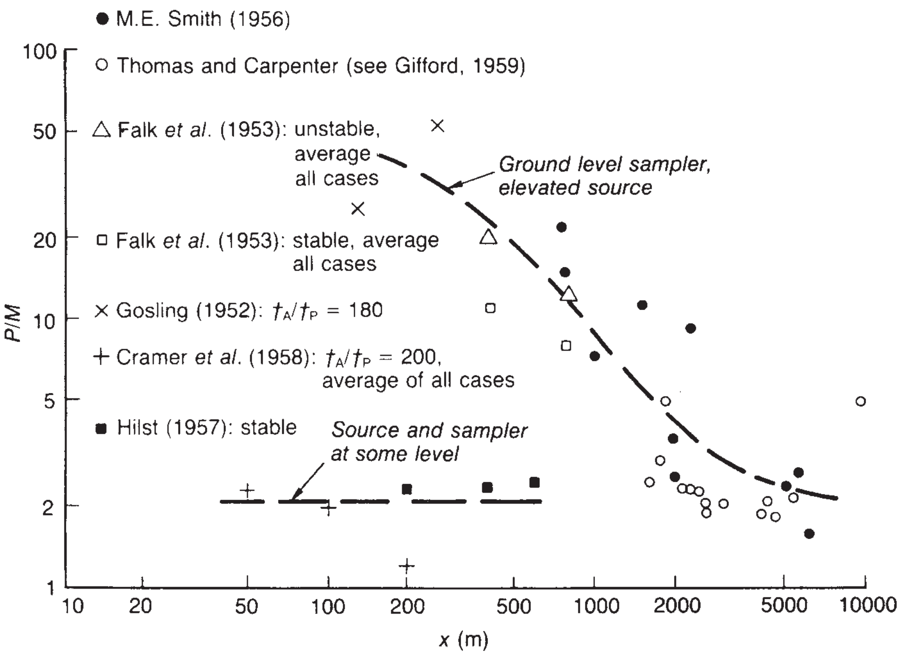

Figure 15.138 *Concentration fluctuations in a meandering plume: effect of distance (Gifford, 1960b) (Courtesy of Pergamon Press)*

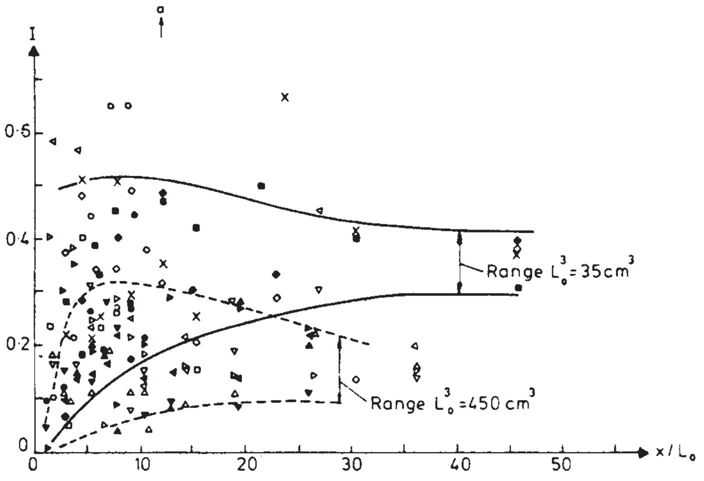

Figure 15.139 *Concentration fluctuations in gas dispersion–concentration fluctuation intensities measured in a wind tunnel (Meroney and Lohmeyer, 1984). Different symbols represent different release volumes, each being the result of at least five runs; I, intensity, L_0 volume released; x, downstream distance (Courtesy of Kluwer Academic Publishers)*

15.45.2 Causes of concentration fluctuation

Fluctuations of concentration have a number of causes. One of these is meandering of the plume due to the variability of wind direction. But even without meander, concentration fluctuations occur due to the normal effects of turbulence.

15.45.3 Measures of concentration fluctuation

Concentration fluctuation may be characterized in a number of ways. These include

(1) peak-to-mean ratio;
(2) intermittency;

(3) intensity;
(4) distributional properties.

The peak-to-mean ratio is the ratio of the maximum instantaneous concentration to the time mean value:

$$\frac{P}{M}=\frac{C_{\max}}{\bar{C}} \qquad [15.45.1]$$

where $\bar{C}$ is the time mean concentration and $C_{\max}$ is the maximum instantaneous concentration.

Csanady (1973) introduced the concept of intermittency. The intermittency of concentration fluctuations, or simply intermittency, is the proportion of time during which the concentration is non-zero:

$$\gamma=\frac{t_s-t_p}{t_s} \qquad [15.45.2]$$

where t_p is the time during which the concentration is zero, t_s is the total sampling time and γ the intermittency. It should be noted that some authors define intermittency as the proportion of time during which the concentration is zero (i.e., the complement of the definition just given).

Two important statistical parameters of the concentration are the mean and the variance:

Mean: $\mu=\bar{C}$

Instantaneous deviation: $c=C-\bar{C}$

Standard deviation: $\sigma=(\bar{c^2})^{1/2}$

The relative intensity i of concentration fluctuations, or simply intensity, is the ratio of the standard deviation to the mean of the concentration:

$$i=\left(\frac{\bar{c^2}}{\bar{C}}\right)^{1/2} \qquad [15.45.3]$$

The distributional properties are the distribution, and its parameters, which best describe the concentration fluctuations. The distribution most favoured is the log–normal distribution, which is characterized by the mean and log standard deviation. Alternatively, the mode may be used instead of the mean.

15.45.4 Time mean concentration

As discussed in Section 15.16, the mean concentration obtained by averaging over a particular sampling interval is a function of that interval. The correction used by D.B. Turner (1970) for this effect is

$$\frac{C}{C_r}=\left(\frac{t_r}{t}\right)^{p} \qquad [15.45.4]$$

where C is the concentration, t is the sampling time interval, p is an index and subscript r denotes reference. The value of p is between 0.17 and 0.2 where the sampling reference time t_r is of the order of 10 min and the other sampling time t is up to 2 h.

Another approach is that described by the CCPS (1987/2). On certain assumptions it can be shown that

$$\frac{\sigma^2(T)}{\sigma^2(0)}=2\left\{\frac{T_1}{T}\left(1-\frac{T_1}{T}\right)\left[1-\exp\left(-\frac{T_1}{T}\right)\right]\right\} \qquad [15.45.5]$$

where T_1 is the integral time scale. They give for T_1 a typical value of 10 s.

Other approaches have been used as described by D.J. Wilson (1991a).

15.45.5 Models for concentration fluctuation

Most of the approaches used to model dispersion may also be applied to the modelling of concentration fluctuations. A review by S.R. Hanna (1984) describes Gaussian, gradient transfer, similarity, meandering plume and distribution function models.

15.45.6 Distribution function for concentration

The form of the distribution function of the instantaneous concentrations at a fixed point in a passive plume has been studied by several workers, including Barry (1971) and Csanady (1973).

As described above, since concentration is zero for a proportion of the time, Csanady introduced the concept of intermittency. The intermittency is close to unity on the centre line of the plume and to zero at the cloud edges.

Csanady adduces theoretical arguments that the distribution function for the non-zero concentrations should be log–normal. He also obtains the log–normal distribution for experimental results given by several authors. Figure 15.140 shows his plot of Gosline's results on log-probability paper, confirming the log–normal form for the concentration distribution.

Barry (1971) has found that the following exponential relation gives a good fit to experimental results:

$$P(C)=P(0)\exp\left(-P(0)\frac{C}{M}\right) \qquad [15.45.6]$$

where $P(0)$ and $P(C)$ are the probabilities that the concentration exceeds 0 and C, respectively, and C and M are

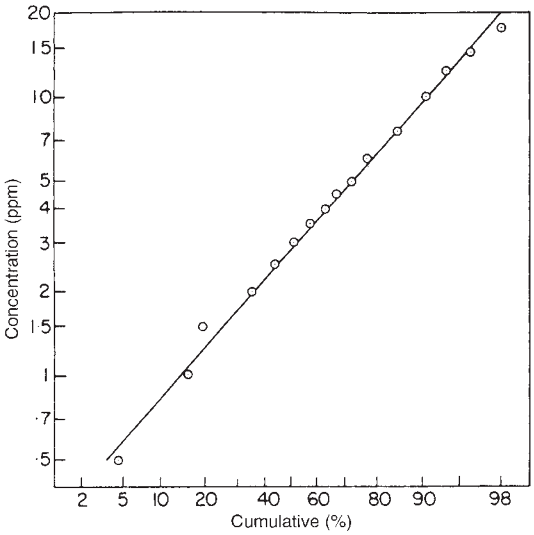

Figure 15.140 *Concentration fluctuations in a meandering plume: distribution function of concentrations (Csanady, 1973) (Courtesy of Reidel Publishing Company)*

the concentrations averaged over the peak sampling time t_p and the total sampling time t_m, respectively.

The form of the distribution function for concentration is also an issue in the work of Wilson, of Chatwin and of Davies, as described below.

15.45.7 Peak-to-mean concentration models

The distribution functions just described may be used as the basis for models of the peak-to-mean ratio.

Barry (1971) points out that the peak-to-mean ratio is simply a special case of the ratio of any short-lived concentration. By definition, the peak concentration is that which occurs only once. Hence the probability $P(P)$ of the peak value is

$$P(P) = t_p/t_m \qquad [15.45.7]$$

But from Equation 15.45.6

$$P(P) = P(0)\exp\left(-P(0)\frac{P}{M}\right) \qquad [15.45.8]$$

Then from equations 15.45.7 and 15.45.8

$$\frac{P}{M} = \frac{1}{P(0)}[1nP(0) - \ln(t_m/t_p)] \qquad [15.45.9]$$

Csanady gives the following approximate treatment of the case where the intermittency factor is unity and the concentration distribution is log–normal. This restriction on the intermittency factor implies that the plume does not meander. The probability density function of the concentration dF/dC is

$$\frac{dF}{dC} = \frac{1}{(2\pi)^{1/2}\sigma_1 C}\exp\left[-\frac{\ln(C/C_{\mathrm{med}})}{2\sigma_1^2}\right] \qquad [15.45.10]$$

and the probability distribution function F is then

$$F = \frac{1}{2}\left\{1 + \mathrm{erf}\left[\frac{[\ln(C/C_{\mathrm{med}})]}{2^{1/2}\sigma_1}\right]\right\} \qquad [15.45.11]$$

where C_{med} is the median concentration and σ is the logarithmic standard deviation. The mean concentration C_m is then

$$C_m = \int_0^1 C\frac{dF}{dC}dC \qquad [15.45.12a]$$

$$= C_{\mathrm{med}}\exp(\sigma_1^2/2) \qquad [15.45.12b]$$

Then from Equation 15.45.11 the probability $P(=1-F)$ that a given peak concentration will not be exceeded is

$$P = 1 - \frac{1}{2}\left\{1 + \mathrm{erf}\left[\frac{\ln(C_p/C_{\mathrm{med}})}{2^{1/2}\sigma_1}\right]\right\} \qquad [15.45.13]$$

and hence the peak concentration C_p is

$$C_p = C_{\mathrm{med}}\exp\left[2^{1/2}\sigma_1\mathrm{erf}^{-1}(1 - 2P)\right] \qquad [15.45.14]$$

Then from Equations 15.45.12b and 15.45.14

$$\frac{C_p}{C_m} = \exp\left[2^{1/2}\sigma_1\mathrm{erf}^{-1}(1 - 2P) - \frac{\sigma_1^2}{2}\right] \qquad [15.45.15a]$$

$$= \frac{P}{M} \qquad [15.45.15b]$$

15.45.8 Gifford meandering plume model

As stated above, concentration fluctuations in a passive plume are due partly to turbulent movements and partly to meandering. The effect of these two influences is shown in Figure 15.141.

A model for a meandering plume has been given by Gifford (1960b). The basis of the model is Equation 15.16.41 for a release Q from a continuous point source at ground level. He treats the dispersion variance σ_y^2 as the sum of two parts: Y^2, the variance attributable to the fluctuations about the instantaneous centre line; and D_y^2, the variance

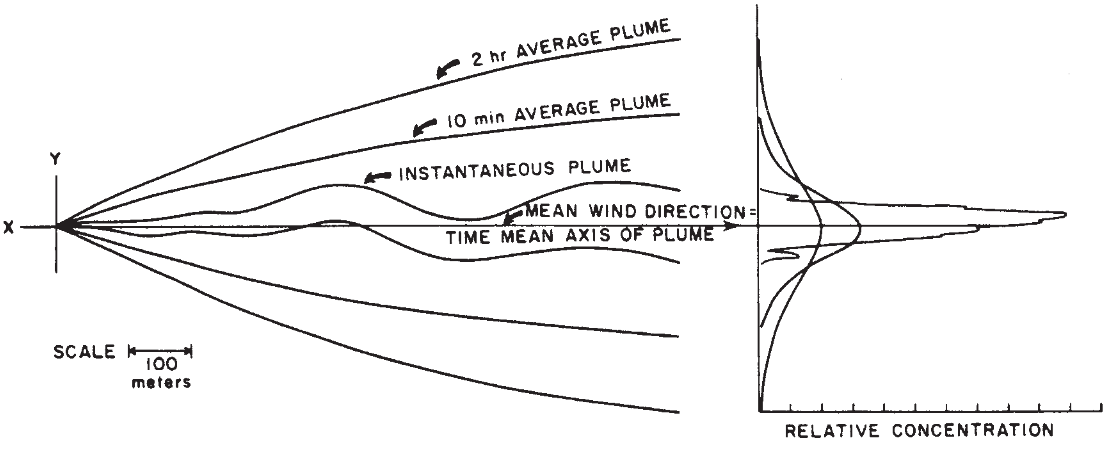

Figure 15.141 *Concentration fluctuations in a meandering plume: effect of combination of meandering and of turbulence (Slade, 1968)*

attributable to the meandering. Similarly, the variance σ_z^2 is taken as the sum of the fluctuation variance z^2 and the meandering variance D_z^2

$$\sigma_y^2 = Y^2 + D_y^2 \qquad [15.45.16a]$$

$$\sigma_z^2 = Z^2 + D_z^2 \qquad [15.45.16b]$$

From Equation 15.16.41 the mean concentration χ_{m} is then taken to be

$$\chi_{\mathrm{m}} = \frac{Q}{2\pi u\left(Y^2 + D_y^2\right)^{1/2}\left(Z^2 + D_z^2\right)^{1/2}} \times \exp\left\{-\left[\frac{y^2}{2\left(Y^2 + D_y^2\right)} + \frac{z^2}{2\left(Z^2 + D_z^2\right)}\right]\right\} \qquad [15.45.17]$$

and the instantaneous concentration to be

$$\chi_{\mathrm{i}} = \frac{Q}{2\pi u\left(Y^2 Z^2\right)^{1/2}} \exp\left\{-\left[\frac{(y - D_y)^2}{2Y^2} + \frac{(z - D_z)^2}{2Z^2}\right]\right\} \qquad [15.45.18]$$

The peak value of the instantaneous concentration χ_{p} occurs at a point on the centre line of the instantaneous plume ($y = D_y, z = D_z$), and hence

$$\frac{\chi_{\mathrm{p}}}{\chi_{\mathrm{m}}} = \frac{\left(Y^2 + D_y^2\right)^{1/2}\left(Z^2 + D_z^2\right)^{1/2}}{\left(Y^2 Z^2\right)^{1/2}} \times \exp\left\{\left[\frac{y^2}{2\left(Y^2 + D_y^2\right)} + \frac{z^2}{2\left(Z^2 + D_z^2\right)}\right]\right\} \qquad [15.45.19]$$

At ground level on the centre line ($y = z = 0$)

$$\frac{\chi_{\mathrm{p}}}{\chi_{\mathrm{m}}} = \frac{\left(Y^2 + D_y^2\right)^{1/2}\left(Z^2 + D_z^2\right)^{1/2}}{\left(Y^2 Z^2\right)^{1/2}} \qquad [15.45.20a]$$

$$= \frac{P}{M} \qquad [15.45.20b]$$

If conditions are such that

$$Y^2 = Z^2 \qquad [15.45.21a]$$

and

$$D_y^2 = D_z^2 = D^2 \qquad [15.45.21b]$$

then

$$\frac{P}{M} = \frac{Y^2 + D^2}{Y^2} \qquad [15.45.22a]$$

$$= 1 + \frac{D^2}{Y^2} \qquad [15.45.22b]$$

But, at large distances, D^2 approaches a constant value, whereas Y^2 continues to grow, and hence

$$\frac{P}{M} \to 1 \qquad [15.45.23]$$

15.45.9 Ride model

A model for the intermittency effect in a passive plume has been given by Ride (1984b). The model envisages the cloud as a number of spheres of equal size and uniform concentration in a matrix with zero concentration between the spheres. It can be shown that the peak-to-mean concentration is

$$\frac{C^*}{\bar{C}} = \frac{1}{1 - \gamma} \qquad [15.45.24]$$

and that

$$\frac{C^*}{\bar{C}} = \left(\frac{\sigma}{\bar{C}}\right)^2 + 1 \qquad [15.45.25]$$

where C^* is the concentration in the sphere, $\bar{C}$ is the true mean concentration, γ is the intermittency and σ is the standard deviation of the instantaneous concentration. This author defines intermittency as the proportion of time the concentration is below a specified value.

If the maximum concentration which can occur over time τ is C_τ, the peak-to-mean ratio for this time is $C_\tau/\bar{C}$. In the limit, C_τ tends to C^* as τ tends to zero and to $\bar{C}$ as τ tends to infinity. The intermittency is then γ_τ.

Equation 15.45.25 holds for spheres of uniform size. Rodean (1982) has derived the more general relation

$$\frac{C_\tau}{C} = k\left(\frac{\sigma}{\bar{C}}\right)^\lambda + 1 \qquad [15.45.26]$$

where k is a constant and λ is an index.

From the foregoing it is possible to derive the relation

$$\frac{C_\tau}{C} = k\left(\frac{\sigma}{\bar{C}}\right)^\tau \psi^{\lambda/2} + 1 \qquad [15.45.27]$$

with

$$\frac{\sigma_\tau}{\bar{C}} = \frac{\sigma}{\bar{C}}\psi^{1/2} \qquad [15.45.28]$$

$$\psi = \left(\frac{\beta}{ut + \beta}\right) \qquad [15.45.29]$$

where β is a constant. From the data of C.D. Jones (1983), Ride (1984b) assigns the values: $k = 11$, $\lambda = 1.5$ and $\beta = 0.4x$. where x is the downwind distance. He gives for $C_\tau/\bar{C}$ a comparison of predicted values with observations made at short ranges by Jones.

In a further treatment, Ride (1984a) omits the factor ψ, equivalent to setting $\psi = 1$.

15.45.10 Wilson model

A model for the intensity of concentration fluctuations in a passive plume has been given by D.J. Wilson (1982). The concentration fluctuation c' is defined as

$$c' = c - \bar{c} \qquad [15.45.30]$$

where c is the concentration, c' is the concentration fluctuation about the mean and $\bar{c}$ is the mean concentration. The concentration variance is $\bar{c}'^2$.

The model is based on the Gaussian description of a plume:

$$\bar{c} = \frac{Q}{2\pi u_c \sigma_y \sigma_z} G_m F_m \qquad [15.45.31]$$

with

$$G_m = \exp\left[-\frac{1}{2}\left(\frac{y}{\sigma_y}\right)^2\right] \qquad [15.45.32]$$

$$F_m = \exp\left[-\frac{1}{2}\left(\frac{z-h}{\sigma_z}\right)^2\right] + \exp\left[-\frac{1}{2}\left(\frac{z+h}{\sigma_z}\right)^2\right] \qquad [15.45.33]$$

where F_m is a height correction, G_m is a crosswind distance correction, h is the height of the source, Q is the mass rate of release and u_c is the advection velocity of the plume.

From the work of D.J.Wilson, Robins and Fackrell (1982), the concept of a variance source strength q is introduced

$$\overline{c'^2} = \left(\frac{q}{2\pi u_c \sigma_y \sigma_z}\right)^2 G_v F_v \qquad [15.45.34]$$

with

$$G_v = \frac{1}{2}\exp\left[-\frac{1}{2}\left(\frac{y}{\sigma_y} - \phi\right)^2\right] + \frac{1}{2}\exp\left[-\frac{1}{2}\left(\frac{y}{\sigma_y} + \phi\right)^2\right] \qquad [15.45.35]$$

$$F_v = \exp\left[-\frac{1}{2}\left(\frac{z-h_v}{\sigma_z}\right)^2\right] - \alpha \exp\left[-\frac{1}{2}\left(\frac{z+h_v}{\sigma_z}\right)^2\right] \qquad [15.45.36]$$

$$\frac{h_v}{\sigma_z} = \left[\left(\frac{h}{\sigma_z}\right)^2 + \phi^2\right]^{1/2} \qquad [15.45.37]$$

where F_v is a height correction, G_v is a crosswind distance correction, h_v is the effective height of the variance source, q is the variance source strength, α is the sink strength factor and ϕ is a location parameter for the variance source. The value of the parameter ϕ is 0.706. The variance source strength is given by the relation

$$\frac{q}{Q} = \frac{0.38\lambda}{\lambda^2 + \lambda_o^2} \qquad [15.45.38]$$

with

$$\lambda = \frac{(\sigma_y \sigma_z)^{1/2}}{H} \qquad [15.45.39]$$

$$\lambda_o = \frac{0.119d}{0.033z_e + d} \qquad [15.45.40]$$

$$z_e = h \exp\left[-\left(\frac{\sigma_z}{h}\right)^2\right] \qquad [15.45.41]$$

where d is the diameter of the source, H is the height of the neutrally stable atmospheric boundary layer, z_e is a scale height, λ is the normalized downwind distance and λ_o is the virtual origin of the variance source. The value of H is taken as 650 m. The intensity i is defined as

$$i = \left(\overline{c'^2}\right)^{1/2} / \bar{c} \qquad [15.45.42]$$

Hence from Equations 15.45.31–15.45.36 and 15.45.42

$$i = \left(\frac{q}{Q}\right)\frac{(G_v F_v)^{1/2}}{G_m F_m} \qquad [15.45.43]$$

The intensity just derived is the total intensity. Use is also made of the conditional intensity i_p based on the time when the concentration is non-zero.

A corresponding set of conditional concentrations is defined

$$c'_p = c - \bar{c}_p \qquad [15.45.44]$$

where c'_p is the conditional concentration fluctuation about the mean, $\bar{c}_p$ is the conditional mean concentration and subscript ρ refers to the time when the concentration is non-zero. The conditional concentration variance is c'^2_p. The conditional intensity i_p is

$$i_p = \frac{\left(\bar{c}'^2_p\right)^{1/2}}{\bar{c}_p} \qquad [15.45.45]$$

The ratio of the mean concentration to the conditional mean concentration is the intermittency γ

$$\gamma = \frac{\bar{c}}{\bar{c}_p} \qquad [15.45.46]$$

This author defines intermittency as the proportion of time the concentration is non-zero. Then from Equations 15.45.42 and 15.45.44–15.45.46

$$i^2 = \frac{i_p^2}{\gamma} + \frac{1-\gamma}{\gamma} \qquad i_p > 0 \qquad [15.45.47]$$

$$i = \left[\frac{1-\gamma}{\gamma}\right]^{1/2} \qquad i_p = 0 \qquad [15.45.48]$$

On certain assumptions it can be shown that the conditional intensity i_p is given by

$$i_p = i_{p\infty}\frac{\left[1 - \alpha \exp\left(-2h_v z/\sigma_z^2\right)\right]^{1/2}}{\left[1 + \exp\left(-2hz/\sigma_z^2\right)\right]} \qquad [15.45.49]$$

with

$$i_{p\infty} = \frac{q_p}{Q}\exp\left(-\phi^2/4\right) \qquad [15.45.50]$$

$$\frac{q_p}{Q} = \frac{0.38\lambda}{\lambda^2 + (0.119)^2} \qquad [15.45.51]$$

where $i_{p\infty}$ is the conditional intensity on the centre line with negligible surface interaction and q_p is the conditional variance source strength. The value of α is taken as 0.6. The results are sensitive to the value used for α.

From Equation 15.45.47 the intermittency γ is

$$\gamma = \frac{i_p^2 + 1}{i^2 + 1} \qquad [15.45.52]$$

The probability of exceeding a particular concentration c is then obtained using an appropriate distribution for the concentration c. The cumulative distribution function F_c for the concentration is

$$F_c = \int_0^c p(c)\,dc \qquad [15.45.53]$$

where p(c) is the probability density function for concentration. With intermittency this latter is

$$p(c) = (1-\gamma)\delta(c) + \gamma p_p(c) \qquad [15.45.54]$$

where $p_p(c)$ is the probability density function for conditional concentration. The delta function $\delta(c)$ is a spike at $c = 0$ and zero elsewhere with the further property that

$$\int_{-\infty}^{\infty} \delta(c)\,dc = 1 \qquad [15.45.55]$$

Hence from Equations 15.45.53–15.45.55

$$F_c = (1-\gamma) + \gamma \int_0^c p_p(c)\,dc \qquad [15.45.56]$$

For the log–normal distribution

$$p_p(c) = \frac{1}{(2\pi)^{1/2}\sigma_1 c} \exp\left[-\frac{\ln^2(c/c_{mp})}{2\sigma_1^2}\right] \qquad [15.45.57]$$

with

$$c_{mp} = \frac{\bar{c}_p}{\left(1+i_p^2\right)^{1/2}} \qquad [15.45.58]$$

$$\sigma_1 = \left[\ln\left(1+i_p^2\right)\right]^{1/2} \qquad [15.45.59]$$

Applying Equation 15.45.46, Equations 15.45.58 and 15.45.59 become

$$c_{mp} = \frac{\bar{c}}{\gamma[\gamma[1+i^2]]^{1/2}} \qquad [15.45.60]$$

$$\sigma_1 = \left\{\ln\left[\gamma\left(1+i^2\right)\right]\right\}^{1/2} \qquad [15.45.61]$$

Then from Equations 15.45.54, 15.45.56 and 15.45.57

$$F_c = (1-\gamma) + \frac{\gamma}{2}\left\{1 + \mathrm{erf}\left[\frac{\ln(c/c_{mp})}{2^{1/2}\sigma_1}\right]\right\} \qquad [15.45.62]$$

It is more convenient to work in terms not of the conditional median concentration c_{mp} but of the conditional mean concentration $\bar{c}_p$. The relation between them is

$$c_{mp} = \bar{c}_p \exp\left(-\sigma_1^2/2\right) \qquad [15.45.63]$$

Then from Equations 15.45.46 and 15.45.63 it can be shown that

$$\ln\left(\frac{c}{c_{mp}}\right) = \ln\left[\frac{\gamma c}{\bar{c}\exp\left(-\sigma_1^2/2\right)}\right] \qquad [15.45.64]$$

But from Equation 15.45.31 the relation between the mean concentration and the mean concentration $\bar{c}_o$ on the centre line is

$$\bar{c} = \bar{c}_o \exp\left(-y^2/2\sigma_y^2\right) \qquad [15.45.65]$$

Hence from Equations 15.45.62, 15.45.64 and 15.45.65

$$F_c = 1 - \gamma\left(1 - \frac{1}{2}\left\{1 + \mathrm{erf}\left[\frac{\ln(\gamma c/\bar{c}_o) + \left(y^2/2\sigma_y^2\right) + \left(\sigma_1^2/2\right)}{2^{1/2}\sigma_1}\right]\right\}\right) \qquad [15.45.66]$$

Equation 15.45.66 is the basic equation of the model, giving the distribution function of c as a function of the intensity i, the conditional intensity i_p and the intermittency γ.

Wilson also discusses the use of alternative distributions. The two distributions which are most appropriate for physical reasons are the log–normal and the exponential. The exponential distribution has advantages for high intermittency, but overall he favours the log–normal distribution.

For the exponential distribution the probability density function in terms of the conditional mean concentration is

$$p_p(c) = \frac{1}{\bar{c}_p}\exp(-c/\bar{c}_p) \qquad [15.45.67]$$

and that in terms of the mean concentration is

$$p_p(c) = \frac{\gamma}{\bar{c}}\exp(-c\gamma/\bar{c}) \qquad [15.45.68]$$

Then from Equation 15.45.56 and Equations 15.45.67 and 15.45.68

$$F_c = 1 - \gamma + \gamma[1 - \exp(-c/\bar{c}_p)] \qquad [15.45.69]$$

$$F_c = 1 - \gamma + \gamma[1 - \exp(-c\gamma/\bar{c})] \qquad [15.45.70]$$

This model has been developed in subsequent work by the authors and coworkers (D.J. Wilson and Simms, 1985; D.J. Wilson, 1991a).

The application of this model to toxic gas clouds is described in Section 15.47.

15.45.11 Concentration ensemble

Concentration measurements in one experiment represent a single realization of a potential ensemble of experiments. The WSL data set described above and shown in Figure 15.109(e) is an illustration of such an ensemble.

The importance of working in terms of the properties of the ensemble rather than of a single experiment has been brought out by Chatwin (1982b), and subsequently developed (Cam and Chatwin, 1985; Cam, 1987; Mole and Chatwin, 1987; Cam, Sherrel and Chatwin, 1988; Chatwin, 1991).

Chatwin (1982b) discusses the concentration $\Gamma(x, t)$ from a single experiment. The mean value of this concentration is $\bar{\Gamma}(x, t)$. The mean value for the ensemble $C(x, t)$ is defined as

$$C(x,t) = \lim_{n\to\infty}\left[\frac{1}{n}\sum_{r=1}^{n}\Gamma^{(r)}(x,t)\right] \qquad [15.45.71]$$

The concentration fluctuation $c(x, t)$ is then

$$c(x,t) = \Gamma(x,t) - C(x,t) \qquad [15.45.72]$$

This fluctuation has a mean value $\bar{c}(x, t) = 0$. The ensemble mean square fluctuation $\bar{c}^2(x, t)$ satisfies

$$\bar{c}^2(x,t) = \bar{\Gamma}^2(x,t) - C^2(x,t) \qquad [15.45.73]$$

The quantities $C(x, t)$ and $c^2(x, t)$ are the mean and variance of the ensemble, respectively.

In a given realization, there is a certain probability of a particular concentration $\Gamma(x, t)$. Let this concentration be $\theta = \Gamma(x, t)$. The ensemble may be characterized by a probability density function (PDF) $p(\theta, x, t)$. It is a property of the PDF that

$$\int_0^1 p(\theta,x,t)\,\mathrm{d}\theta = 1 \qquad [15.45.74a]$$

or for the case where air is entrained so that $\theta_{\max} < 1$

$$\int_0^{\theta_{\max}} p(\theta,x,t)\,\mathrm{d}\theta = 1 \qquad [15.45.74b]$$

The PDF is related to the mean and variance as follows:

$$C(x,t) = \int_0^1 \theta p(\theta,x,t)\,\mathrm{d}\theta \qquad [15.45.75]$$

$$\bar{c}^2(x,t) = \int_0^1 (\theta - C)^2 p(\theta,x,t)\,\mathrm{d}\theta \qquad [15.45.76]$$

The intensity i is

$$i = \frac{(\bar{c}^2(x,t))^{1/2}}{C(x,t)} \qquad [15.45.77]$$

If the PDF can be characterized by one of the standard distributions, such as the normal or log–normal distributions, the probability may be obtained analytically. Otherwise it must be obtained by numerical integration of the PDF. Thus if the PDF fits the normal distribution, then, for example, there is 90% confidence that the concentration θ lies between the limits $C(x,t) \pm 1.65[\bar{c}^2(x,t)]^{1/2}$.

A typical application of the PDF approach is the determination of the probability P that a concentration in a steady state cloud or jet will lie between the lower flammability limit θ_{L} and the upper flammability limit θ_{U}. Then

$$P = \int_{\theta_{\mathrm{L}}}^{\theta_{\mathrm{u}}} p(\theta,x)\,\mathrm{d}\theta \qquad [15.45.78]$$

Such an application is illustrated in the work of Birch, Brown and Dodson (1980) on the concentration fluctuations, and hence ignition probabilities, in methane jets. Figure 15.142(a) shows PDFs as a function of radial distance measured in such jets and Figure 15.142(b) shows the probability of ignition of the jets.

The experimental determination of a concentration ensemble from which statistical properties are to be derived requires considerable care. The experimental variables which can cause variability in concentration must be fully defined.

The properties of the ensemble are affected by the framework, absolute or relative, in which the measurements are made. If an absolute framework is chosen, the properties depend significantly on any feature which influences the motion of the cloud as a whole. This implies the need for a much larger number of experiments.

The relationships between the intermittency and the other quantities in this scheme have been given by Cam and Chatwin (1985). If the concentration θ is assumed to have only one of two values, θ_{o} or 0:

$$p(\theta,x,t) = \gamma(x,t)\delta(\theta - \theta_{\mathrm{o}}) + [1 - \gamma(x,t)]\delta(\theta) \qquad [15.45.79]$$

where γ is the intermittency and δ is the delta function. These authors define intermittency as the proportion of time the concentration is non-zero. Then from Equation 15.45.79 and Equations 15.45.75 and 15.45.76 the mean and variance are

$$C(x,t) = \theta_{\mathrm{o}}\gamma(x,t) \qquad [15.45.80]$$

$$\bar{c}^2(x,t) = \theta_{\mathrm{o}}^2[\gamma(x,t) - \gamma^2(x,t)] \qquad [15.45.81]$$

Hence from Equations 15.45.77 and 15.45.81 the intensity is

$$i(x,t) = \left[\frac{\theta_{\mathrm{o}}}{C(x,t)} - 1\right]^{1/2} \qquad [15.45.82a]$$

$$= \left[\frac{1}{\gamma(x,t) - 1}\right]^{1/2} \qquad [15.45.82b]$$

15.45.12 Concentrations for dense gas: intensity parameter

In an extension of this work, Cam (1987) has addressed the problem of concentration fluctuations in dense gas clouds. He defines an intensity parameter R which is the square of the intensity I so that

$$R(C) = \frac{\bar{c}^2(x,t)}{\bar{C}^2} \qquad [15.45.83]$$

Thorney Island trials 7–19 were analysed and empirical values of this intensity parameter were obtained as shown in Figure 15.143. It was found that $R(C)$ was constant for a substantial proportion of the total record of $C(t)$ and

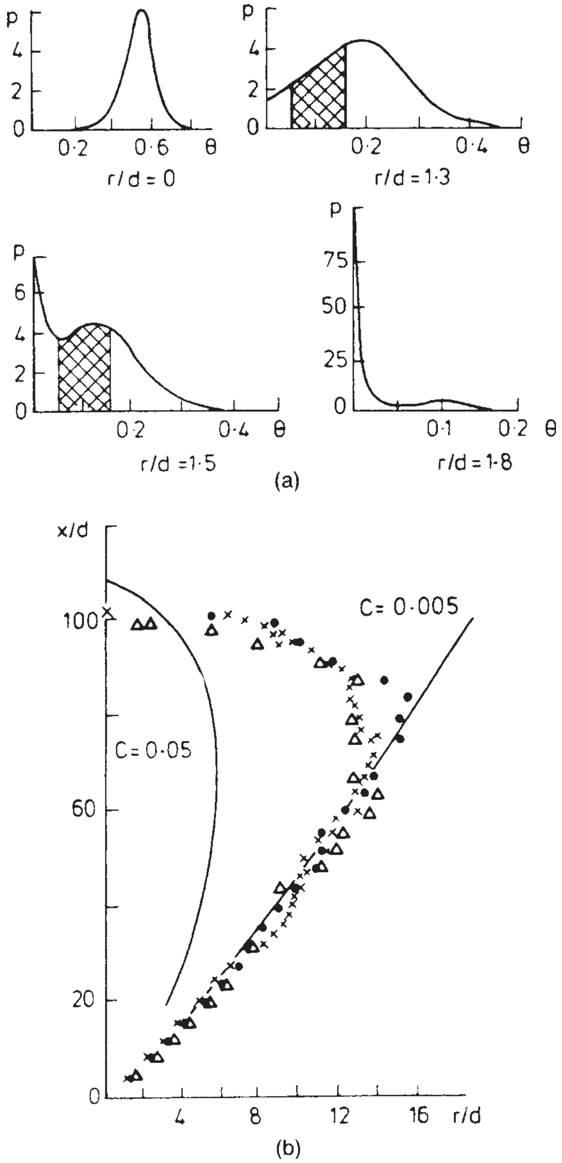

Figure 15.142 Concentration fluctuations in gas dispersion – concentration and ignition probability in gas jets: (a) probability density functions of concentration in a methane jet (Birch et al., 1978) Courtesy of Cambridge University Press; (b) ignition probability in radial plane of a natural gas jet (Birch, Brown and Dodson, 1980; reproduced by permission) C, concentration; d, diameter; p, probability; r, radial distance; x, axial distance. In (b) measurements made at Reynolds number 12,500 (Δ), 16,700 (×) and 20,900 (•). Curve of measured ignition probabilities is different from that of the LFL (C = 0.05)

constant over much of the area of the cloud, but there were also some substantial variations of $R(C)$ even at constant $\bar{C}$.

Carn quotes the following empirical relation, due to Chatwin (1982b), for the bound on $R(C)$:

$$R(C) = \epsilon(1/\overline{C} - 1) \qquad [15.45.84]$$

where ϵ is a constant. The suggested value of ϵ is 0.04. The behaviour of $R(C)$ was further investigated by obtaining an area-averaged value. This started at a peak of about 5, fell over some 30 s to about 1 and held this value for a period of 30–150 s and then rose to a plateau of about 4 some 160 s after the release.

15.45.13 Concentrations for dense gas: *Workbook*

The *Workbook* by Britter and McQuaid (1988) is primarily concerned with the provision of a method of estimating the mean concentrations in dense gas dispersion. It does,

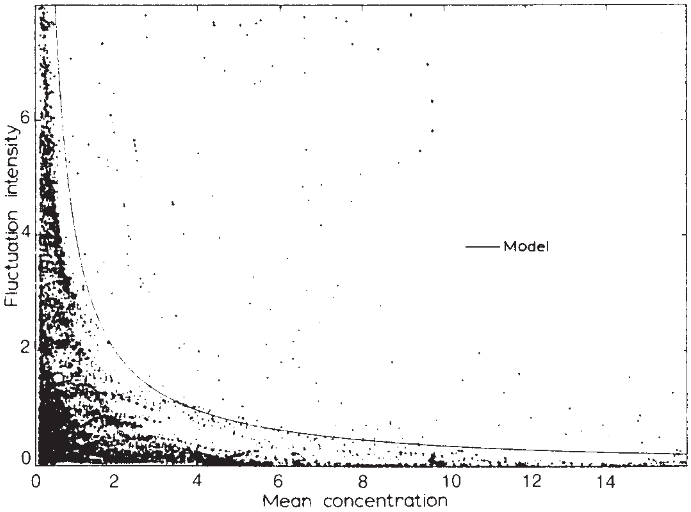

Figure 15.143 *Concentration fluctuations in gas dispersion – concentration fluctuation intensity factor for Thorney Island Phase 1 trials (Cam, 1987) (Courtesy of Elsevier Science Publishers)*

however, include a discussion of concentration fluctuations. It points out that, even for passive dispersion, there is uncertainty about the definition and quantification of concentration. The treatments available for dense gas dispersion are rudimentary.

It is possible, however, that for dense gas dispersion the problem may be simpler than for passive dispersion. The more deterministic nature of dense gas dispersion may result in smaller concentration fluctuations. Moreover, in dense gas dispersion the release is usually at ground level and the cloud remains near the ground. Work on passive dispersion has shown that fluctuations are less for ground level and near ground level releases.

15.45.14 Jets and plumes

The concentration fluctuations in jets have been measured by a number of workers. On the basis of this work Long (1963) has proposed that for the estimation of the maximum instantaneous concentration in a jet the value of the constants k_2k_3 to be used in Equation 15.20.8 should be 9 and 2, respectively, and that for the maximum instantaneous concentration in a plume the value of the constant k_4 to be used in Equation 15.20.96 should be 17; he does not propose a value for the constant k_5.

The work of Brown, Birch and Dodson (1980, 1981) on the probability density function approach to concentration fluctuations in jets has been described above.

15.46 Flammable Gas Clouds

It is often necessary to be able to estimate the mass of gas within the flammable range in a cloud from a flammable gas release. Workers who have studied this problem include Burgess *et al.* (1975), Eisenberg, Lynch and Breeding (1975), V.J. Clancey (1977c), van Buijtinen (1980) and J.G. Marshall (1977, 1980).

The treatments are mainly for jets and plumes at the point of release or for clouds with passive dispersion. The cases considered here are

(1) instantaneous source;
(2) continuous source;
(3) momentum jet;
(4) buoyant plume.

The flammable mass in a dense gas cloud is also discussed.

Approaches to dealing with the effect of concentration fluctuations on the determination of the flammable cloud are described.

15.46.1 Instantaneous source

A simple treatment for the mass of gas in the cloud from the instantaneous release of a neutral density gas has been given by V.J. Clancey (1977a), who uses the following equations derived from Equation 15.16.40 with Equation 15.14.5:

$$\chi = \frac{2Q^*}{(2\pi)^{3/2}\sigma^3}\exp\left(-\frac{1}{2}\frac{r^2}{\sigma^2}\right) \qquad [15.46.1]$$

$$\chi_{\mathrm{cc}} = \frac{2Q^*}{(2\pi)^{3/2}\sigma^3} \qquad [15.46.2]$$

where Q^* is the mass released, r is the radial distance, σ is the dispersion coefficient, χ is the concentration and the subscript cc denotes the cloud centre.

The mass W of flammable gas between the radii r_1 and r_2 may then be calculated as

$$W = \int_{r_1}^{r_2} 2\pi r^2 \exp\left(-\frac{1}{2}\frac{r^2}{\sigma^2}\right)\mathrm{d}r \qquad [15.46.3]$$

where r_1 is the inner radius, r_2 is the outer radius and W is the mass of flammable gas. For $r_1 = 0$ and $r_2 = \infty$, Equation 15.46.3 gives $W = Q^*$.

The maximum quantity of flammable mixture, and hence the maximum hazard, occurs when the concentration χ_{cc} at the centre of the cloud equals the upper flammability limit χ_{U}:

$$\chi_{\mathrm{U}} = \chi_{\mathrm{cc}} \qquad [15.46.4]$$

$$= \frac{2Q^*}{(2\pi)^{3/2}\sigma_{\mathrm{m}}^2} \qquad [15.46.5]$$

where σ_{m} is the value of σ at maximum hazard. The lower flammability limit χ_{L} and the radius r_{L} at which this occurs are given by the equations

$$\chi_{\mathrm{L}} = \chi_{\mathrm{U}} \exp\left(-\frac{1}{2}\frac{r_{\mathrm{L}}^2}{\sigma_{\mathrm{m}}^2}\right) \qquad [15.46.6]$$

$$r_{\mathrm{L}} = [2\sigma_{\mathrm{m}}^2 \ln(\chi_{\mathrm{U}}/\chi_{\mathrm{L}})]^{1/2} \qquad [15.46.7]$$

The mass F of flammable gas between the flammability limits at maximum hazard is

$$F = \int_0^{r_{\mathrm{L}}} 2\pi r^2 \chi_{\mathrm{U}} \exp\left(-\frac{1}{2}\frac{r_{\mathrm{L}}^2}{\sigma_{\mathrm{m}}^2}\right) \mathrm{d}r \qquad [15.46.8]$$

The evaluation of Equation 15.46.8 is assisted by noting that it may be rewritten as

$$F = \int_0^{r_{\mathrm{L}}} \frac{2Q^* r^2}{\sigma_{\mathrm{m}}^2} \left[\frac{1}{\sigma_{\mathrm{m}}(2\pi^{1/2})} \exp\left(-\frac{1}{2}\frac{r_{\mathrm{L}}^2}{\sigma_{\mathrm{m}}^2}\right)\right] \mathrm{d}r \qquad [15.46.9]$$

where the expression inside the square brackets is the Gaussian distribution.

This model indicates that the ratio $\chi_{\mathrm{U}}/\chi_{\mathrm{L}}$ of the upper and lower flammability limits is an important quantity in determining the fraction of the cloud within the flammable range and thus available for combustion.

For a typical hydrocarbon the ratio of the upper to the lower flammability limit is in the range 4–6, so that the ratio of gas within the flammable range to the total gas in the cloud at maximum hazard is

$$F/Q^* \approx 2/3 \qquad [15.46.10]$$

The growth of the cloud prior to this point may be determined from Equations 15.46.1–15.46.3. As a first approximation, however, the mass of gas within the flammable range may be taken as rising linearly from the initial value to the value at maximum hazard with a rapid fall-off thereafter.

A further treatment for an instantaneous release from a point source has been given by van Buijtenen (1980). Formulating his model in terms of mass and mass concentrations of gas, the starting point is the following relation for an instantaneous release from an elevated source, of height H, derived from Equations 15.16.40b and 15.16.43:

$$\chi(x,y,z,t) = \frac{Q^*}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z} \exp\left[-\frac{(x-ut)^2}{2\sigma_x^2}\right] \exp\left(\frac{-y^2}{2\sigma_y^2}\right) \times \left\{\exp\left[-\frac{(z-H)^2}{2\sigma_z^2}\right] + \exp\left[\frac{(z+H)^2}{2\sigma_z^2}\right]\right\} \qquad [15.46.11]$$

Then from Equation 15.46.11 the fraction of gas between the flammability limits is

$$\frac{Q_{\mathrm{e}}^*}{Q^*} = \mathrm{erf}\left[(\ln\chi_{\mathrm{cc}}/\chi_{\mathrm{L}})^{1/2}\right] - \mathrm{erf}\left[(\ln\chi_{\mathrm{cc}}/\chi_{\mathrm{U}})^{1/2}\right] - 2\frac{\chi_{\mathrm{L}}}{(\pi)^{1/2}\chi_{\mathrm{cc}}} \left[(\ln\chi_{\mathrm{cc}}/\chi_{\mathrm{L}})^{1/2}\right] + \frac{2\chi\mathrm{U}}{(\pi)^{1/2}\chi_{\mathrm{cc}}} \left[\left(\ln\chi_{\mathrm{cc}}/\chi_{\mathrm{U}}^{1/2}\right)^{1/2}\right] \quad \chi_{\mathrm{cc}} > \chi_{\mathrm{U}} \qquad [15.46.12a]$$

$$= \mathrm{erf}\left[(\ln\chi_{\mathrm{cc}}/\chi_{\mathrm{L}})^{1/2}\right] - \frac{2\chi_{\mathrm{L}}}{\pi^{1/2}\chi_{\mathrm{cc}}} [(\ln\chi_{\mathrm{cc}}/\chi_{\mathrm{L}})^{1/2}] \quad \chi_{\mathrm{cc}} < \chi_{\mathrm{U}} \qquad [15.46.12b]$$

where Q^* is the mass of gas released and Q_{e}^* is the mass of gas within the flammable range. Equation 15.46.12 applies to a cloud completely free of the ground or, alternatively, to a cloud at ground level ($H = 0$).

The maximum value of the fraction Q_{e}^*/Q^* of gas within the flammable range is obtained by differentiating Equation (15.46.12a) with respect to χ_{cc}which gives

$$\ln\chi_{\mathrm{cc}} = \frac{\chi_{\mathrm{U}}^2 \ln\chi_{\mathrm{U}} - \chi_{\mathrm{L}}^2 \ln\chi_{\mathrm{L}}}{\chi_{\mathrm{U}}^2 - \chi_{\mathrm{L}}^2} \qquad [15.46.13]$$

Substituting for χ_{cc} from Equation 15.46.13 into Equation 15.46.12a gives

$$\left(\frac{Q_{\mathrm{e}}^*}{Q^*}\right)_{\mathrm{max}} = \mathrm{erf}\left(v_2^{1/2}\right) - \mathrm{erf}\left(v_1^{1/2}\right) - \frac{2\exp(-v_2)v_2^{1/2}}{\pi^{1/2}} + \frac{2\exp(-v_1)v_1^{1/2}}{\pi^{1/2}} \qquad [15.46.14]$$

with

$$v = \chi_{\mathrm{U}}/\chi_{\mathrm{L}} \qquad [15.46.15a]$$

$$v_1 = \ln(v)/(v^2 - 1) \qquad [15.46.15b]$$

$$v_2 = v^2\ln(v)/(v^2 - 1) \qquad [15.46.15c]$$

where the subscript max denotes the maximum value.

The influence of the ratio $\chi_{\mathrm{U}}/\chi_{\mathrm{L}}$ of the flammability limits on the fraction Q_{e}^*/Q^* of gas between the flammability limits according to Equation 15.46.14 is shown in Figure 15.144.

The application of this model can be extended if necessary by the use of the virtual source method. Van Buijtenen also gives an equation for an instantaneous source of finite size.

The problem of the amount of gas available for combustion has also been considered by Eisenberg, Lynch and Breeding (1975). These authors list three assumptions which may be made about this quantity:

(1) all the fuel above the lower flammability limit;
(2) all the fuel between the upper and lower flammability limits;
(3) all the fuel between the upper and lower flammability limits for which oxygen is available.

The third assumption is the most accurate. For this latter case the mass of gas available for combustion is

$$W_{\mathrm{F}} = \int_{V_{\mathrm{LS}}} \chi\,\mathrm{d}V + \int_{V_{\mathrm{SU}}} \chi F(c)\,\mathrm{d}V \qquad [15.46.16]$$

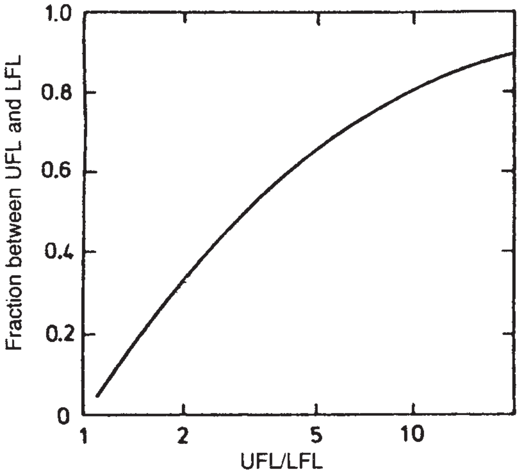

Figure 15.144 *Flammable gas clouds – effect of ratio of flammability limits on fraction of gas within flammable range for release from an instantaneous point source (van Buijtenen, 1980), LFL, lower flammability limit; UFL, upper flammability limit (Courtesy of Elsevier Science Publishers)*

where $F(c)$ is the weighting function giving the fraction of fuel present that enters into the combustion reaction, V_{LS} is the volume of the cloud between the lower flammability limit and the stoichiometric concentration (m^3), V_{SU} is the volume of the cloud between the stoichiometric concentration and the upper flammability limit (m^3) and W_{F} is the mass of fuel available for combustion (kg). The weighting function $F(c)$ is defined as

$$F(c) = \frac{n_{\mathrm{c}}}{n_{\mathrm{p}}} \qquad [15.46.17]$$

where n_{c} is the number of moles of fuel consumed and n_{p} is the number of moles of fuel present. Then if 1 mol of fuel reacts with L mol of oxygen

$$n_{\mathrm{c}} = \frac{0.21 n_{\mathrm{a}}}{L} \qquad [15.46.18]$$

where n_{a} is the number of moles of air in the rich mixture. Hence

$$F(c) = \frac{0.21}{L}\frac{n_{\mathrm{a}}}{n_{\mathrm{p}}} \qquad [15.46.19]$$

15.46.2 Continuous source

Van Buijtenen also gives a model for a continuous source, derived from Equation 15.16.43. In this case it is necessary to use a correlation for the crosswind and vertical dispersion coefficients. The relations used are

$$\sigma_y = ax^b \qquad [15.46.20a]$$

$$\sigma_z = cx^d \qquad [15.46.20b]$$

where a and c are constants and b and d are indices.

Then the ratio Q_{e}/Q of the mass of gas within the flammability limits to the mass of gas released is

$$\frac{Q_{\mathrm{e}}}{Q} = \frac{b+d}{b+d+1}\frac{x_{\mathrm{L}} - x_{\mathrm{U}}}{u} \qquad [15.46.21]$$

where u is the wind speed, and x_{L} and x_{U} are the maximum distances to the lower and upper flammability limits, respectively. Equation 15.46.21 applies to a cloud completely free of the ground or, alternatively to a cloud at ground level.

An alternative formulation of Equation 15.46.21 may be obtained by substituting for x_{L} and x_{U} from Equation 15.16.43 in Equation 15.46.21 to obtain for a plume at ground level

$$\frac{Q_{\mathrm{e}}}{Q} = \frac{b+d}{(b+d+1)u}\left(\frac{Q}{\pi uac}\right)^{1/(b+d)} \times \left[\left(\frac{1}{\chi_{\mathrm{L}}}\right)^{1/(b+d)} - \left(\frac{1}{\chi_{\mathrm{U}}}\right)^{1/(b+d)}\right] \qquad [15.46.22]$$

For a plume free of the ground the term πuac in Equation 15.46.22 is replaced by $2\pi uac$. If the concentration at the source is below the upper flammability limit χ_{U}, x_{U} in Equation 15.46.21 and the term in χ_{U} in Equation 15.46.22 are zero.

Values given by van Buijtenen of the parameters in Equation 15.46.20 for use in this model are shown in Table 15.55.

For typical values of the indices b and d, the rate of increase of the ratio Q_{e}/Q with Q exceeds a linear rate. The application of this model can be extended, if necessary, by the use of the virtual source method. This is discussed by van Buijtenen. A rather similar model for a continuous source has been given by J.G. Marshall (1980), who writes Equation 15.16.41 in the form

$$\chi(x,y,z) = \frac{\dot{m}_{\mathrm{o}}}{\pi\sigma_y\sigma_z u}\exp\left[-\frac{1}{2}\left(\frac{y^2}{\sigma_y^2} + \frac{z^2}{\sigma_z^2}\right)\right] \qquad [15.46.23]$$

where $\dot{m}_{\mathrm{o}}$ is the mass rate of release. Thus for the concentration on the center line at ground level ($y = z = 0$)

$$\chi(x,0,0) = \frac{\dot{m}_{\mathrm{o}}}{\pi\sigma_y\sigma_z u} \qquad [15.46.24]$$

Use is made of the following correlation for the product of the crosswind and vertical dispersion coefficients

$$\sigma_y\sigma_z = Dx^f \qquad [15.46.25]$$

where D is a constant and f an index.

On the assumption that the crosswind isopleths are semielliptical in shape, substitution for $\sigma_y\sigma_z$ from Equation 15.46.25 in Equation 15.46.23 yields

$$Q_{\mathrm{FL}} = \left(\frac{1}{\pi D}\right)^{1/f}\frac{f}{f+1}\left(\frac{\dot{m}_{\mathrm{o}}}{u}\right)^{(f+1)/f}\left(\frac{1}{\chi_{\mathrm{L}}^{1/f}} - \frac{1}{\chi_{\mathrm{U}}^{1/f}}\right) \qquad [15.46.26]$$

where Q_{FL} is the mass of gas within the flammability limits. Values given by Marshall of the parameters in Equation 15.46.25 for use in this model are shown in Table 15.56.

15.46.3 Momentum jet

J.G. Marshall (1977) has also treated the cases of a flammable momentum jet and a buoyant plume. The basis of the

model for a jet is the work of Long (1963). For a momentum jet the concentration in the jet is given by the equation

$$c(z,r) = \frac{k_1 d_o}{z}\frac{M_o T_a}{M_a T_o}\frac{\bar{M}}{M_o}\exp\left[-\left(\frac{k_2 r}{z}\right)^2\right] \qquad [15.46.27]$$

where c is the concentration (volume fraction), d_o is the effective diameter of the discharge (m), M is the molecular weight, $\bar{M}$ is the mean molecular weight of the gas mixture at an axial distance z, r is the radial distance from the axis (m), T is the absolute temperature (K), z is the axial length or vertical height (m), k_1 and k_2 are constants, and subscripts a denote air and o the original discharge.

Marshall states that d_o is the effective diameter of the jet after it has expanded to atmospheric pressure but before any entrainment has occurred. For a vent this will be the diameter of the vent, whereas for a plant failure it will be related to the effective 'hole' size and internal pressure.

The distance at which transition from jet to plume occurs is governed by the internal Froude number Fr:

$$Z_{tr} = k_3 \mathrm{Fr} d_o \qquad [15.46.28a]$$

$$= \frac{k_3 w_o d_o}{(g' d_o)^{1/2}} \qquad [15.46.28b]$$

with

$$g' = g\frac{M_a T_o - M_o T_a}{M_a T_o} \qquad [15.46.29]$$

where w is the velocity (m/s), k_3 is a constant and subscript tr denotes transition.

Equation 15.46.27 may be used to determine an axial length and may be integrated for volume and for quantity of flammable material. In order to simplify the integration Marshall assumes that $\bar{M}$ is equal to M_a. The effect of this simplification for a gas of lower molecular weight than air is to overestimate the axial distance at which the upper and lower limit concentrations are reached, the former more than the latter. For a gas of higher molecular weight than air the opposite is true. For most flammable gases the error in axial distance or quantity is much less than 20%.

The equations for the jet are then

$$z_L = \frac{k_1 d_o}{c_L}\left(\frac{M_a T_a}{M_o T_o}\right)^{1/2} \quad [15.46.30]$$

$$V_{FL} = \frac{\pi k_1^3}{9k_2^2}\left(\frac{M_a T_a}{M_o T_o}\right)^{3/2} d_o^3\left(\frac{1}{c_L^3} - \frac{1}{c_U^3}\right) \quad [15.46.31]$$

$$Q_{FL} = \frac{\pi k_1^3}{6k_2^2}\frac{273}{22.4}\left(\frac{M_a}{T_o}\right)^{3/2}\left(\frac{T_a}{M_o}\right)^{1/2} d_o^3\left(\frac{1}{c_L^2} - \frac{1}{c_U^2}\right) \quad [15.46.32]$$

where Q_{FL} is the mass of flammable material in the cloud between the flammability limits (kg), V_{FL} is the volume of the cloud between the flammability limits (m^3) and subscript L denotes the lower flammability limit and U the upper flammability limit.

The values of the constants used by Marshall are as follows. For k_1 and k_2, the values recommended by Long (1963) as giving the maximum instantaneous concentrations are 9 and 2, respectively. But these two constants are not independent. If the radial spread of velocity and concentration in the jet are the same

$$k_2 = (2)^{1/2} k_1 \quad [15.46.33]$$

Marshall uses values of 9 and 12.7 for k_1 and k_2, respectively. For k_3, values of 1.39 and 1.74 have been obtained by B.R. Morton (1959) and by J.S. Turner (1966) for the case where momentum and buoyancy forces are directly opposed. Marshall takes k_3 as 1.55, which is the mean of these two values.

For this model a comparison can be made between the length of the jet to the lower flammability limit and the length of the corresponding jet flame. The length of a turbulent jet flame has been given by Hawthorne, Weddell and Hottel (1949). Their equation is quoted in Chapter 16 as Equation 16.3.3. Rewriting this in Marshall's notation

$$z_F = \frac{5.3 d_o}{c_s}\left\{\frac{T_F}{\alpha T_o}\left[c_s + (1 - c_s)\left(\frac{M_a}{M_o}\right)\right]\right\}^{1/2} \quad [15.46.34]$$

where α is the ratio of the number of moles of unreacted and reacted gas and subscript F denotes the flame and s the stoichiometric mixture. Then, making the following assumptions,

$$T_o = T_a \quad [15.46.35a]$$

$$\frac{T_F}{\alpha T_o} \approx 8 \quad [15.46.35b]$$

$$c_s \approx 2c_L \quad [15.46.35c]$$

$$c_s(1 - c_s)\frac{M_a}{M_o} \approx \frac{M_a}{M_o} \quad [15.46.35d]$$

it can be shown from Equations 15.46.30 and 15.46.34 that

$$\frac{z_F}{z_L} = 0.83 \quad [15.46.36]$$

15.46.4 Buoyant plume

For the buoyant plume the basis of the model given by Marshall is the work of B.R. Morton, Taylor and Turner, (1956), Yih (1951) and Rouse, Yih and Humphreys (1952). The basic treatment is for neutral stability conditions, but other stability conditions are also taken into account, as described below.

For a buoyant plume the concentration in the plume is given by the equation

$$c(z, r)\,\frac{k_4 \dot{v}_o^{2/3}}{z^{5/3} g^{1/3}}\left(\frac{M_a T_o}{M_a T_o - M_o T_a}\right)^{1/3} \exp\left[-\left(\frac{k_5 r}{z}\right)^2\right] \quad [15.46.37]$$

where g is the acceleration due to gravity (m/s^2), $\dot{v}$ is the volumetric flow (m^3/s) and k_4 and k_5 are constants.

The equations for the length and volume of the flammable zone in the plume and for the mass of flammable gas in it are

$$z_L = \frac{k_4^{3/5} \dot{v}_o^{2/5}}{g^{1/5} c_L^{3/5}}\left(\frac{M_a T_o}{M_a T_o - M_o T_a}\right)^{1/5} \quad [15.46.38]$$

$$V_{FL} = \frac{5\pi k_4^{9/5} \dot{v}_o^{6/5}}{27 k_5^2 g^{3/5}}\left(\frac{M_a T_o}{M_a T_o - M_o T_a}\right)^{3/5}\left(\frac{1}{c_L^{9/5}} - \frac{1}{c_U^{9/5}}\right) \quad [15.46.39]$$

$$Q_{FL} = \frac{5\pi M_o k_4^{9/5} \dot{v}_o^{6/5}}{12 T_a k_5^2 g^{3/5}}\frac{273}{22.4} \times \left(\frac{M_a T_o}{M_a T_o - M_o T_a}\right)^{3/5}\left(\frac{1}{c_L^{4/5}} - \frac{1}{c_U^{4/5}}\right) \quad [15.46.40]$$

The dispersion is affected by three separate but related aspects of the atmospheric conditions. These are (1) the degree of turbulence, (2) the wind speed, and (3) the stability conditions.

These characteristics are not independent. Inversions in which the temperature increases with height occur more frequently in conditions of low turbulence and low wind speed. This is the combination of conditions least conducive to dispersion.

The effect of temperature gradient may be taken into account by using the parameter G:

$$G = \frac{g}{T_a}(\mathrm{d}T_a/\mathrm{d}z + \Gamma) \quad [15.46.41]$$

where Γ is the dry adiabatic lapse rate (= 0.0098°C/m). Equation 15.46.41 is related to the Richardson number.

It is not uncommon in the United Kingdom to have temperature gradients $\mathrm{d}T_a/\mathrm{d}z$ of the order of 0.01°C/m, while gradients of 0.1°C/m are not unknown. The corresponding values of the parameter Γ are:

dT_a/dz (°C/m)	G (s^{-2})
0 (isothermal)	0.000334
0.01	0.000674
0.1	0.00374

For an atmosphere in which the temperature gradient is greater than that of a neutral adiabatic atmosphere ($\Gamma > 0$) and in which these conditions continue sufficiently far upward, there will come a height at which the density of a plume of positive buoyancy equals that of the surrounding air. Marshall gives the following equation for the height of a plume based on the work of B.R. Morton, Taylor and Turner (1956):

$$z_{\max} = \frac{k_6 \dot{v}_o^{1/4}}{G^{3/8}} \left(\frac{M_a T_o - M_o T_a}{M_a T_o} \right)^{1/4} \qquad [15.46.42]$$

where k_6 is a constant.

Equation 15.46.42 sets a limit on the rise of the plume in stability conditions where the temperature increases with height. The plume height $z_{\max}$ calculated from Equation 15.46.42 may be compared with the height z_L at which the concentration reaches the lower flammability limit as given by Equation 15.46.38. If $z_{\max}$ is less than z_L, the plume does not rise sufficiently high to be diluted below the lower flammability limit.

The values of the constants used by Marshall are as follows. For k_4, the value recommended by Long as giving the maximum instantaneous concentration is 17, and this is used by Marshall. For k_5, Marshall assumes that the ratio k_5/k_4 is the same as for time mean values and thus obtains for k_5 a value of 13; for k_6 he uses the value of 6.65 given by B.R. Morton, Taylor and Turner (1956).

15.46.5 Comparative cloud sizes

J.G. Marshall (1977, 1980) has presented a number of illustrative calculations of the dimensions of and quantities of flammable material in clouds from a continuous source, a jet and a buoyant plume for hydrocarbon gases. J.G. Marshall (1980) gives the following summary of his equations.

Continuous source

$$Q_{FL} = \frac{0.321}{D^{0.59}} \frac{\dot{m}_o^{1.59}}{u^{1.59}} \left(\frac{1}{\chi_L^{0.59}} - \frac{1}{\chi_u^{0.59}} \right) \qquad [15.46.43]$$

Equation 15.46.43 is obtained from Equation 15.46.26 with the value of the index f applicable to Pasquill stability categories D–F, which is 1.7.

Momentum jet

$$Q_{FL} = 3.4\, \rho_a^{1.5} \left(\frac{\dot{m}_o}{w_o} \right)^{1.5} \left(\frac{1}{\chi_L^2} - \frac{1}{\chi_U^2} \right) \qquad [15.46.44]$$

Buoyant plume

$$Q_{FL} = \frac{1.45 T_o^{1.8}}{T_a^{1.8}} \left(\frac{\rho_a^{0.6} \rho_o^{0.6} \dot{m}_o^{12}}{\Delta \rho_o^{0.6}} \right) \left(\frac{1}{\chi_L^{0.8}} - \frac{1}{\chi_U^{0.8}} \right) \qquad [15.46.45]$$

with

$$\Delta \rho_o = \rho_a - \rho_o \qquad [15.46.46]$$

where $\dot{m}_o$ is the mass rate of release (kg/s), u is the wind speed (m/s), $\Delta\rho_o$, is the density difference between air and the gas (kg/m^3) and χ is the concentration (kg/m^3).

The results shown in the table below were obtained by J.G. Marshall (1977) for jets of methane and ethylene at 288 K, from Equations 15.46.30 and 15.46.32:

	M_o	c_L (v/v)	c_U (v/v)	z_L/d_o	$\dot{m}/d_o^2$ (kg/m^2 s)	Q_{FL}/d_o^3 (kg/m^3)	z_F/z_L
CH_4	16	0.05	0.15	243	236	1388	0.83
C_2H_4	28	0.027	0.36	340	304	4020	0.73

For buoyant plumes of the same gases at the same temperature, from Equations 15.46.38 and 15.46.42:

	$\dot{m}$ (kg/s)	z_L (neutral atmosphere) (m)	$z_{\max}$ *(stable atmosphere)*	
			$G = 0.00034$ (m)	$G = 0.001$ (m)
CH_4	100	181	374	248
	1000	455	665	441
C_2H_4	100	346	175	116
	1000	870	311	206

Marshall also gives results for jets of ethane, propane and n-butane and at temperatures of 423 and 573 K.

For buoyant plumes the results show the relation between the maximum height attained by the plume $z_{\max}$ and the height required for dilution to the lower flammability limit z_L. For methane, which has a large positive buoyancy, $z_{\max} > z_L$ approximately in all the cases considered. For ethylene, which has only a small positive buoyancy, $z_L > z_{\max}$ in all the cases considered.

Both for jets and buoyant plumes the residence time is of interest as giving the lower limit for the time required for the flammable cloud to form. For the cases of jets considered by Marshall the residence times within the flammable envelope were in the range 2.5–11 s for mass flows of 100 kg/s and 8–24 s for mass flows of 1000 kg/s. For the cases of plumes the minimum residence times were 3 and 5 s for mass flows of 100–1000 kg/s, respectively. The results also show that emission rates of 100–1000 kg/s can give rise to vapour clouds containing at least 1 te of flammable material.

In a second study extending the comparison to a continuous source also, J.G. Marshall (1980) gives the emission rates necessary to produce clouds containing given amounts of gas as follows:

Type of release	*Emission rate* (kg/s) *to give cloud containing*	
	1000 kg	10,000 kg
Continuous source	6–100	25–440
Jet	13–110	50–600
Buoyant plume	16–110	100–700

He also gives the graphical comparison shown in Figure 15.145. In each of the three cases the critical parameter is different: for the continuous source in Figure 15.145(a) it is the stability category and wind speed u; for the jet in Figure 15.145(b) it is the pipe velocity w_o; and for the buoyant plume in Figure 15.145(c) it is the hydrocarbon species. In the case of the continuous source calculation assumes a hypothetical hydrocarbon with lower and upper flammability limits of 0.039 and 0.176 kg/m^3, respectively. In the case of the jet, which is for a typical lower paraffin, the

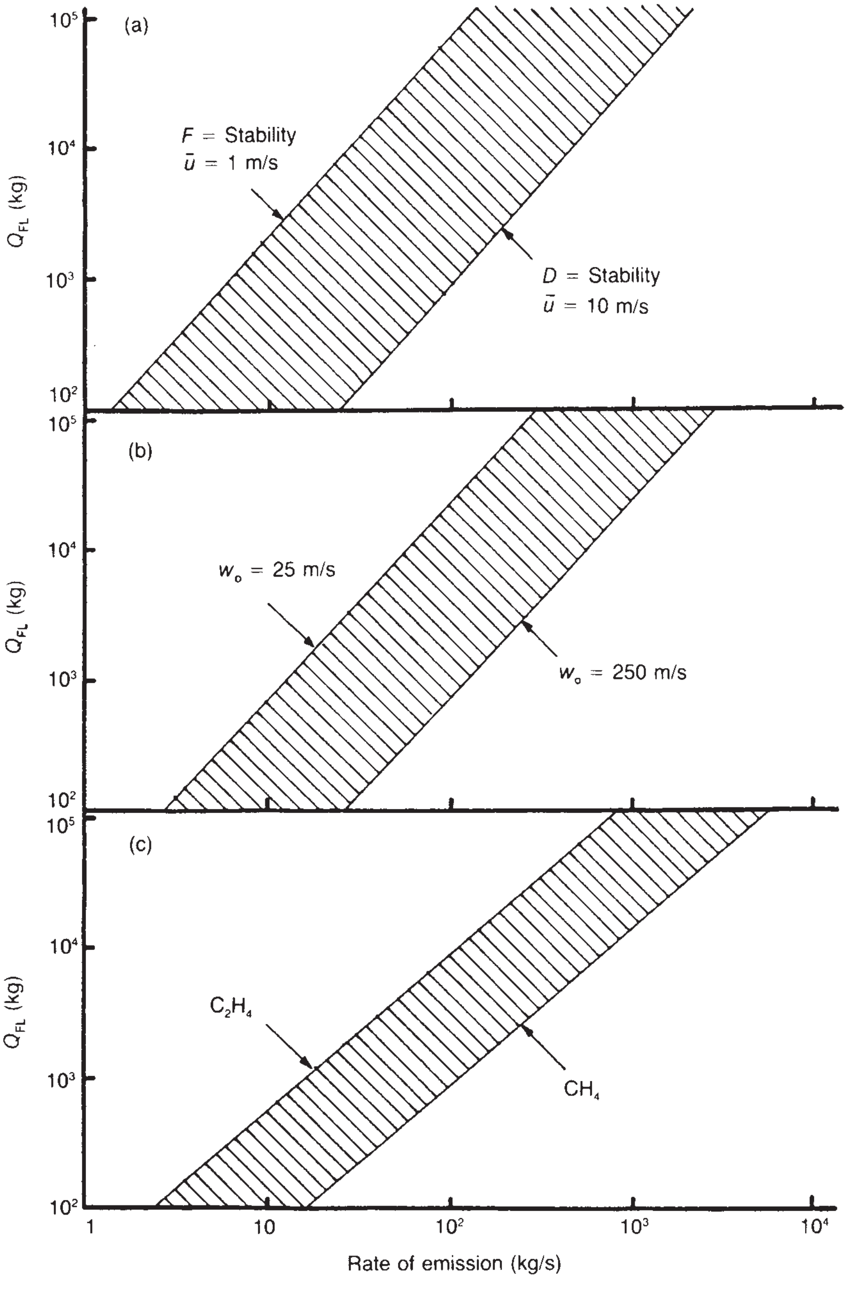

Figure 15.145 *Flammable gas clouds – mass of gas within flammable limits in gas cloud in some principal dispersion situations (J.G. Marshall, 1980): (a) passive gas dispersion; (b) jet dispersion; (c) plume dispersion. $\bar{u}$, mean wind speed; w_o, jet discharge velocity (Courtesy of the Institution of Chemical Engineers)*

lower pipe velocity is close to the limiting value below which jet dispersion would no longer be the controlling mechanism, while the upper velocity is close to the sonic velocity. In the case of the plume, methane has been taken as the most positively buoyant material likely to be of interest, other than hydrogen, while ethylene at 288 K represents the limiting gas density above which other modes of dispersion would predominate. This study indicates that in respect of the mass of gas within the flammable limits for a given size of release the three types of release appear remarkably similar.

15.46.6 Dense gas clouds

For dense gas clouds, the approach taken depends on the type of model used. A box model gives the cloud dimensions directly. The *Workbook* method gives correlations for the area within a given concentration.

15.46.7 Empirical relations

An empirical equation for the radius of a vapour cloud has been given in the Second Report of the Advisory Committee on Major Hazards (ACMH) (Harvey, 1979b):

$$R = 30M^{1/3} \quad [15.46.47]$$

where M is the mass of vapour (te) and R is the radius of the cloud (m).

Equation 15.46.47 is based on the assumption that the ratio of the cloud radius to cloud height is 5 : 1. It appears to agree reasonably well with the estimated size of the clouds at Flixborough and at Beek. If it is assumed that the quantities released in these two incidents were 40 and 5.5 te, respectively, the cloud sizes as calculated from Equation 15.46.47 are 103 and 53 m, which compare with the estimated cloud sizes of 102 m (kidney-shaped cloud) (Sadee, Samuels and O'Brien, 1976–77) and of 50 m (Ministry of Social Affairs, 1976), respectively.

15.46.8 Concentration fluctuations

It has long been recognized that the effect of concentration fluctuations is to extend beyond the nominal mean lower flammability limit (LFL) concentration values the range and the area of the cloud which is susceptible to ignition.

Feldbauer *et al.* (1972) allowed for this by the use of an effective limit, replacing the LFL value by an effective value, which they took as the 0.5 LFL value. This approach has been widely utilized.

It has been suggested by Pikaar (1985) that the Maplin Sands vapour cloud fire tests indicate that for this purpose use may be made of a practical peak/mean concentration ratio of 1.4, which translates to a 0.7 LFL value. The account given by this author is discussed in more detail in Chapter 17.

More sophisticated approaches may be used, based on the modelling of concentration fluctuations, as described in Section 15.45. In the work of Birch, Brown and Dodson (1980, 1981) on ignition in jets, the relationship between the gas concentration and the occurrence of ignition is expressed as a probability distribution.

A discussion of the problem in the context of dense gas dispersion has been given by McQuaid (1984a). The deficiencies of applying averaging to turbulence phenomena have been discussed by Spalding (1983). For instance, the average obtained depends on the averaging time selected. There is no simple solution.

15.46.9 Cloud size estimation procedures

A number of companies have developed procedures for estimating the size of the flammable vapour cloud to be considered in plant design. Essentially these define the scenarios to be treated, such as the size and duration of the leak. Accounts of such procedures include those by Exxon (n.d.), Brasie (1976a), FMRC (1990) and Industrial Risk Insurers (IRI) (1990), and a review is given by the CCPS (1994/15).

The procedure of Brasie (1976a) for a continuous leak utilizes for the leak rate from a short nozzle or pipe the relation

$$W_{\mathrm{lr}} = 2343P^{0.7} \quad [15.46.48]$$

where P is the operating pressure (bar) and W_{lr} is the mass flow per unit area (kg/m^2 s). The flow of vapour into the cloud is obtained from the flash fraction. The mass of vapour in the cloud above the LFL is a function of time. The maximum time is the time span for the cloud concentration to fall below the LFL. For this use is made of the relation

$$t = 516(W/Mf) \quad [15.46.49]$$

where f is the lower flammability limit (%), M is the molecular weight, W is the mass flow (kg/s) and t is the time span (s).

The CCPS (1994/15) describes an unpublished procedure of Exxon (n.d.). This distinguishes between releases of (1) gas, (2) liquid and (3) two-phase or flashing liquid. For a gas release, the mass of vapour entering the cloud is taken as the lesser of (1) the total inventory or (2) the product of the flow and the time to stop the leak. For a liquid release, the quantity spilled is taken as the lesser of (1) the total inventory or (2) the product of the flow and the time to stop the leak. The mass of vapour entering the cloud is then taken as the product of the liquid evaporation rate and the time to find a likely source of ignition. For a liquid which is two-phase or flashing, the mass of vapour entering the cloud is the lesser of (1) the total inventory times twice the flash fraction or (2) the product of the rate of release and the time to stop the leak and twice the flash fraction.

The procedure of the Factory Mutual Research Corporation (FMRC, 1990) is oriented towards the estimation of the loss potential in insurance. In this method the credible releases are taken as: (1) 10-min releases from (a) the largest connection on the largest vessel or vessel train, (b) atmospheric or pressure storage, credit being given for the operation of excess flow valves, or (c) above-ground pipelines conveying material from a remote, large capacity source; and (2) the total inventory of mobile tanks, such as tank trucks or rail tank cars.

Another insurance-related procedure is that of the Industrial Risk Insurers (IRI, 1990). For the catastrophic loss potential, the mass released is based on the content of vessels or vessel trains, storage tanks and pipelines to storage. For the latter a guillotine fracture is assumed with a release duration of 30 min. No credit is allowed for shut-off valves between vessels. For the probable maximum loss potential, a credible release is determined, allowing for the operation of emergency shut-off and blowdown. The minimum release is the inventory of the largest process vessel and the maximum that of the largest train of vessels which are interconnected and not isolated.

15.47 Toxic Gas Clouds

The effect of exposure to a cloud of toxic gas is a function of the concentration–time profile and of the toxic characteristics of the gas. An account of the concentration behaviour of gas clouds was given in Section 15.45, whilst the toxic characteristics of gases are described in Chapter 18. This section describes the attempts made to marry these two features.

15.47.1 Toxic load and probit

As described in Chapter 18, the inhalation toxicity of a gas is characterized by the toxic load L which produces some defined toxic effect which is typically of the form

$$L = \int_0^T C^n \, \mathrm{d}t \qquad [15.47.1a]$$

$$= C^n T \qquad [15.47.1b]$$

$$= \sum_{i=1}^{p} C_i^n t_i \qquad [15.47.1c]$$

where C is the concentration, L is the toxic load, t is the time, T is the time of exposure and n is an index.

The proportion of the exposed population which will suffer, or the probability that a single individual will suffer, this defined degree of injury is generally expressed in terms of a probit equation of the form

$$Y = k_1 + k_2 \ln L \qquad [15.47.2]$$

where Y is the probit and k_1 and k_2 are constants. The probability P of injury is a function of the probit Y. The use of probit equations is discussed in Chapter 9.

Equation 15.47.1 is the form typically taken by correlation of experimental work. There is usually little information on its applicability to combinations of values of (C,t) where C is high and t is short. There must therefore be doubt as to the appropriateness of applying it in a mechanistic way.

15.47.2 Intermittency and its effects

Griffiths and co-workers (R.F. Griffiths and Megson, 1984; R.F. Griffiths and Harper, 1985) have drawn attention to the implications of concentration intermittency when combined with the toxic load relation 15.47.1. The intermittency γ is defined as the fraction of time for which the concentration is zero:

$$\gamma = \frac{t_\mathrm{s} - t_\mathrm{pe}}{t_\mathrm{s}} \qquad [15.47.3]$$

where γ is intermittency and subscripts pe and s denote exposure and sampling, respectively. These authors define intermittency as the proportion of time the concentration is zero. The average concentration $\bar{C}$ is

$$\bar{C} t_\mathrm{s} = C_\mathrm{p} t_\mathrm{pe} \qquad [15.47.4]$$

where $\bar{C}$ is the average concentration and C_p is the concentration over time t_pe. Then from Equations 15.47.2–15.47.4

$$Y = k_1 + k_2 \ln\left[\left(\frac{1}{1-\gamma}\right)^{n-1} \bar{C}^n t_\mathrm{s}\right] \qquad [15.47.5]$$

For the usual case of $n > 1$, the probit Y, and hence the probability P of injury, increase as the intermittency increases. The effect can be pronounced.

15.47.3 Ride model

The model given by Ride (1984b) for concentration fluctuations in a passive plume was described above. He has applied this model to the determination of toxic load.

From Equation 15.45.27, with $\psi = 1$

$$\frac{C_\tau}{\bar{C}} = k\left(\frac{\sigma_\tau}{\bar{C}}\right)^\lambda + 1 \qquad [15.47.6]$$

From this equation, with Equation 15.45.24

$$[k(\sigma_\tau/\bar{C})^\lambda + 1]^{-1} = 1 - \gamma_\tau \qquad [15.47.7]$$

Then for a receptor with response time τ Ride obtains from Equation 15.47.la for toxic load with Equations 15.47.6 and 15.47.7

$$L = C_\tau^n (1 - \gamma_\tau) T \qquad [15.47.8]$$

$$= \bar{C}^n T \omega \qquad [15.47.9]$$

with

$$\omega = [k(\sigma_\tau/C)^\lambda + 1]^{n-1} \qquad [15.47.10]$$

where ω is an enhancement factor which takes account of concentration fluctuations.

The enhancement factor ω is never less than unity and can be large. Table 15.57 given by Ride shows values of this factor obtained taking Jones' values of $k = 11$ and $\lambda = 1.5$ with values of n quoted in the literature for several gases and with postulated values of the intensity $\sigma_\tau/\bar{C}$ the values of $\sigma_\tau/\bar{C}$ from Jones' data are about 1–2.

15.47.4 Wilson model

The model of D.J. Wilson (1982) for concentration fluctuations in a passive plume and for the distribution function of the concentration was given in Section 15.45. If the relevant effect is toxic concentration rather than toxic load, that model may be applied as described by D.J. Wilson and Simms (1985). The model gives the distribution function for concentration and from this it is possible to determine the distribution function for the probability of fatality given such concentration fluctuations.

This is obtained by the authors as follows. The probability F_c that the concentration will not exceed a value c is given by Equation 15.45.66. Then the probability V_c that it will exceed this value is the complement:

$$V_\mathrm{c} = 1 - F_\mathrm{c} \qquad [15.47.11]$$

V_c is the probability of exceeding the concentration c over the exposure time T_e. Over some small time δt_I, the probability of exceeding c is $V\delta t$ and that of not exceeding it is $1 - V\delta t$. If the number of breaths over time T_e is N_b the probability $S(T_\mathrm{e})$ of not exceeding c, and thus of surviving, is

$$S(T_\mathrm{e}) = (1 - VT_\mathrm{e}/N_\mathrm{b})^{N_\mathrm{b}}$$

$$= \exp(-VT_\mathrm{e}) \quad N_\beta \to \infty \qquad [15.47.12]$$

If the effect is one of toxic load, an extension of the model is required, giving the distribution function of the toxic load as defined by Equation 15.47.1b. This extension has been discussed by D.J. Wilson and Simms (1985) and D.J. Wilson (1991b).

Table 15.57 *Effect of variations in concentration on toxic load (Ride, 1984a) (Courtesy of Elsevier Science Publishers)*

Intensity of fluctuations $\sigma_\tau/\bar{C}$	*Enhancement factor,* ω		
	HCN $n = 1.8$	*Ammonia* $n = 2.0$	*Chlorine* $n = 2.75$
0	1.0	1.0	1.0
1	7.2	12.0	77.4
2	16.1	32.1	433
5	47.3	124	4607

An illustration of the effect of concentration fluctuations has been given by D.J. Wilson (1991b) for the case of continuous release of hydrogen sulphide using a value of $n = 2.5$ in Equation 15.47.1a. Figure 15.146(a) shows the contours for the probability of fatality given by the mean toxic load, Figure 15.146(b) those for the median load and Figure 15.146(c) those for the 99% percentile.

15.47.5 Davies model

A model for the effective dosage based on concentration and dosage distributions obtained from concentration profiles for an ensemble have been given by J.K.W. Davies (1987, 1989a).

J.K.W. Davies (1987) starts from a consideration of the ensemble of 21 concentration profiles obtained in the work at Warren Spring Laboratory (WSL) by D.J. Hall, Hollis and Ishaq (1982) shown in Figure 15.147(a). Analysis of the WSL data for concentration C showed that at the 95% confidence level the mean $\mu(C)$ is constant over the period 2.4–4.4 s and the standard deviation $\sigma(C)$ is constant over the range 2.4–5.4 s, as shown in Figure 15.147(b) and (c),

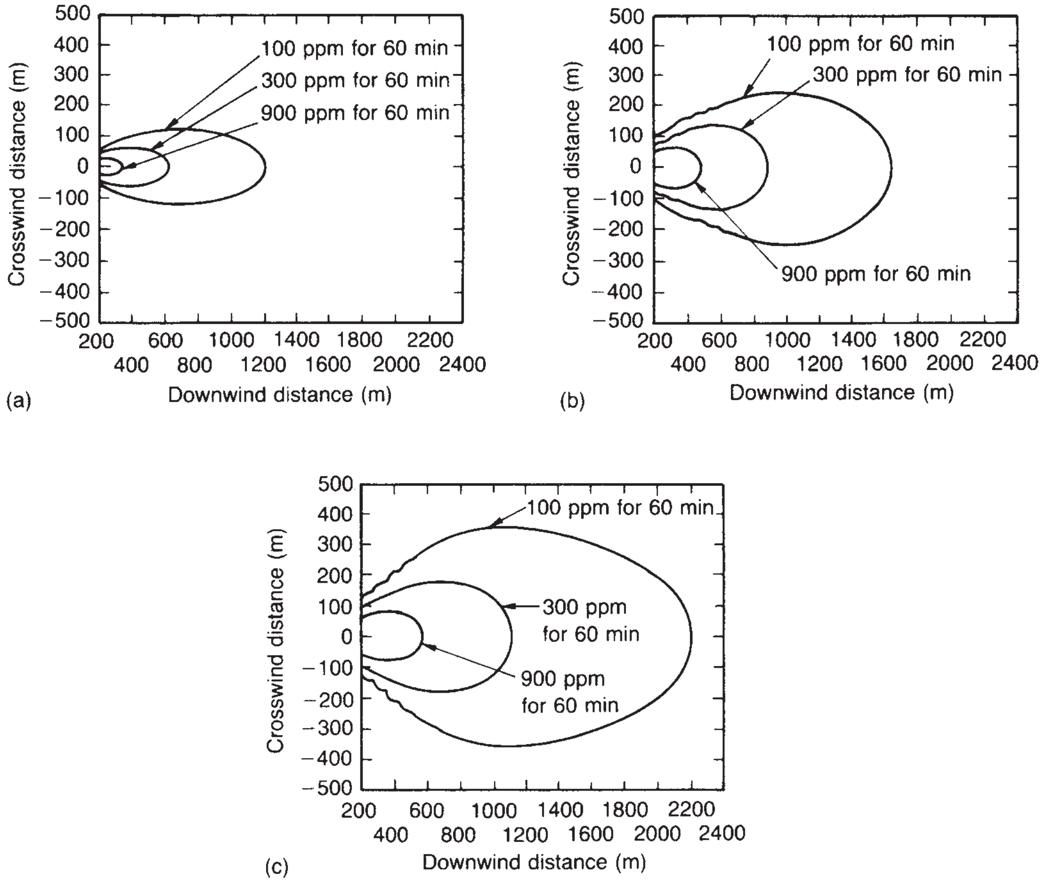

Figure 15.146 *Toxic gas clouds – contours of toxic load for a continuous release of hydrogen sulphide (D.J. Wilson, 1991a); (a) without concentration fluctuations; (b) with concentration fluctuations, median; (c) with concentration fluctuations, 99% percentile (Courtesy of the American Institute of Chemical Engineers)*

respectively. The variations of concentration at a given time between the members of the ensemble were fitted to various distributions. The distributions which best fitted the concentration varied over the time period, the log–normal distribution being the best for the critical period 1.7–2.7 s containing the concentration peak.

The distribution was also determined for dosage D, defined as

$$D(t) = \int_0^t C\,\mathrm{d}t \qquad [15.47.13a]$$

$$= Ct \qquad C = \text{constant} \qquad [15.47.13b]$$

and

$$D(t) = \int_0^t C^n\mathrm{d}t \qquad [15.47.14a]$$

$$= C^n t \qquad C = \text{constant} \qquad [15.47.14b]$$

where n is an index. In both cases the best fit was obtained using the log–normal distribution.

These findings have been applied by J.K.W. Davies (1989a) to devise a method of estimating the probability θ of fatality due to exposure to a toxic gas cloud. For this he utilizes the following alternative form of the probit relation. The probability θ of fatality is given by the distribution function ϕ:

$$\theta(D) = \phi(\delta) \qquad [15.47.15]$$

with

$$\delta = k\ln(D/D_{50}) \qquad [15.47.16]$$

where the dosage D is defined by Equation 15.47.14, D_{50} is the median fatal dosage, k is a constant and δ is a standardized log dose. The relation between Equations 15.47.28 and 15.47.15 is then

$$\phi^{-1}(\theta) = k\ln(D/D_{50}) \qquad [15.47.17a]$$

$$= -k\ln D_{50} + k\ln D \qquad [15.47.17b]$$

$$Y = \phi^{-1}(\theta) + 5 \qquad [15.47.18]$$

$$k_1 = 5 - k\ln D_{50}$$

$$k_2 = k$$

and

$$\phi(\theta) = (Y-5)^{-1} \qquad [15.47.19]$$

$$k = k_2 \qquad [15.47.20]$$

$$D_{50} = \exp\left(\frac{5-k_1}{k}\right) \qquad [15.47.21]$$

The model given by Davies is then as follows. The dose D is log-normally distributed. Thus, $\ln D$ is normally distributed:

$$\ln D = N[\ln\bar{D}, \sigma^2(\ln D)] \qquad [15.47.22]$$

where $N[\cdots]$ signifies the normal distribution and $\bar{D}$ is the mean dose. Then the standardized log dose δ, defined by

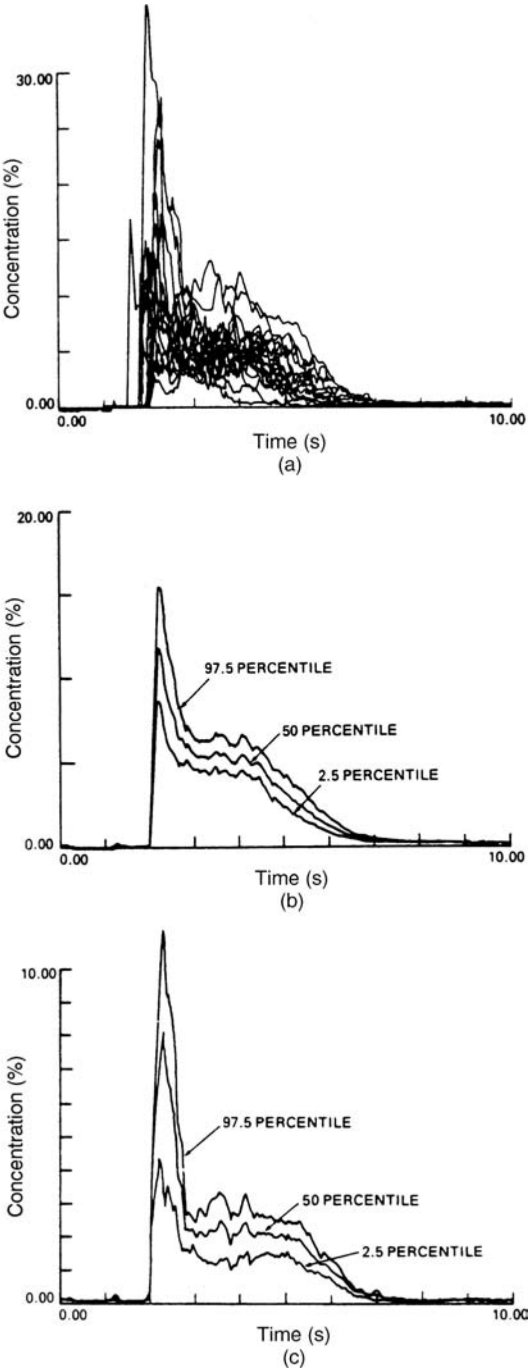

Figure 15.147 *Concentration fluctuations in gas dispersion – statistical parameters of a data set (J.K.W. Davies, 1987): (a) set of 21 concentration vs time traces obtained in repeat experiments in a wind tunnel (the WSL data set); (b) 95% confidence limits on mean concentration; (c) 95% confidence limits on ensemble standard deviation (Courtesy of Elsevier Science Publishers)*

equation [15.47.16], is also taken as normally distributed

$$\delta = N[\bar{\delta}, \sigma(\delta)] \qquad [15.47.23]$$

with

$$\bar{\delta} = k \ln(\bar{D}/D_{50}) \qquad [15.47.24]$$

$$\sigma^2(\bar{\delta}) = k^2 \ln(\ln D) \qquad [15.47.25]$$

where $\bar{\delta}$ is the mean standardized log dose.

An effective dose D^* is defined as the dose which gives rise to the same mean number of fatalities as would be obtained by averaging the number of fatalities observed in successive realizations of the ensemble in which dose D is allowed to vary log–normally.

An effective standardized log dose δ^* is also introduced, defined as the standardized log dose which gives rise to the same mean number of fatalities as would be obtained by averaging the number of fatalities observed in successive realizations of the ensemble in which the standardized log dose δ is allowed to vary normally. It is defined as

$$\delta^* = k \ln(D^*/D_{50}) \qquad [15.47.26]$$

An ideal gas dispersion model will produce for the standardized log dose a prediction $\bar{\delta}$ and the corresponding probability of fatality will be $\phi(\bar{\delta})$. The true probability of fatality is $\phi(\delta^*)$. The difference $\phi(\delta^*) - \phi(\bar{\delta})$ is a measure of the error in the prediction of fatality, even by an ideal model due to variations between members of the ensemble.

The equivalent standardized log dose δ^* may be determined by selecting values of δ from the normal distribution, calculating the corresponding values of the probability of fatality $\phi(\delta)$ and taking the mean value of this probability as $\phi(\delta^*)$. Table 15.58 (from Davies) shows the results of such a calculation.

The case of $\sigma(\delta) = 0$ corresponds to no concentration fluctuation, whilst $\sigma(\delta) = 1$ is typical of the value in the body of the cloud and $\sigma(\delta) \gg 1$ of values at the edges. For $\bar{D} > D_{50}$ the use of $\bar{\delta}$ instead of δ^* results in an overestimate of the probability of fatality, whilst for $\bar{D} < D_{50}$ it results in an underestimate. This misestimate is less than 10% in absolute terms for $\sigma(\delta) < 1$, but for $\sigma(\delta) > 1$ it becomes progressively greater, reaching a value of about 30% at $\sigma(\delta) = 5$.

An illustrative example is shown in Table 15.59. The case considered is the toxic effects 1000 m downwind of a 20 te release of chlorine in $D/3$ conditions. The index n is taken as 3.49, which is at the upper end of the range of published estimates. The effect of concentration fluctuations on toxic load is most marked towards the edges of the cloud.

15.48 Dispersion over Short Distances

It is necessary in some applications, particularly in relation to plant layout, to estimate dispersion over short distances.

15.48.1 Dispersion of passive plume

The relationships for passive dispersion are commonly used over relatively large distances, but the question of the range of his model was specifically considered by O.G. Sutton (1950). He describes experiments on the dispersion of a vertical jet of hot gas for which he obtained a value of the diffusion coefficient C. This value is similar to that obtained in the dispersion of smoke from a smoke generator over a distance of 100 m, provided that for comparability use is made in the latter case of the instantaneous rather than the time width of the plume. Sutton states:

> This leads to the striking conclusion that the same coefficient of diffusion is valid for the spread of smoke over hundreds of meters as for the mixing of a tiny column of hot air with the cold air of a laboratory.

The use of the Sutton model for estimation of dispersion in relation to hazard areas around vents has been treated by Long (1963), who devotes an appendix to the applicability of the model over short ranges. He discusses both the basic assumptions and the available experimental results. He reviews the assumptions systematically and finds no fundamental inapplicability for short ranges. In particular, the semi-angle of divergence of the roughly conical plume predicted using the values given by Sutton for the diffusion coefficient is about 10° and 16° in the vertical and horizontal directions, respectively, which compares well with semi-angles in the range 9–16° found for jets and plumes.

Table 15.58 *Effect of variations in dose between members of an ensemble on predicted fatality: $\phi(\delta^*) - \phi(\bar{\gamma})$ (J.K.W. Davies, 1989a) (Courtesy of Elsevier Science Publishers)*

$\sigma(\delta)$	$\phi(\delta^*) - \phi(\delta)$			
	δ			
	0	1	2	3
0	0	0	0	0
0.2	0	0	0	0
0.5	0	–0.03	–0.02	0
1	0	–0.08	–0.06	–0.02
2	0	–0.17	–0.17	–0.09
5	0	–0.20	–0.28	–0.29

Table 15.59 *Effect of variations in dose between members of an ensemble on predicted fatality: 20 te chlorine release*[a] *(J.K.W. Davies, 1989a) (Courtesy of Elsevier Science Publishers)*

Crosswind distance (m)	$\ln C^n t$	Y	δ	σ	$\phi(\delta)$	$\phi(\delta^*) - \phi(\delta)$
52	28.80	8	3	0.5	1	0
215	26.84	6.04	1.04	1	0.85	–0.08
235	26.32	5.52	0.52	1.2	0.70	–0.04
287	24.96	4.16	–0.84	2	0.20	–0.17

[a] Table relates to conditions 1000 m downwind of an instantaneous release of 20 te chlorine in $D/3$ conditions, assuming a source term in which 400 te of air is entrained. The cloud radius, defined as 10% of the centre line concentration, at this distance is 417 m.

[b] Toxicity parameters: $n = 3.49$; $k = 1$; $\ln D_{50} = 25.8$.

The only experimental work found by Long was that of Katan (1951). Using values of the Sutton coefficient based on a 3-min sampling time, Long found that the Sutton equations tend to overestimate the concentration somewhat.

15.48.2 Dispersion of dense gas plume

Some guidance on the dispersion of a dense gas plume over short ranges has been given by McQuaid (1980) in the context of the design of water spray barriers. He takes the plume as issuing at an angle of 35° and having a height of 1 m.

15.48.3 Dispersion from vents and reliefs

It is common practice in the process industries to discharge material to atmosphere. Intended discharges occur through chimneys, vents and relief devices. The treatment here is mainly confined to the problem of the safety of discharges occurring in an emergency, usually as a result of the operation of relief devices. Discharges to flare are discussed in Chapter 12 and disposal of material vented from chemical reactors in Chapters 12 and 17.

Recent years have seen a marked tightening up in the extent to which discharge to atmosphere is permissible and, although the situation varies as between countries, the trend is clear. Accounts of safe discharge include those given in the various editions of API RP 520 and RP 521 and by Long (1963), Loudon (1963), Bodurtha, Palmer and Walsh (1973) and Gerardu (1981). The topic is also frequently discussed by authors of models developed to assist with this problem.

An early review is that by Loudon (1963), who identifies the hazards arising from such a release as including, for flammable or toxic material

(1) hazardous concentration, particularly at ground level; and, for flammables
(2) vapour cloud explosion;
(3) jet flame.

Another hazard is flashback of flame into a vent.

For discharges, a distinction is to be made between those which have high momentum and/or buoyancy and those which do not. If the release has a high velocity, and thus high momentum, this promotes entrainment of air and dilution of the cloud. Another aspect is the height to which the material discharged travels before it starts to descend to the ground, the effective 'stack' height. This is increased if the release has high buoyancy and, for a discharge directed upwards, high momentum.

Safe discharge is generally addressed by a combination of engineering measures and hazard assessment. The former centre mainly on the height of the vent and on the velocity of the discharge, whilst the latter involves the use of suitable models to assess the hazards listed above.

Widespread use has been made of the equation in API RP 520 for the estimation of concentration of contaminant as a function of distance for use in high velocity discharge calculations based on the recommendations on discharge velocity. This equation is given in Chapter 12.

There are a considerable number of models for the estimation of the ground level concentration resulting from an elevated release. They include: the early models of Bosanquet (1935) and Bosanquet and Pearson (1936); O.G. Sutton (1952); the Pasquill model (Pasquill, 1961) and the Pasquill–Gifford model (Pasquill, 1961, 1962; Gifford, 1961); the model of Cude (1974b); and that of G.A. Briggs (1965, 1969). Other models have been developed to obtain the ground level concentration for elevated releases of a dense gas. Amongst these are the models of Hoot, Meroney and Peterka (1973), Bodurtha, Palmer and Walsh (1973), Ooms, Mahieu and Zelis (1974), Jagger and Edmondson (1984), Emerson (1986a), J.L. Woodward (1989a) and McFarlane (1991). Accounts of many of these models are given in Sections 15.20, 15.43 and 15.44.

The mass of gas from a discharge which is within the flammability limits and thus available to participate in a vapour cloud fire or explosion may be obtained from models of jets and plumes. There are also some models which specifically address this problem. These include the families of models given by Hess and co-workers (Hess and Stickel, 1970; Hess, Leuckel and Stoeckel, 1973), J.G. Marshall (1977, 1980), Palazzi *et al.* (1984) and Stock and co-workers (Stock and Geiger, 1984; Stock, 1987; Stock, Geiger and Giesbrecht, 1989). The effects of ignition may be estimated using models for vapour cloud fires or explosions, which are dealt with in Chapters 16 and 17, respectively.

Ignition of a sustained high momentum discharge gives a jet flame. Early models of jet flames developed for the assessment of such situations include those by Craven (1972, 1976) and Kovacs and Honti (1974). There are now a number of jet flame models, as described in Chapter 16.

Several authors have described sets of models used for the estimation of the hazards from discharges. They include Kovacs and Honti (1980) and Gerardu (1981). The models cover ground level concentration, jet flame radiation and vapour cloud overpressure.

Mention has already been made of the work of Katan (1951) on safe dispersion distances for aircraft fuelling. More recent work in this area has been described by Thorne (1986), who gives models for the plumes from circular, slot and elliptical vents. The results from these models show distances for dilution of the jet fuels below the LFL in the range 1.5–4 m.

15.48.4 ASME equation

A formula for plume rise from a momentum source widely used in design for safe discharge is that given by the American society of Mechanical Engineers (ASME, 1969/1). This is

$$h = D\left(\frac{v_s}{u}\right)^{1.4} \qquad [15.48.1]$$

where D is the internal diameter of the stack (m), Δh is the plume rise (m), v_s is the velocity of the stack gas (m/s) and u the wind speed at stack height (m/s).

The equation quoted for the maximum concentration at ground level is Equation 15.16.55. The applicability of the ASME equation is to a stack gas which is essentially of neutral density.

15.48.5 Bodurtha and Walsh method

An early method for safe discharge which applies to a dense gas mixture is that of Bodurtha and Walsh, described in Bodurtha, Palmer and Walsh (1973). Figure 15.133 shows photographs of the simulation of a dense gas plume in a wind tunnel obtained by these workers. The difference between the three tests lies in the density of the gas discharged relative to that of air, the relative densities in Figures 15.133(a)–(c) being 1.0, 1.52 and 5.17, respectively.

On the basis of these admittedly limited tests, Bodurtha and Walsh obtained the following design equation:

$$h_s = 1.33ED^2 \qquad [15.48.2]$$

where D is the diameter of the vent tip (ft), E is the number of dilutions with air of the stack gas required to reduce its concentration to the lower flammability limit and h_s is the height of the vent above the exposure level (ft). As a design equation, the relation is conservative. The authors state their belief that it contains ample safety factors. They also say, however, that it is intended only for short period releases of dense gases.

15.48.6 Hanzevack method

Another experimentally based method is that by Hanzevack (1982), who conducted tests in which he measured the ground level concentration from elevated releases of both ambient and high density gas mixtures. He gives a model for the ground level concentration due to a continuous emission which is based on a modification of the ASME plume rise formula described in Section 15.48.4. The modification allows for differences in the density of the stack gas mixture and includes a constant to improve the fit to his experimental data.

The equations given by Hanzevack for the plume rise from a momentum source and for the maximum ground level concentration are

$$\Delta h = C_1 D\left(\frac{v_s}{u}\right)^{1.4}\left(\frac{\rho_a}{\rho_s}\right)^{1.4} \qquad [15.48.3]$$

and

$$\chi_{cr} = C_2 \frac{Q}{h^{1.29}D^{0.71}v_s}\left(\frac{\rho_s}{\rho_a}\right) \qquad [15.48.4]$$

where D is the internal diameter of the stack (m), h is the height of the stack (m), Δh is the plume rise (m), Q is the mass rate of release (g/s), u is the wind speed (m/s), v_s is the stack gas outlet velocity (m/s), ρ is the density of the gas mixture (kg/m^3), χ_{cr} is the critical ground level concentration (μg/m^3) and subscripts a and s denote air and stack gas, respectively. The relations apply to a 1-h time-averaged concentration.

C_1 and C_2 are empirical constants obtained from the experimental data. In adjusting concentrations averaged over other time periods to the 1-hour average, use was made of Equation 15.16.45 with a value of the index p measured as 0.5.

For design, a more conservative approach is suggested with the two constants C_1 and C_2 replaced by constants C_3 and C_4, respectively. The values given for the four constants are:

	C_1	C_2	C_3	C_4
$\rho_s \le \rho_a$	6	0.012	3	0.02
$\rho_s > \rho_a$	2	0.027	1	0.044

The more conservative values thus incorporate a safety factor of about 2.

15.48.7 Method of de Faveri, Hanzevack and Delaney

Recognizing that in many instances the release of interest is not a continuous one, but a relatively short one, de Faveri, Hanzevack and Delaney (1982) have described an extension to Hanzevack's method which allows for this. The authors conducted experiments in which 10-min time-averaged concentrations were measured for (1) continuous releases and (2) 10-min releases, and obtained the ratio of the two time-averaged concentrations. This ratio should theoretically lie between 1 and 3. Their results indicate a ratio of approximately 2.

15.48.8 Bodurtha method

In addition to the method of Bodurtha and Walsh, described in Section 15.48.5, Bodurtha (1988) has also given another method for safe discharge of dense flammable gases.

The method is based on an adaptation of the Hoot, Meroney and Peterka (HMP) model. As discussed by Bodurtha (1980), the touchdown concentration passes through a maximum with stack gas outlet velocity, which the author terms the critical stack gas outlet velocity $v_{s,cr}$. The expression given by the author for this velocity is

$$v_{s,\,cr} = \frac{3.73D^{0.684}(\beta C_s/L)^{1.05}}{u^{0.368}A^{2.05}} \times 10^{-3} \qquad [15.48.5]$$

with

$$A = s^{0.67}/(s-1)^{0.33} \qquad [15.48.6]$$

$$s = M_w T_a/29T_s \qquad [15.48.7]$$

$$C_m = L/\beta \qquad [15.48.8]$$

where C_m is the maximum permissible value of the touchdown concentration of the contaminant (% v/v), C_s is the concentration of the contaminant in the stack gas (% v/v), D is the internal diameter of the stack (mm), L is the lower flammability limit (% v/v), M_w is the molecular weight of the stack gas mixture, s is the specific gravity of the stack gas mixture relative to air, T_a is the absolute temperature of the ambient air (K), T_s is the absolute temperature of the stack gas (K), u is the wind speed (m/s), v_s is the velocity of the stack gas (m/s), A is a parameter, β is the applicable peak/mean concentration ratio, and subscript cr denotes critical. The value of the touchdown concentration C_m passes through a maximum with specific gravity, this maximum occurring at a value of $s = 2$, and thus $A = 1.59$.

Substitution of the critical value $v_{s,cr}$ of the stack gas outlet velocity in the HMP model yields the following expression for the required height of the stack:

$$h_s = \frac{43.8D^{1.35}(\beta C_s/LA)^{1.05}}{u^{0.702}} \times 10^{-6} \qquad [15.48.9]$$

where h_s is the height of the stack (m).

The model is applicable to a release directed vertically upwards and only for stack gas specific gravity $s > 1.15$ and for stack gas outlet velocity v_s less than the choked, or sonic, value. The author suggests that for design purposes the value of the wind speed be taken as $u = 1$ m/s.

For the peak/mean concentration ratio ft Bodurtha quotes minimum and maximum values of 2.5 and 5, respectively, and states that the former is used in current practice. This method is conservative in that the calculation of the required stack height is based on the critical value $v_{\mathrm{s,cr}}$ of the stack outlet velocity, whereas use of the actual stack outlet velocity v_{s} will generally give a much lower stack height.

Bodurtha gives several sample calculations. As an illustration, consider the first of his examples. The problem is stated in terms of the following values of the variables:

$$C_{\mathrm{s}} = 100\ \mathrm{v/v};\quad L = 2.2\%\ \mathrm{v/v};\quad M_{\mathrm{w}} = 44;\quad T_{\mathrm{a}} = 298\,\mathrm{K};$$
$$T_{\mathrm{s}} = 298\,\mathrm{K};\quad u = 1\,\mathrm{m/s};\quad v_{\mathrm{s}} = 152.3\,\mathrm{m/s};\quad \beta = 2.5$$

Hence $s = 1.52$, $A = 1.64$, $v_{\mathrm{s,cr}} = 8.6$ m/s and $h_{\mathrm{s}} = 6.6$ m. The degree of conservatism is indicated by the fact that the actual velocity v_{s} is very much greater than the critical value $v_{\mathrm{s,cr}}$.

15.49 Hazard Ranges for Dispersion

It is convenient for certain purposes, such as comparison of models or preliminary hazard assessment, to have simple expressions for the downwind extent of particular concentrations, such as lower flammability limits or toxic concentrations; in other words, for the hazard range.

The variables which enter into the simpler correlations are generally the concentration, the downwind distance, the mass rate of release and the wind speed, and the treatment here is confined to these.

15.49.1 Passive dispersion

For passive dispersion of an instantaneous release from a point source the relevant expression in the Pasquill-Gifford model is Equation 15.16.40b. Considering concentration at the centre of the cloud at ground level so that $x = ut$, $y = 0$ and $z = 0$, this equation reduces to

$$x \propto \frac{Q^*}{\sigma_x \sigma_y \sigma_z} \qquad [15.49.1]$$

From the correlations of Slade given in Table 15.31 and noting that it is usual to take $\sigma_x = \sigma_y$:

$$\sigma_x = \sigma_y \propto x^{0.92} \qquad [15.49.2a]$$

$$\sigma_z \propto x^{0.7} \qquad [15.49.2b]$$

Then relations 15.49.1 and 15.49.2 give for the hazard range x

$$x \propto Q^{*0.39} \qquad [15.49.3]$$

In this case the hazard range is a function of the mass released, but not of the wind speed.

For passive dispersion of a continuous release from a point source the relevant expression in the Pasquill–Gifford model is Equation 15.16.41. Considering concentration on the centre line at ground level so that $y = 0$ and $z = 0$ this equation reduces to

$$x \propto \frac{Q}{\sigma_y \sigma_z u} \qquad [15.49.4]$$

From the correlations given in Table 15.31

$$\sigma_y \propto x^{0.9} \qquad [15.49.5a]$$

$$\sigma_z \propto x^{0.85} \qquad [15.49.5b]$$

Then relations 15.49.4 and 15.49.5 give for the hazard range χ

$$x \propto \left(\frac{Q}{u}\right)^{0.57} \qquad [15.49.6]$$

In this case the hazard range is a function both of the mass rate of release and of the wind speed.

15.49.2 Dense gas dispersion

It is less easy to derive analytical expressions for the hazard range of a dense gas. One approach is to correlate results from a number of runs of a dense gas dispersion model. The *Second Canvey Report* gives for an instantaneous release the following correlation derived from DENZ for propane and butane:

$$R = kM^{0.4} \qquad [15.49.7]$$

where M is mass of release (te), R is the downwind range (km) and k is a constant. It also gives the following additional relations for distance (km): maximum width $= k_1R$; distance to maximum width, $X = k_2R$, and upwind range $= k_3R$. The values of the constants are shown in Table 15.60.

A more detailed treatment on the same lines has been given by Considine and Grint (1985), who used DENZ and CRUNCH to obtain for propane and butane correlations for instantaneous and continuous releases, respectively. For a quasi-instantaneous release they give for any given distance or dimension L the relation

$$L = kM^n \qquad [15.49.8]$$

where L is a distance/dimension (m), M is the mass released (te), k is a constant and n is an index for the

distance/dimension L. These parameters are given for the following dimensions: R_{LFL}, the downwind range to the LFL (m); R_{UFL} the downwind range to the UFL (m); U_{LFL}, the upwind range to the LFL (m); $Y_{\max}$, the maximum crosswind range of the LFL (m); and h the height of the cloud (m).

The crosswind distance Y at any distance R downwind is given by

$$Y = Y_{\max}\left\{1 - 4\frac{[R - (R_{\mathrm{LFL}} - U_{\mathrm{LFL}})/2]^2}{(R_{\mathrm{LFL}} + U_{\mathrm{LFL}})^2}\right\}^{1/2} \qquad [15.49.9]$$

For the cloud radius R_c at any downwind distance R

$$R_c = R_{LFL} - R \qquad R > R_{cr} \qquad [15.49.10]$$

$$R_c = [Y_1^2 + (R - X_1)^2]^{1/2} \qquad R < R_{cr} \qquad [15.49.11]$$

with

$$R_{cr} = R_{LFL} - \frac{2Y_{max}^2}{R_{LFL} + U_{LFL}} \qquad [15.49.12]$$

$$X_1 = \left[R - \frac{4Y_{max}^2(R_{LFL} - U_{LFL}}{2(R_{LFL} + U_{LFL})^2}\right] \Big/ \left[1 - \frac{4Y_{max}^2}{(R_{LFL} + U_{LFL})^2}\right] \qquad [15.49.13]$$

$$Y_1 = Y_{max}\left\{\frac{1 - 4[X_1 - (R_{LFL} - U_{LFL})/2]^2}{(R_{LFL} + U_{LFL})^2}\right\}^{1/2} \qquad [15.49.14]$$

where R is the downwind distance (m), R_c is the radius of the cloud (m), R_{cr} is a range transition criterion value (m), X_1 is a downwind dimension (m), Y is the crosswind distance (m) and Y_1 is a crosswind dimension (m).

For a continuously formed cloud the authors give for any given distance or dimension L the relation

$$L = k\dot{m}_v^n \qquad [15.49.15]$$

where L is a distance/dimension (m), $\dot{m}_v$ is the mass rate of release of vapour (kg/s), k is a constant and n is an index for the distance/dimension L. These parameters are given for the following dimensions: R_{UFL}, the downwind range to the LFL (m); R_{UFL}, the downwind range to the UFL (m); h, the height of the cloud (m); and k^*, a constant (defined below). Then for a downwind distance R the crosswind distance Y is

$$Y = k^* R^{2/3} \qquad [15.49.16]$$

The values of the constants are shown in Table 15.61. The flammable inventory of the cloud is

$$I = \frac{\dot{m}_v R_{LFL}}{u} \qquad [15.49.17]$$

where I is the inventory (kg) and u is the wind speed (m/s).

The authors also give guidance for the case of a flammable gas cloud where the release is neither truly instantaneous nor continuous, but transient. The procedure suggested is to evaluate R_{LFL} and the arrival time T_a from

$$T_a = R_{LFL}/u \qquad [15.49.18]$$

where T_a is the arrival time (s). The release is treated as continuous if $T_d > T_a/4$, where T_d is the duration of the release (s); otherwise the release is treated as an instantaneous one, based on the total mass released over the duration time.

Correlations obtained in this way are only as good as the model from which they are derived. The reliability of the hazard ranges predicted by dense gas dispersion models has been discussed in Section 15.41.

Explicit expressions for the downwind extent, or hazard range, are given in the *Workbook* by Britter and McQuaid (1988). For an instantaneous release Equation 15.34.21 gives for the downwind distance x

$$x \propto Q_o^{0.25} u_{ref}^{0.5} \qquad [15.49.19]$$

where Q_o is the volume released, u_{ref} is the wind speed at the reference height and x is the downwind distance. For a continuous release Equation 15.34.10 yields

$$x \propto q_o^{0.4} \qquad [15.49.20]$$

where q_o is the volumetric rate of release. In this case there is no dependence on wind speed. Further details, including the range of applicability of these equations, are given in Section 15.34.

15.50 Transformation and Removal Processes

There are various transformation and removal processes which a gaseous or particulate pollutant may undergo in the atmosphere. These may need to be considered in relation to acute accidental releases, although in general they are more relevant to long-term pollution. Accounts of these processes include those given by Chamberlain (1953), van der Hoven (1968), Csanady (1973), Hosker (1974), Gifford (1976a), Hales (1976) and S.R. Hanna, Briggs and Hosker (1982). Processes of transformation and removal include:

(1) chemical transformations;
(2) physical transformations;
(3) dry deposition
    (a) gravitational settling,
    (b) small particle deposition;
(4) wet deposition
    (a) rainout,
    (b) washout.

An account is now given of the models and parameters for these various processes.

15.50.1 Chemical transformations

Atmospheric reactions may occur in the gaseous or aqueous phase and may be conventional reactions or photochemical reactions. There is a large literature on atmospheric chemistry which includes Chemistry of the Atmosphere (McEwan and Phillips, 1975), Atmospheric Chemistry (Heicklen, 1976) and Atmospheric Chemistry (Meszaros, 1981). Information on conventional reactions is given in standard texts and information on photochemical reactions is given by Leighton (1961), Calvert and Pitts (1966) and Demerjian, Kerr and Calvert (1974). A review of atmospheric photochemical reactions is given by Hales (1976).

The decay of concentration due to chemical reaction is frequently modelled by a first order decay model:

$$\chi(t) = \chi(0)\exp(-t/\tau_c) \qquad [15.50.1]$$

where χ is the concentration of the pollutant and τ_c is a chemical decay time constant.

From Equation 15.50.1, the half-life $t_{1/2}$ of the concentration is

$$t_{1/2} = 0.693/\tau_c \qquad [15.50.2]$$

15.50.2 Physical transformations

Physical transformations are relevant principally to liquid particles, or aerosols. They include: nucleation, in which a liquid particle is created by condensation of vapour; condensation, in which further vapour condenses onto an existing particle; and coagulation, in which particles come together to form a larger particle. Another relevant physical process is the absorption of soluble gas in water particles.

A case of particular relevance here is the behaviour of ammonia in humid air. A detailed discussion is given by Haddock and Williams (1978 SRD R103). An outline of their treatment of ammonia is presented in Section 15.42.

15.50.3 Dry deposition

In dry deposition of particles from a plume there are two distinct regimes. Deposition of larger particles is governed essentially by gravitational settling, while that of smaller particles is determined by turbulent motion.

Gravitational settling of the larger particles, say of radius >5 μm, is given by Stokes law, or modifications of it. Stokes law, for spherical particles, is

$$v_t = \frac{2r^2 g \rho_p}{9\mu} \qquad [15.50.3]$$

where r is the radius of the particle, v_t is the terminal velocity of the particle, μ is the viscosity of the air, and ρ_p is the density of the particle.

For particles of radius greater than about 10–30 μm, Stokes' law requires modification to take account of inertia and slip flow. Terminal velocities incorporating these corrections have been given by Hage (1964) for a particle of density 5 g/cm^3. Hage's work is described by van der Hoven (1968), and a plot derived from this work by S.R. Hanna, Briggs and Hosker (1982) is shown in Figure 15.148. For a particle of another density ρ_{p2} the corresponding value of the terminal velocity v_{t2} may be obtained from the standard value of the density ρ_{p1} and from the velocity v_{t1} as given by the figure using the approximate relation, based on Equation 15.50.3:

$$v_{t2} = v_{t1}\frac{p_{p2}}{p_{p1}} \qquad [15.50.4]$$

For a non-spherical particle, an equivalent radius r_e may be defined as

$$r_e = \left(\frac{3V_p}{4\pi}\right)^{1/3} \qquad [15.50.5]$$

where V_p is the volume of the particle. The terminal velocity v_{tn} of the particle may be estimated from the terminal velocity v_{ts} of a spherical particle with radius r equal to its equivalent radius r_e using an empirical dynamical shape factor α defined by

$$v_{tn} = v_{ts}/\alpha \qquad [15.50.6]$$

Values of the dynamical shape factor are given by Chamberlain (1975). For a cylinder with a 1 : 1 ratio of axes the value of the factor is 1.06 and for a ratio of 4 : 1 it is 1.32.

As stated above, the gravitational settling regime starts at a particle radius of about 5 μm, which corresponds to a terminal velocity of about 1 cm/s. There are a number of models for dry deposition and the appropriate model depends on the regime, and hence on the particle radius. For deposition of particles with a terminal velocity > 100 cm/s, which corresponds to a radius of about 100 μm, it is suggested by van der Hoven that gravitational settling is so fast that it may be determined from the terminal velocity and the wind speed using a conventional ballistic approach.

For particles with terminal velocity in the range 1–100 cm/s the deposition rate ω is defined as

$$\omega = v_g \chi \qquad [15.50.7]$$

where v_g is the fall velocity.

The main model in this regime is the tilted plume model for an elevated source. In this model the height H of the source is modified with distance by the term xv_g/u as shown in Figure 15.149. Then the Sutton relation for a release from an elevated continuous point source given in Equation 15.16.29 may be modified to give

$$\chi = \frac{2Q}{\pi C_y C_z u x^{2-n}} \exp\left\{-x^{n-2}\left[\frac{y^2}{C_y^2} + \frac{(H - xv_g/u)^2}{C_z^2}\right]\right\} \qquad [15.50.8]$$

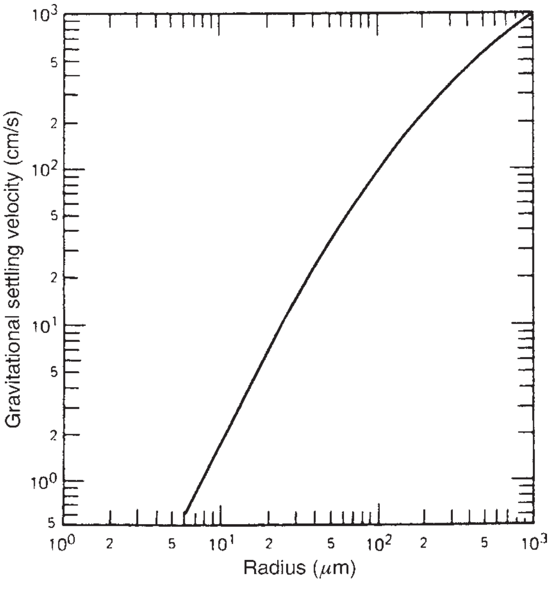

Figure 15.148 *Dry deposition from a dispersing cloud – gravitational settling speed of particles near earth's surface (S.R. Hanna, Briggs and Hosker, 1982). Particle density 5 g/cm^3*

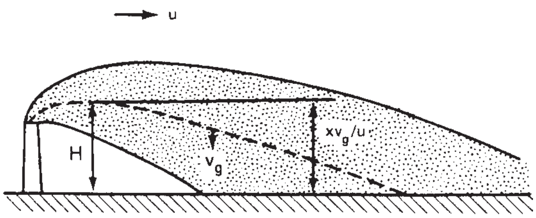

Figure 15.149 *Dry deposition from a dispersing cloud – tilted plume model (S.R. Hanna, Briggs and Hosker, 1982)*

The effect of depletion of the cloud may be taken into account by modifying Equation 15.50.7 by a depletion factor F, so that the deposition rate becomes

$$\omega = F v_g \chi \qquad [15.50.9]$$

This depletion factor has been given by Csanady (1955) as

$$F = 1 - \frac{1}{(1 - n/2)(Hu/xv_g - 1) + 2} \qquad [15.50.10]$$

The tilted plume model is applicable only in the well-mixed boundary layer such as occurs in daytime adiabatic conditions.

For smaller particles with a terminal velocity of <1 cm/s, the deposition rate is defined in terms of the deposition velocity v_d:

$$\omega = v_d \chi \qquad [15.50.11]$$

Models available for the deposition of such particles are discussed by van der Hoven (1968). One is the model by Chamberlain (1953). For a ground level continuous point source this author modifies the Sutton relations to obtain for an initial source strength Q_o an effective source strength Q_x at distance x using the depletion term

$$\frac{Q_x}{Q_o} = \exp\left(-\frac{4v_d x^{n/2}}{nu\pi^{1/2}C_z}\right) \qquad [15.50.12]$$

This correction is then applied to Sutton's relation for a release from a ground level continuous point source given by Equation 15.16.27 to yield for the ground level concentration

$$\chi(x, y, 0) = \frac{2Q_x}{\pi C_y C_z u x^{2-n}} \exp\left(-x^{n-2}\frac{y^2}{C_y^2}\right) \qquad [15.50.13]$$

and for the deposition rate from Equations 15.50.11 and 15.50.13

$$\omega = \frac{2Q_x v_d}{\pi u C_y C_z^{2-n}} \exp\left(-x^{n-2}\frac{x^{n-2}y^2}{C_y^2}\right) \qquad [15.50.14]$$

Chamberlain has also given a model for an elevated source.

An alternative model given by van der Hoven is derived from the Pasquill–Gifford equations. The depletion of the source is obtained as follows:

$$\frac{dQ_x}{dx} = \int_{-\infty}^{\infty} \omega \, dy$$

$$= -\left(\frac{2}{\pi}\right)\frac{v_d Q_x}{u\,\sigma_z}\exp\left(-\frac{h^2}{2\sigma_z^2}\right) \qquad [15.50.15]$$

which on integration yields

$$\frac{Q_x}{Q_o} = \left[\exp\int_0^x \frac{dx}{\sigma_z \exp(h^2/\sigma_z^2)}\right]^{-(2/\pi)^{1/2}(v_d/u)} \qquad [15.50.17]$$

This correction is then applied to the Pasquill–Gifford equation for a release from an elevated continuous point source (Equation 15.16.43) to yield for the ground level concentration

$$\chi(x, y, 0) = \frac{Q_x}{\pi\sigma_y\sigma_z u}\exp\left[-\left(\frac{y^2}{2\sigma_y^2} + \frac{h^2}{2\sigma_z^2}\right)\right] \qquad [15.50.18]$$

and for the deposition rate from Equations 15.50.11 and 15.50.18

$$\omega = \frac{Q_x v_d}{\pi\sigma_y\sigma_z u}\exp\left[-\left(\frac{y^2}{2\sigma_y^2} + \frac{h^2}{2\sigma_z^2}\right)\right] \qquad [15.50.19]$$

Evaluations of Equation 15.50.17 based on numerical integration have been made by van der Hoven (1968) for Pasquill categories A–F for a wind speed $u = 1$ m/s and a deposition velocity $v_d = 10^{-2}$ m/s. Figure 15.150 shows

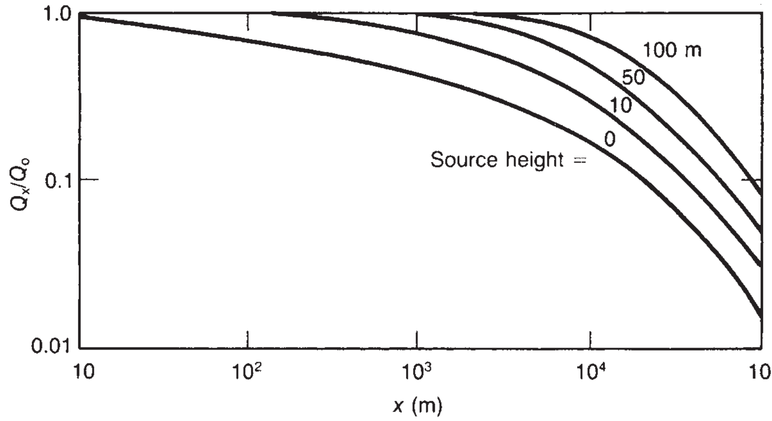

Figure 15.150 *Dry deposition from a dispersing cloud – effect of distance on source depletion fraction (van der Hoven, 1968). Weather conditions D/1; wind speed = 1 m/s; deposition velocity* 10^{-2} *m/s*

his plot for D conditions, while Table 15.62 summarizes the other plots in terms of the times at which Q_x falls to half its initial value of Q_o. For other wind speeds and deposition velocities use may be made of the relation

$$\left(\frac{Q_x}{Q_o}\right)_2 = \left(\frac{Q_x}{Q_o}\right)_1^{u_1 v_{d2}/u_2 v_{d1}} \qquad [15.50.20]$$

where subscripts 1 and 2 refer to the standard conditions used by van der Hoven, as given in Figure 15.150, and to the conditions of interest, respectively.

Another model used for small particles is the partial reflection model of Overcamp (1976). The model is based on the Pasquill–Gifford relations and incorporates both the tilted plume approach to deal with the gravitational settling of larger particles and a reflection coefficient α which qualifies the 'image' term, or term containing $(z + h)$. The basic equation is

$$\begin{aligned}\chi(x,y,z) &= \frac{Q}{2\pi\sigma_y\sigma_z u}\exp\left(-\frac{y^2}{2\sigma_y^2}\right) \\ &\quad\times\left(\exp\left\{-\frac{[z-(h-v_t x/u)]^2}{2\sigma_z^2}\right\}\right. \\ &\quad\left.+\,\alpha(x_G)\exp\left\{-\frac{[z+(h-v_t x/u)]^2}{2\sigma_z^2}\right\}\right) \qquad [15.50.21]\end{aligned}$$

where

$$\alpha(x) = 1 - \frac{2v_d}{v_t + v_d + (uh - v_t x)\sigma_z^{-1}(\mathrm{d}\sigma_z/\mathrm{d}x)} \qquad [15.50.22]$$

and where x_G is obtained from the implicit equation

$$\left(h - \frac{v_t x_G}{u}\right)\frac{\sigma_z(x)}{\sigma_z(x_G)} = z + \left(h - \frac{v_t x}{u}\right) \qquad [15.50.23]$$

***Table 15.62** Source depletion fraction Q_x/Q_o given by the van der Hoven model for dry deposition (after van der Hoven, 1968)*

Pasquill stability category	*Source height* (m)	*Distance* (m)			
		10	100	1000	10,000
A	0	0.90	0.82	0.75	
	10	1.0	0.96	0.90	
	100	1.0	1.0	1.0

	10	0.98	0.95	0.80	
	100	1.0	1.0	1.0	
C	0	0.90	0.70	0.60	0.45
	10	1.0	1.0	0.80	0.60
	100	1.0	1.0	1.0	0.80
E	0	0.90	0.60	0.15	0.012
	10	1.0	1.0	0.80	0.10
	100	1.0	1.0	1.0	0.80
F	0	0.90	0.65	0.40	0.07
	10	1.0	1.0	0.80	0.20
	100	1.0	1.0	1.0	0.80

Another model is the surface depletion model of Horst (1977).

A comparison of the models available has been made by Horst (1979), who found that in the near field the partial reflection model was reasonably accurate and easy to use, while in the far field the source depletion model performed better.

These models incorporate the deposition velocity which, as described below, is subject to considerable uncertainty and may be at least as great a source of error as inadequacies in a particular model.

15.50.4 Deposition velocity

Reviews of the deposition velocity, which include extensive data, have been given by McMahon and Denison (1979) and by Sehmel (1980). The deposition velocity is defined by Equation 15.50.11. It should be noted that the surface area for deposition implied in this equation is the normal ground surface area, not the actual vegetation surface, which can be much greater.

Sehmel lists a large number of variables which affect deposition velocity, divided into four categories: meteorology, surface, particle and gas. For particles of diameter >1 μm gravitational settling is dominant, while the movement of particles of diameter <0.1 μm is governed by Brownian motion. The deposition velocity tends to pass through a minimum with particle diameter and it may vary by two orders of magnitude. These effects are illustrated in Figure 15.151, which shows the variation of deposition velocity with particle diameter for grass surfaces.

Deposition velocity is applicable to gases also. Inert gases have almost negligible deposition velocity, say $10^{-4} - 10^{-3}$ cm/s, but chemically or biologically active gases tend to have a much larger deposition velocity, typically in the range 0.5–3 cm/s. Of interest in the present context are the deposition velocities of toxic gases. From data given by Sehmel, the ranges of deposition velocities of some typical toxic gases are as follows:

Gas	*Deposition velocity* (cm/s)
Cl_2	1.8–2.1
SO_2	0.04–7.5
HF	1.6–3.7
H_2S	0.015–0.38

Deposition velocity is affected very strongly by the surface on which deposition takes place. Again there are order of magnitude differences between different surfaces. Surfaces differ in the actual vegetation surface exposed. They also have different retention properties. Some deposition velocities for selected surfaces are shown in Figure 15.152.

Deposition velocity is also affected by wind speed, roughness length and friction velocity, but these effects are less readily characterized and are a matter of some debate.

A method for prediction of deposition velocity has been given by Sehmel and Hodgson (1978), but prediction remains subject to considerable uncertainty.

15.50.5 Wet deposition

In wet deposition due to rain, a distinction may in principle be made between scavenging within clouds (or rainout) and below clouds (or washout), but in practice these two are generally treated as a single process.

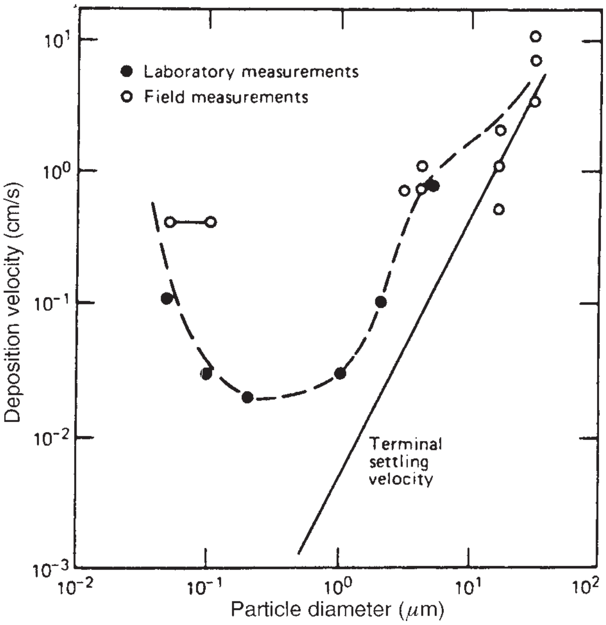

***Figure 15.151** Dry deposition from a dispersing cloud – effect of particle diameter on deposition velocity of particles to grass (McMahon and Denison, 1979) (Courtesy of Pergamon Press)*

Wet deposition of a pollutant is often treated empirically in terms of the washout ratio W_r:

$$W_r = k_o/\chi_o \qquad [15.50.24]$$

where χ is the concentration of pollutant in the air, k is the concentration of pollutant in the rainwater and subscript o denotes the reference height.

Use is also made of an alternative washout ratio W'_r

$$W'_r = \rho_a k'_o/\chi_o \qquad [15.50.25]$$

where k' is the concentration of pollutant in the rainwater and ρ_a is the density of air. The difference between k and k' is that the first has units of mass per unit volume and the second has units of mass per unit mass. The relation between the two washout ratios is:

$$W'_r = \rho_a W_r/\rho_w \qquad [15.50.26]$$

where ρ_w is the density of water. The flux of pollutant to the surface F_w is

$$F_w = k_o J_o \qquad [15.50.27]$$

where J_o is the equivalent rainfall rate. Hence from Equation 15.50.24

$$F_w = W_r \chi_o J_o \qquad [15.50.28]$$

A wet deposition velocity v_w may be defined

$$\begin{aligned} v_w &= F_w/\chi_o && [15.50.29a] \\ &= W_r J_o && [15.50.29b] \end{aligned}$$

An alternative approach is that based on the washout coefficient, or scavenging coefficient Λ. The decay of the concentration of pollutant due to scavenging is frequently modelled by a first-order decay model

$$\chi(t) = \chi(0)\exp(-\Lambda t) \qquad [15.50.30]$$

It may readily be shown, by deriving Equation 15.50.8 from the unsteady-state mass balance, that the same washout coefficient may also be defined in terms of the relation between the interphase transport rate w and the concentration χ:

$$w = \Lambda\chi \qquad [15.50.31]$$

The flux of pollutant F_w through a wetted plume of height z_w is

$$\begin{aligned} F_w &= \int_0^{z_w} w\,dz && [15.50.32a] \\ &= \int_0^{z_w} \Lambda\chi\,dz && [15.50.32b] \end{aligned}$$

For a Gaussian plume from a continuous point source the concentration χ may be obtained from Equation 15.16.41. Then, integrating this equation with respect to z from 0 to ∞, the effective concentration χ_e over the height z_w is

$$\chi_e = \frac{Q}{(2\pi)^{1/2}\sigma_y u z_w}\exp\left(-\frac{y^2}{2\sigma_y^2}\right) \qquad [15.50.33]$$

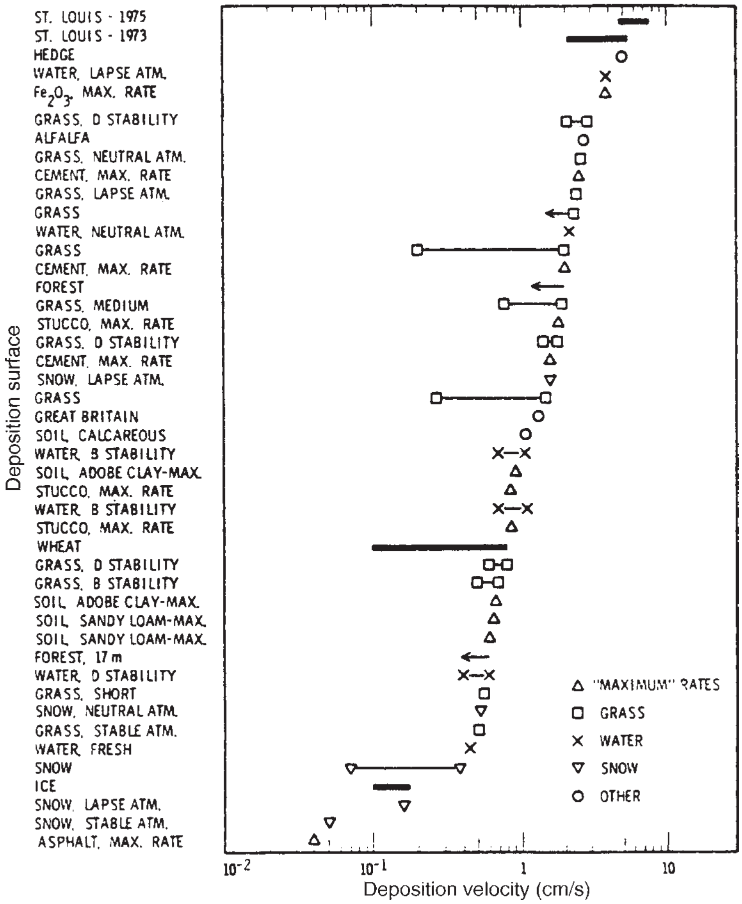

***Figure 15.152** Dry deposition from a dispersing cloud – effect of deposition surface on deposition velocity of sulfur dioxide (Sehmel, 1980) (Courtesy of Pergamon Press)*

Assuming constant Λ and substituting χ_e from Equation 15.50.33 for χ in Equation 15.50.32b gives

$$F_w = \frac{\Lambda Q}{(2\pi)^{1/2}\sigma_y u}\exp\left(\frac{y^2}{2\sigma_y^2}\right) \qquad [15.50.34]$$

On the centre line

$$F_w = \frac{\Lambda Q}{(2\pi)^{1/2}\sigma_y u} \qquad [15.50.35]$$

The use of a constant washout coefficient is a rather crude approximation. Strictly, it is applicable only to single size, or monodisperse, rain drops. Data on the washout coefficient for polydisperse systems have been given by Dana and Hales (1976).

It may be noted that for a polydisperse system the use of the geometric mean drop size tends appreciably to underestimate the washout coefficient. Another problem in the use of a constant washout coefficient concerns the absorption of gas in rain drops. If an absorbed gas does not undergo an irreversible reaction, it is liable to be desorbed as it passes through a zone of lower gas concentration.

15.50.6 Washout ratio and washout coefficient

The washout ratio W_r is an essentially empirical parameter. Data on the washout ratio have been given by McMahon and Denison (1979). The washout ratio tends to decrease with rainfall. As a rule of thumb, it halves for each order of magnitude increase in rainfall. The washout coefficient, or scavenging coefficient, Λ has been estimated theoretically for certain situations. The following relation has been given by Chamberlain (1953):

$$\Lambda = \int_0^{s_{max}} A_s N_s v_s E \, ds \qquad [15.50.36]$$

where A_s is the cross-sectional area of a drop of radius s, N_s is the number of drops per unit volume per unit time, v_s is the velocity of the drops and E is the collection efficiency and subscript max denotes maximum.

Chamberlain used Equation 15.50.36 to determine theoretical values of the washout coefficient as a function of the velocity v_s and the rainfall, as shown in Figure 15.153. Experimental work by F.G. May (1958) on the washout of Lycopodium spores has shown good agreement with theory, as shown in Table 15.63.

The washout coefficient is a function of the physical and chemical characteristics and of the raindrop size distribution and the rainfall. In many cases where the system is not so well defined as that just described theoretical estimates may be less satisfactory. In such cases it is necessary to fall back on empirical values. Data on the washout coefficient have been given by McMahon and Denison (1979).

15.51 Infiltration into Buildings

In most toxic release scenarios, the major part of the population in the path of the gas cloud is likely to be indoors. The mitigating effect of such shelter can be appreciable. It is therefore necessary to be able to estimate the indoor concentrations. Discussions of air infiltration relevant to hazard assessment have been given in Meteorology and Atomic Energy (Slade, 1968) and the Rasmussen Report (AEC, 1975) and by Haastrup (1984) and P.C. Davies and Purdy (1986).

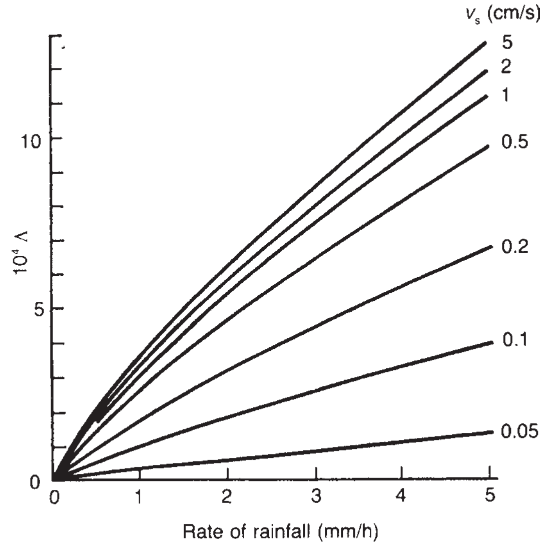

Figure 15.153 *Wet deposition from a dispersing cloud – effect of rate of rainfall on washout coefficient (Chamberlain, 1953) (Adapted from Deposition of Aerosols and Vapours in Rain, graph of A.C. Chamberlain (1955), the original graph being used by kind permission of AEA Technology)*

The degree of protection given by a building depends on the frequency of the air changes, or ventilation rate. The latter is a function of the construction and topographical situation of the building, of the wind speed and direction, of the difference between the outside and inside temperatures and of the number of doors and windows left open.

15.51.1 Models of infiltration

The infiltration of air into a building is usually modelled by assuming that the air in the building space is perfectly mixed so that

$$\frac{dc_i}{dt} = \lambda(c_o - c_i) \qquad [15.51.1]$$

where c is the concentration (various units), t is the time (h) and λ is the ventilation constant (h^{-1}) and subscripts i and o refer to indoor and outdoor, respectively. The ventilation constant is equal to the frequency of the air changes, is generally also referred to as the ventilation rate and is most often expressed as air changes per hour (ach). Imperfect mixing may be allowed for, as described below.

In the general case, where the outdoor concentration profile $c_o t$ is arbitrary, the indoor concentration is obtained from Equation 15.51.1 numerically.

For the case where the outdoor concentration profile, or forcing function, takes the form of a pulse, with

$$c_o(t < t_o) = c_o \qquad [15.51.2a]$$

$$c_o(t > t_o) = 0 \qquad [15.51.2b]$$

as shown in Figure 15.154(a), an analytical solution is available. If the outdoor concentration undergoes a step change from zero to c_o and then persists to time t_o, the rise of the indoor concentration is obtained by integrating Equation 15.51.1 to give

$$c_i = c_o[1 - \exp(-\lambda t_o)] \qquad [15.51.3]$$

Table 15.63 *Washout coefficient for Lycopodium spores (after May, 1958) (Courtesy of The Royal Meteorological Society)*

Type of rain	*Rate of rainfall* (mm /h)	*Wind velocity* (cm/s)	*Washout coefficient,* $\Lambda\ 10^{-4}$/s	
			Observed	*Theoretical*
Frontal	3.91	320	10.2	9.7
Frontal	1.12	543	4.2	3.6
Heavy frontal	14.1	845	30.8	26.8
Frontal	1.01	334	3.2	3.2
Continuous rain of showery type	3.64	332	8.9	9.2

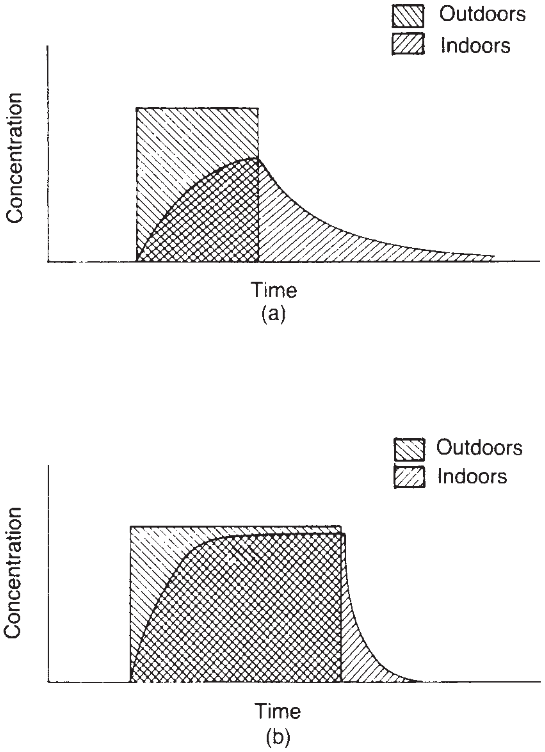

Figure 15.154 *Infiltration of gas into buildings – outdoor and indoor concentration profiles for a rectangular pulse forcing function (Pietersen, 1986c): (a) short pulse, low ventilation rate; and (b) long pulse, high ventilation rate*

If the outdoor concentration then falls to zero, the decay of the indoor concentration from its maximum value $c_i(t_o)$ is again obtained by integrating Equation 15.51.1:

$$c_i = c_i(t_o)\exp[-\lambda(t - t_o)] \qquad [15.51.4]$$

$$= c_o[1 - \exp(-t_o)]\exp[-\lambda(t - t_o)] \qquad [15.51.5]$$

This yields the concentration profile shown in Figure 15.154(b).

This rectangular pulse model may be used to obtain an approximate estimate of the indoor concentrations both for a puff from a nominally instantaneous release and for a plume from a short-duration continuous release. For a long-duration continuous release the appropriate model is a step forcing function and the indoor concentration is given by Equation 15.51.3.

In assessing the effect of a toxic gas, however, it is frequently necessary to work in terms of toxic dose or, more generally, toxic load rather than of concentration. The toxic dose is defined as

$$D = \int c\,\mathrm{d}t \qquad [15.51.6]$$

and the toxic load is generally defined as

$$L = \int c^n\,\mathrm{d}t \qquad [15.51.7]$$

where D is the toxic dose (units h) and L is the toxic load (units^n h).

It is shown below that for the pulse model the ratio of the indoor dose D_i to the outdoor dose D_o is unity. For the step model it is readily shown from Equation 15.51.3 that

$$\frac{D_i}{D_0} = 1 - \frac{1 - \exp(-\lambda t)}{\lambda t} \qquad [15.51.8]$$

An extension of the pulse model in terms of toxic load has been given by Haastrup (1984), who has derived the following relations:

$$L_o = \int c_o^n\,\mathrm{d}t \qquad [15.51.9]$$

$$L_i(t < t_o) = \int_0^{t_o} c_i^n\,\mathrm{d}t \qquad [15.51.10a]$$

$$= c_o^n \int_0^{t_o} [1 - \exp(-\lambda t)]^n\,\mathrm{d}t \qquad [15.51.10b]$$

$$L_i(t > t_o) = \int_{t_o}^{\infty} c_i^n\,\mathrm{d}t \qquad [15.51.10c]$$

$$= c_o^n \frac{[1 - \exp(-\lambda t_o)]^n}{\lambda^n} \qquad [15.51.10d]$$

The ratio R of the indoor to the outdoor toxic load is then

$$R = \frac{[1 - \exp(-\lambda t_o)]^n}{n\lambda t} + \frac{1}{t}\int_0^{t_o} [1 - \exp(-\lambda t)]^n\,\mathrm{d}t \qquad [15.51.11]$$

It may be noted that if $n = 1$, Equation 15.51.11 simplifies to

$$R = \frac{D_i}{D_o} = 1 \qquad [15.51.12]$$

For low values of the group λt_o it can be shown that

$$L_i(t > t_o) \gg L_i(t < t_o) \qquad [15.51.13]$$

In other words, the total indoor load is dominated by the load during the decay period, or tail. For this case

$$\exp(-\lambda t) \approx 1 - \lambda t \quad \lambda t < 0.1 \qquad [15.51.14]$$

Then

$$L_i \approx L_i(t > t_o) \qquad [15.51.15]$$

and from Equations 15.51.10b and 15.51.14

$$L_i = \frac{c_o^n t_o^n \lambda^{n-1}}{n} \qquad [15.51.16]$$

If the building space is not perfectly mixed, the effect of imperfect mixing may be taken into account in the model by substituting for the ventilation rate λ an effective ventilation rate λ'. The effective ventilation rate may be determined by applying to the ventilation rate a mixing efficiency factor k:

$$\lambda' = k\lambda \qquad [15.51.17]$$

15.51.2 Ventilation rate

The ventilation of a building may be natural or mechanical. For the assessment of toxic hazard it is normally natural ventilation which is relevant. Information on ventilation is available from a number of sources. These include *Principles of Modern Building* (Building Research Establishment, 1959), the CIBS *Guide Part 1 A4 Air Infiltration* (Chartered Institute of Building Services, 1976) and BS 5925: 1991 *Code of Practice: Ventilation Principles and Designing for Natural Ventilation*.

The equations for air infiltration given by these sources have been reviewed by Brighton (1986). They are all based on following relation:

$$Q = k_1 A\left(\frac{\Delta p}{\rho_o}\right)^{1/2} \qquad [15.51.18]$$

where A is the area of the aperture (m^2), Δp is the pressure drop (N/m^2), Q is the volumetric flow of air (m^3/s), ρ_o is the density of the ambient air (kg/m^3) and k_1 is a constant. Equation 15.51.18 is based on Bernouilli's theorem and the constant is related to the contraction ratio of the emerging jet. For this constant k_1 Brighton gives a compromise value of 0.88.

Work on air infiltration into houses is done for a number of purposes. These include the comfort of the occupants, the safety of gas appliances and the saving of energy. In the latter case the emphasis is on eliminating infiltration, and work in this area illustrates the high degree of leak-tightness which can be achieved.

Studies of air infiltration into houses in Britain have been done at the Building Research Establishment (BRE). Work has been published by Dick (1949, 1950a,b), Dick and Thomas (1951), Brundrett (1977) and Warren and Webb (1980a,b).

Air infiltration is due to the existence of pressure difference between the outside and inside of the building and this pressure difference may be caused by wind or by air temperature, and hence air density, or buoyancy, difference. The ventilation rate due to wind effects may be expressed as

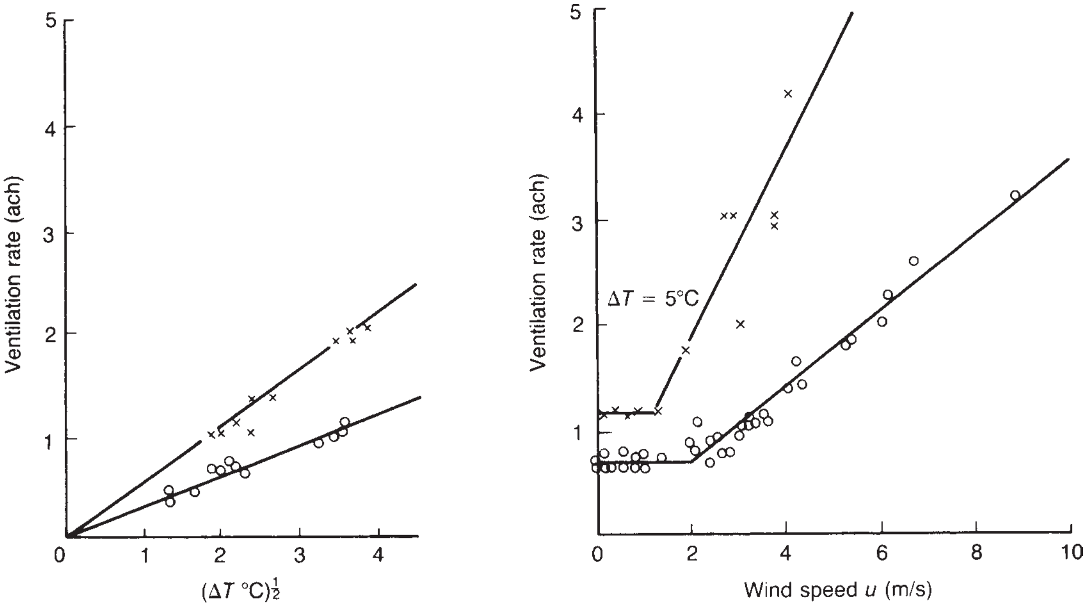
$$\lambda_w = k_2 u \qquad [15.51.19]$$

and that due to buoyancy effects as

$$\lambda_b = k_3(\Delta T)^{1/2} \qquad [15.51.20]$$

where ΔT is the temperature difference between outdoors and indoors (°C), u is the wind speed (m/s), λ_b is the ventilation rate due to buoyancy (m^3/h), λ_w is the ventilation rate due to wind (m^3/h), and k_2 and k_3 are constants. Figure 15.155 shows data obtained by Dick and Thomas (1951) in work at the BRE on the effect of temperature difference and wind speed on ventilation rate.

In considering ventilation rate it is necessary to distinguish between closed houses and occupied houses, the



(a)

(b)

Figure 15.155 *Infiltration of gas into buildings – effect of buoyancy and wind on house ventilation rate (Dick and Thomas, 1951): (a) effect of buoyancy (temperature difference); (b) effect of wind speed,* ○, *house with no vents open;* ×, *house with three bedroom vents open. (Courtesy of the Chartered Institution of Building Services Engineers)* difference being that the latter typically have some windows open. The BRE work includes correlations for the ventilation rate of a closed house as a function of wind speed. P.C. Davies and Purdy (1986) have presented versions of these equations modified so that the wind speed is that at the standard 10 m height. These are:

Exposed site

$$\lambda = 0.87 + 0.13u \qquad [15.51.21]$$

Sheltered site

$$\lambda = 0.88 \quad u < 4.2 \qquad [15.51.22a]$$

$$\lambda = 0.22u \quad u > 4.2 \qquad [15.51.22b]$$

Davies and Purdy give the following relation as the most recent BRE infiltration model:

$$\lambda = \lambda_s(k_4\Delta T^{1.2} + k_5u^{2.4})^{0.5} \qquad [15.51.23]$$

where λ_s is the ventilation rate measured at standard conditions (h^{-1}) and k_4 and k_5 are constants.

The distribution of infiltration between the different apertures in the building has been investigated by Warren and Webb (1980b). For a typical house with a pressure difference of 50 Pa and an air infiltration rate of 3000 m^3/h they found the following distribution:

	Contribution to air infiltration	
	(m^3/h)	(%)
Windows and WC fan	940	31.3
Back door	280	9.3
Skirting boards	575	19.2
Lights, plugs, pipes, etc.	85	2.8
Other sources	1120	37.4

For occupied houses it is necessary to take into account the effect of open windows. The relation given by Dick and Thomas (1951) for houses with open windows is

$$\lambda = 0.87 + 0.13u + 0.23(n + 1.4m) + 0.05(n + 1.4m)u \qquad [15.51.24]$$

where m is the number of open casement windows and n is the number of open top-vent windows. Equation 15.51.24 is based on a study on an estate at Abbotts Langley. The following data were obtained on the number of windows open:

	Abbotts Langley	*Bucknalls Close*
Casement windows open, m	0.25	0.4
Vent windows open, n	1.75	3

Abbotts Langley is an exposed site and Bucknalls Close a sheltered one.

The number of windows open depends on a number of factors, including the degree of exposure, the season, the time of day, the wind speed, the outside temperature and the number of occupants. These factors are discussed in detail by Davies and Purdy. Many of the factors tend to cancel out. For example, the number of windows open on an exposed site tends to be less than on a sheltered site. Likewise, the number open in summer is greater than in winter, but the buoyancy effect is less.

Information on room ventilation rates from the work of Warren and Webb is given Table 15.64. The best estimates of whole house ventilation rates given by Davies and Purdy are shown in Table 15.65.

Data for air infiltration into British houses are not necessarily applicable in other countries. The ventilation rates for American houses are less and those for Swedish houses much less. Data given by Kronvall (1978) indicate that ventilation rates for Swedish houses are about a quarter those in Britain. Data on ventilation rates for buildings in the United States have been given by Handley and Barton (1973). The work of Handley and Barton also shows, however, that there is a wide range of ventilation rates. They found values from 0.07 to 3.0 air changes/h.

15.51.3 Hazard assessments

The mitigating effect of shelter is considered in the *First Convey Report* in Appendix 7 by Beattie, who quotes Equation 15.51.3 and suggests that a suitable value of the ventilation rate λ is 1 change/h for a modern building, but that this may rise to 2–3 changes/h if doors or windows are left ajar.

In the Rijnmond Report credit is taken for the effect of shelter using Equation 15.51.1. A ventilation rate of 2 changes/h is used, but it is stated that this could be as low as 1 or as high as 3.

Table 15.64 *Room ventilation rates*[a] *(after P.R. Warren and Webb, 1980b) (Courtesy of the Chartered Institute of Building Services Engineers)*

Room	*Room ventilation rate* (air changes/h)		
	Mean	*Minimum*	*Maximum*
Living room	0.89	0.24	1.64
Kitchen	1.43	0.43	3.50
Small bedroom (<15 m^3)	0.87	0.28	2.90[b]
Large bedroom (>15 m^3)	0.65	0.25	1.19
Bathroom	1.81	0.25	3.19

[a] Number of rooms in sample ranged from 14 to 29.

[b] This value corrected from one of 3.9 in the original paper (P.R. Warren, 1992).

Table 15.65 *Whole house ventilation rates (after P.C. Davies and Purdy, 1986) (Courtesy of the Institution of Chemical Engineers)*

	Ventilation (air changes/h)[a,b]			
	D/2.4	*D/4.3*	*D/6.7*	*F/2.4*
Closed house	1	1	1.5	1
Normal occupied house	2	2	3	2

[a] Best estimate.
[b] Values used by Pape and Nussey (1985) for these four stability category/wind speed combinations are 0.7, 1, 1.5 and 0.5 air changes/h, respectively.

15.52 Source and Dispersion Modelling: CCPS Guidelines

The CCPS has issued two publications giving practical guidance on emission and dispersion of hazardous materials. These are now described.

15.52.1 Guidelines for Use of Vapor Cloud Dispersion Models

The CCPS *Guidelines for the Use of Vapor Cloud Dispersion Models* (the CCPS *Vapor Cloud Dispersion Model Guidelines*) (1987/2) covers both emission and dispersion. The *Guidelines* give an overview of release scenarios, particularly pipe ruptures, vessel rupture and reactor venting, review the dominant phenomena of initial acceleration and dilution, buoyancy and atmospheric turbulence, and give a decision tree for handling the scenarios. A selection of release scenarios is given, and amplified in an appendix. The characteristics of routine and accidental releases are compared.

Models are given for the determination of emission flows. These include: two-phase flow; flow from tanks under liquid head as well as pressure; and flow from pipelines. Models for various types of jet are covered. Models for vaporization from pools include both heat and mass transfer limited cases and spreading pools. A critical review is given of pool vaporization models.

For gas dispersion, separate treatments are given for ground level and elevated releases. An overview is given of passive gas dispersion, including the Pasquill–Gifford model, the Pasquill stability categories and correlations for dispersion coefficients. The set of six models contained in the EPA UNAMAP6 system is outlined.

The variety in type and origin of dense gas dispersion models is described. The authors state that there are some 100 models, with 10 further models being created annually. Many existing models continue to undergo development and to acquire new features.

Dense gas dispersion is considered first in the absence of heat effects. The box model of van Ulden is outlined. The authors then derive for dense gas dispersion a number of simplified relations for cloud dimensions and concentration, and compare them with the Thorney Island trials data.

Accounts are then given of the thermodynamic and heat transfer phenomena and of correlations used for air entrainment. The three-dimensional models considered are FEM3 and MERCURE-GL. The review given of the criteria utilized by various workers for effectively passive dispersion brings out the large disparities in the criteria adopted. Physical modelling is described, particularly in respect of plume lift and complex terrain. The implications of concentration fluctuations are treated and the effect of sampling time and volume are discussed.

A review is given of some principal dispersion models, covering some 40 models and giving a tabulation of the characteristics of each model. Four models are described in more detail: AIRTOX, DEGADIS, FEM3 and INPUFF.

For elevated releases of dense gas the *Guidelines* give an overview of models for momentum jets and buoyant plumes. The use is described of an effective height in the Pasquill–Gifford model for handling plume rise and gas density. Momentum jet scenarios are classified and the model of D.J. Wilson (1979b) for a momentum jet from a pipeline is described. For plumes reference is made to the models of G.A. Briggs (1984) which are utilized in UNAMAP. An account is given of the models of Ooms, Mahieu and Zelis (1974) and of Hoot, Meroney and Peterka (1973). A criterion is given for effectively dense gas dispersion in an elevated release.

The *Guidelines* consider the extent to which models have been validated against field trials and the uncertainty in model estimates, and list some of the comparisons made between models and trials. They refer to the Environmental Protection Agency set of model evaluation procedures for passive dispersion and give a number of measures of performance.

The *Guidelines* give one of the few quantitative treatments of uncertainty in modelling. The sources of uncertainty considered are model physics, random variability and input data errors. A treatment is given of the effect on uncertainty of the number of model parameters.

15.52.2 Workbook of Test Cases for Vapor Cloud Source Dispersion Models

The CCPS *Vapor Cloud Dispersion Model Guidelines* are supplemented by the CCPS *Workbook on Test Cases for Vapor Cloud Source Dispersion Models* (the CCPS *Vapor Cloud Source Dispersion Model Workbook*) (1989/8). The *Workbook* gives a set of emission, pool vaporization and jet models, and describes methods of matching the output of these models with the input required by selected dispersion models. The principal models treated are: for emission, the Fauske–Epstein models for liquids, subcooled liquids and saturated liquids; for vaporization, the Fleischer model for an evaporating pool; for jets, the Briggs momentum jet model and the Hoot, Meroney and Peterka dense gas jet model; and for gas dispersion, the Pasquill–Gifford model, CAMEO, the Ooms model, SPILLS, SLAB and DEGADIS.

The criterion used to determine whether it is necessary to use for a continuous release a dense gas dispersion model is $\mathrm{Ri} \gg 10$ with

$$\mathrm{Ri} = \frac{\pi}{4} g' \frac{u_o D}{u_*^2 u} \qquad [15.52.1]$$

$$u_* \approx 0.065u \qquad [15.52.2]$$

where D is the initial diameter of the plume, g' is the reduced gravity, u is the wind speed, u_o is the velocity of release and u_* is the ambient friction velocity. Five release scenarios are treated:

(1) continuous jet release of gaseous butane from a vent stack;
(2) continuous release of liquefied ammonia from a storage vessel
  (a) nozzle failure (liquid release),
  (b) line rupture (two-phase release);
(3) continuous jet release of high pressure carbon monoxide gas from a low level source;
(4) continuous two-phase release of liquefied chlorine from a storage vessel;
(5) continuous release of liquid acetone into a bund.

These are all continuous releases, the choice being deliberate, since the models for instantaneous or transient releases are subject to more uncertainty. Likewise, the first four cases were selected because the excess density is significant and it is necessary to use a dense gas dispersion model.

The *Workbook* gives detailed working for these five cases, with hand calculation of the sections on emission, vaporization, jet behaviour and interface to the dispersion model being followed by results of the gas dispersion computer codes. Several sample outputs are given from CAMEO, SPILLS, SLAB and DEGADIS.

15.53 Vapour Release Mitigation: Containment and Barriers

There are a number of methods of preventing or mitigating the dispersion of gases. They include the use of:

(1) bunds
(2) foam
(3) solid barriers
(4) fluid barriers
  (a) water spray barriers
  (b) steam curtains.

An account of the effect of some of these devices on gas dispersion is given in Section 15.40. The results of field trials and of physical modelling are given in Sections 15.37–15.39. Guidelines for vapour release mitigation have been given by Prugh (1985–, 1987b,c). The various methods of prevention and mitigation are now considered.

15.53.1 Bunds

The rate of evaporation of a spill, particularly that of a refrigerated liquefied gas, can be greatly reduced if the spill is contained within a bund. In turn, the evaporation from the bund may be much reduced by appropriate design. Two principal features are the geometry and the substrate of the bund. A bund around a storage tank is generally designed to contain the contents of the tank. A bund with a smaller floor area but higher walls presents a smaller surface to heat up and vaporize the liquid. The higher wall also acts as a barrier to the flow of the vapour.

The use of a suitable material for the substrate can greatly reduce the rate of heat transfer to the liquid. The relations for this heat transfer process are given in Section 15.10. From Equation 15.10.30 the rate of heat transfer is proportional to the heat transfer parameter $(k_s \rho_s c_s)^{1/2}$. Table 15.66 lists some values of this parameter for different substrates, as given by Dilwali and Mudan (1987). As the table indicates, there are differences of up to 16 in the values of the parameter. These authors describe a hazard assessment of the dispersion of the vapour from a spill of liquid chlorine into a bund. The study considered various designs of bund and showed that the distance to the concentration immediately dangerous to life and health could be reduced from 2.6 km for the base case to 320 m for an alternative design. Further, the provision of a bund facilitates the use in suitable cases of foam, which can effect a further large reduction in evaporation.

15.53.2 Foam

The use of foam is an effective means of reducing the rate of evaporation, where a suitable foam is available. Accounts of the testing of foams at facilities in 1986 at Pueblo, Colorado, and in 1988 at the Nevada Test Site (NTS) have been given by Dimaio, Norman and co-workers (Dimaio and Norman, 1988, 1990; Norman and Dimaio, 1989; Norman and Swihart, 1990).

Foams tested included: Hazmat 2, an acid resistant foam; ARAFFF, an alcohol resistant AFFF foam; and a fluoroprotein foam. Chemicals tested included bromine, chlorine, hydrogen fluoride, monomethylamine, phosphorous oxychloride, phosphorous pentachloride and sulphur dioxide. Using Hazmat 2 the proportional vapour suppressions achieved were as follows: bromine >95%; chlorine 67–82%; hydrogen fluoride 70–85%; sulfur dioxide >61%.

Foam acts by insulating the surface of the spill and preventing vaporization. Other modes of action include absorption of the vapour and scrubbing out of aerosol and particulate matter. Any foam used must be suitable for the application; the wrong foam can do more harm than good. A guide to the use of foam on hazardous materials has been published by Norman (1987). Likewise, water should only be used advisedly; incorrect use can make things worse.

Table 15.66 *Some values of the heat transfer parameter $(k_s \rho_s c_s)^{1/2}$ for different substrates (after Dilwali and Mudan, 1987) (Courtesy of the American Institute of Chemical Engineers)*

Material	*Heat transfer parameter* $(k_s \rho_s c_s)^{1/2}$ ($\mathrm{W\,s^{1/2}/m^2\,K}$)
Soil (dry)	2570
Sand (dry)	2660
Sand (wet: 3% moisture)	2335
Uninsulated concrete	3750
Insulated concrete	230–440
Polyurethane	140
Other insulating materials	
Celofoam	99
Foamglass	74

Foam should be applied gently, possibly with continuous application or frequent reapplication. Personnel should be trained and should have suitable protective equipment, including self-contained breathing apparatus.

15.53.3 Solid barriers

A solid barrier such as a fence or wall can serve either to contain a gas cloud entirely or to effect an appreciable dilution. An impermeable barrier designed for this purpose and erected within the works is generally know as a vapour barrier. A barrier does not need to be impermeable to mitigate a gas release. A plantation of trees may provide a worthwhile degree of dilution of a gas cloud.

15.53.4 Vapour barriers: Hawk programme

As described in Section 15.37, two series of field trials have been conducted at the NTS on the mitigation of hydrogen fluoride releases. These trials were largely concerned with water spray barriers and are considered in Section 15.53.13. The second investigation, the Hawk programme, under the auspices of ICHMAP, also included a study of vapour barriers. An account of this work is given here.

The programme on vapour barriers included a review of the effectiveness of vapour barriers and wind tunnel tests on such barriers. The review concluded that, whilst a vapour barrier reduces the near field concentrations, in the far field this effect decays.

In the wind tunnel work, two types of configuration were tested. One consisted of vapour barriers or fences, with only partial enclosure of the gas cloud, and the other of vapour boxes, with complete enclosure. In addition, the effect of other types of plant obstacle was investigated.

The work demonstrated that the effect of a vapour barrier is extremely dependent on the nature of the release, the site where the release occurs and the barrier design. The results were expressed as the ratio of the concentration without a vapour barrier or box to the concentration with a barrier or box – the concentration reduction factor. Typically, concentration reduction factors were of the order of 2–10 in the near field, falling to factors of unity in the far field, but with the latter ranging up to 4.

There was concern that the use of a vapour box might aggravate the hazard of a vapour cloud explosion. Overpressure increases with cloud height; a vapour box increases the cloud height and may therefore be expected to increase the overpressure. The effect was investigated using the FLAGS explosion simulation code. This confirmed that the use of a vapour box does increase overpressure. This effect may be mitigated by reducing the height of the box or by installing vents in it, but the overpressure is still higher than without a box.

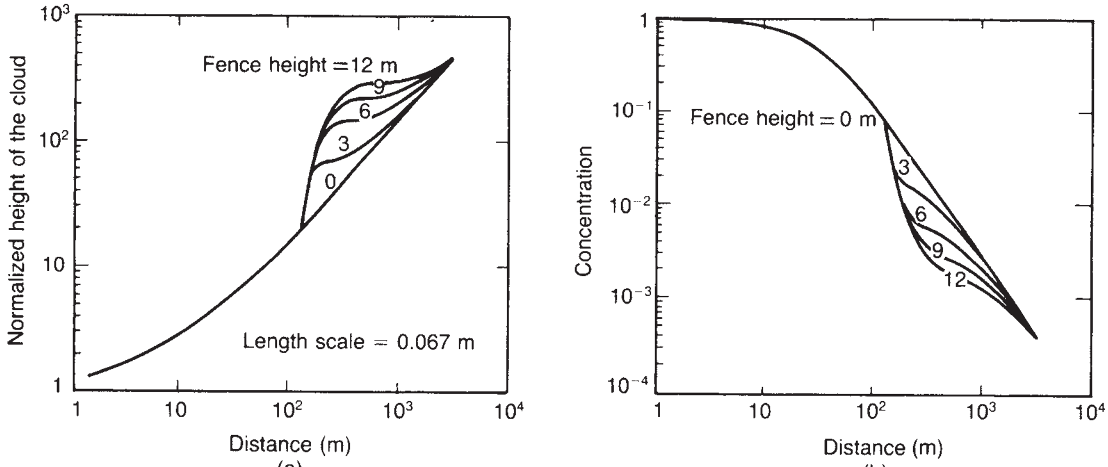
15.53.5 Vapour barriers: FENCE62

Meroney (1991) has described the use of a set of models with the generic title FENCE to simulate the behaviour of a dense gas cloud at a fence used as a vapour barrier, in particular FENCE62.

Models for the simulation of the dilution of a cloud of hydrogen fluoride are adaptations of the box model DENS62 and the slab model DENS23. For simulation of the effects of a vapour barrier the corresponding models are FENCE62 and FENCE23 and those for the effects of a water spray barrier are SPRAY62 and SPRAY23; SPRAY 65 is a modification of SPRAY62.

These models were used to simulate the Goldfish field trials on the dispersion by a fence of a continuous release of hydrogen fluoride. Figure 15.156(a) shows the effect of fence height on the height of the cloud and Figure 15.156(b) the effect on the downwind concentration. These effects decay so that by about 200 fence heights downwind they have largely disappeared.

The fence was found to be more effective in diluting the gas cloud if located near the source. For a fence placed within 400 m of the source, the dilution effects did not persist beyond about 1000 m. For a fence located 100 m from



(a)

(b)

Figure 15.156 *Dispersion of dense gas at obstacles – predictions of FENCE62 for dispersion of hydrogen fluoride across barrier for Goldfish trial 1 (Meroney, 1991): (a) effect on plume height; (b) effect on centre line concentration (Courtesy of the American Institute of Chemical Engineers)* the source there was little effect of wind speed in the range 1–8 m/s on either downwind cloud height or concentration.

15.53.6 Water spray barriers

A good deal of work has been done on the development of water spray barriers, or water curtains, as a means of mitigating the hazard from a gas release. The systems used include fixed water spray installations and mobile water spray monitors. Fixed installations are typically a set of spray nozzles several metres off the ground with the spray directed downwards. Such systems are used both in the open air and in buildings. A typical mobile monitor system is a set of spray nozzles inclined at an angle of approximately 45° to the horizontal. Water sprays and curtains are used mainly against flammable gases, but may be applied against toxic gases also.

A water spray directed vertically through a gas cloud will have a number of effects. These include:

(1) mechanical effects of acting as a barrier to the passage of gas, of imparting upward momentum to a gas or of dispersion and dilution by air entrainment;
(2) thermal effects by warming of cold gas;
(3) physico-chemical effects of absorption of gas, without or with chemical reaction.

A water spray barrier may be used for any of these purposes.

Where a water spray barrier is used, consideration should be given to the need for arrangements to drain away the water used, particularly if the application may be prolonged.

15.53.7 Water spray barriers: early work

An experimental investigation of the effectiveness of water sprays against gas clouds has been described by Eggleston, Herrera and Pish (1976). The experimental rig was a set of water spray nozzles mounted on a frame initially 15 ft high, later modified to 20 ft, and directed downwards. Clouds of ethylene and vinyl chloride monomer vapour were directed towards the spray system at ground level.

The water spray was effective as a vapour barrier in some experiments but not in others. The spray entrains air and pumps it down and horizontally outwards. If the velocity of this air exceeds that of the vapour cloud, the spray acts as a barrier, otherwise it does not. Thus vapour clouds with velocities of 3 and 9 mile/h were stopped by sprays with 100 psig nozzle pressure, but only the former was stopped when the nozzle pressure was reduced to 40 psig. The vapour tended to spread out at ground level in front of the spray, but did not go over the top.

The air entrainment rates obtained were in the range 87–213 ft^3/min air per US gal/min water with nozzle pressures in the range 20–90 psig. Total entrained air rates were in the range 1242–7107 ft^3/min. The velocity of the air pumped by the spray was low and the flow was therefore sensitive to any obstruction. In cases where the vapour cloud passed through the spray barrier there was still an appreciable dilution effect. The gases used are highly insoluble and the absorption effects were negligible.

The effect of the water spray on the ignition of a flammable vapour cloud and on the flame speed in the cloud was also investigated. It was found that the water spray did not prevent ignition occurring and that the flame speed actually increased, probably due to the greater turbulence.

Further experimental work on water sprays has been described by J.W. Watts (1976). Again the experimental rig was a set of nozzles mounted on a 20 ft high frame and directed downwards. Clouds of propane vapour were directed towards the spray system at ground level.

Some experiments were done in which ignition sources in the form of cans of burning gasoline were located on the far side of the sprays. In cases where the spray was not an effective barrier the vapour cloud ignited and the flame passed back through the spray.

Further experiments were carried out in a 13 ft high open rig with a single nozzle with the introduction of ethylene vapour through a pipe just below the nozzle. The flow of ethylene was increased until the concentration measured by gas detectors near the ground rose to just below the lower flammability limit. The maximum flow of ethylene controllable by the spray was 2609 lb/h with a calculated air entrainment rate of 23,600 ft^3/min.

Other experiments were done in which volumes of ethylene–air mixture held in polyethylene chambers were ignited by pentaerithrytol tetranitrate (PETN) and observations were made of the conditions under which deflagration and detonation were obtained. The volumes used were 500, 4000 and 10,000 ft^3. The authors state that given a sufficient charge of PETN detonation could be obtained, that the explosion yield was generally much higher with detonation than with deflagration, that the detonation limits were 5–10.5% and were thus narrower than the flammability limits, and that with a water spray in the chamber the strength of the PETN charge necessary to obtain detonation was considerably increased.

The effectiveness of water sprays in suppressing combustion in mists of heat transfer media, specifically Dowtherm A, has been investigated by Vincent *et al.* (1976a) in a 6.5 ft diameter spherical vessel. It was shown that combustion could be suppressed and it was tentatively concluded that, for such mist droplets, the mechanism was one of scrubbing rather than quenching.

Although in Watts' work water sprays were not effective in arresting the passage of flames, Brasie (1976b) has described work at the Bureau of Mines in which flames in gas clouds were quenched by the use of very high nozzle pressures in the range 1000–2000 psig, which give a much finer spray. In this case the mechanism was considered to be one of quenching, the distance between the drops being less than the quenching distance of the gas.

Experiments on the use of a water curtain generated by mobile monitors against a chlorine gas cloud have been described by the Ministry of Social Affairs (1975) in the Netherlands. A water curtain was successfully used to protect a small area against the gas cloud.

15.53.8 Water spray barriers: air entrainment

The design and application of a water spray barrier to entrain air into a gas cloud has been described in a series of studies by McQuaid. These include: the entrainment characteristics of a water spray barrier (McQuaid, 1975); the use of a water spray barrier to effect ventilation in mines (McQuaid, 1976a); the design of a water spray barrier to dilute flammable gas clouds (McQuaid, 1977); a comparative review of water spray barriers and steam curtains for dilution of flammable gas clouds (McQuaid, 1980); and the application to dense gas clouds. These aspects are described below.

An account of work on the entrainment of air by a water spray barrier has been given by McQuaid (1975), who has also described the application of this work to the design of water spray barriers for dispersion of gas clouds (McQuaid, 1977).

In order to dilute a gas cloud it is necessary to deliver air not only in sufficient quantity but also at a sufficient velocity. The relation for the flow of air Q_a and the air velocity V at the base of the cone of spray cone with base diameter D is

$$D = \left(\frac{4Q_a}{\pi V}\right)^{1/2} \qquad [15.53.1]$$

where D is diameter of the spray cone (m), Q_a is the volumetric flow of air (m^3/s) and V is the velocity of the entrained air (m/s).

McQuaid obtained the following correlation for entrainment of air into a spray nozzle:

$$\frac{Q_a}{Q_w} = f\left(\rho_w^{1/2}\frac{F_N}{D^2}\right) \qquad [15.53.2]$$

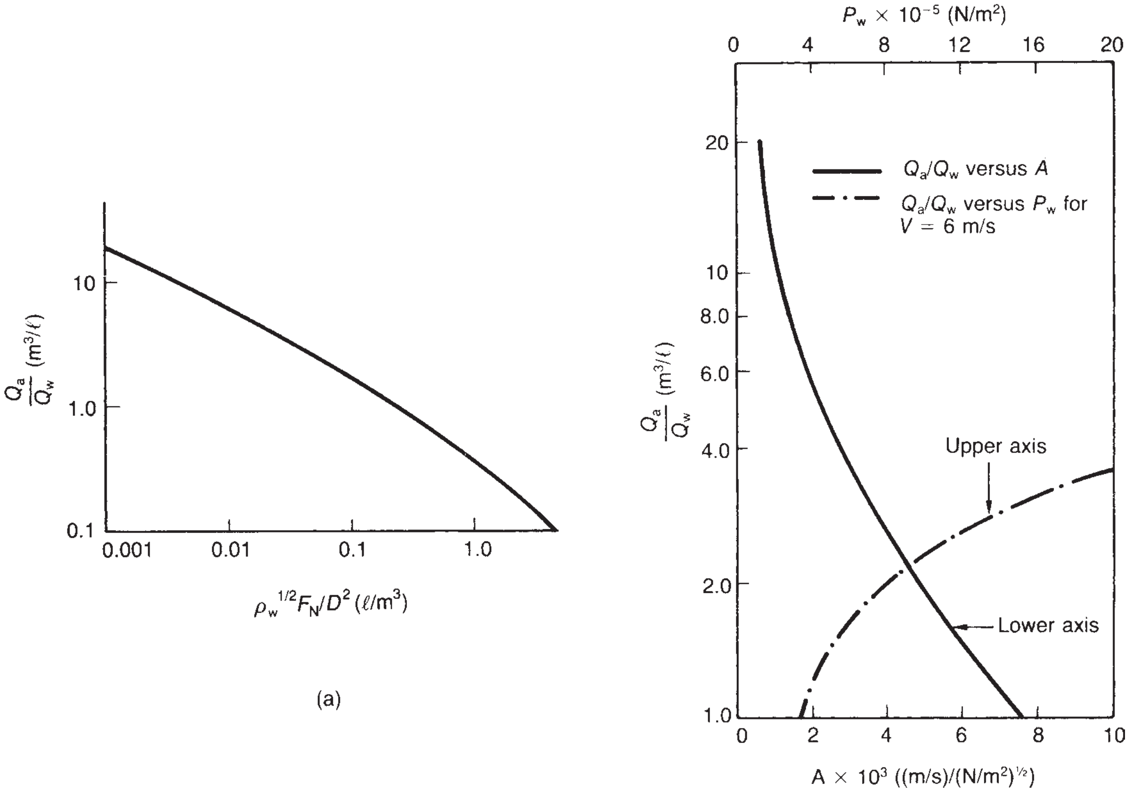
with

$$F_N = \frac{Q_w}{P_w^{1/2}} \qquad [15.53.3]$$

where F_N is the flow number of the nozzle ((l/s) $\cdot$ (kN/m^2)$^{1/2}$), P_w is the pressure of water at the nozzle (kN/m^2) (gauge) Q_w is the volumetric flow of water (l/s) and ρ_w is the density of water (kg/m^3). This correlation is given in Figure 15.157(a). The ratio Q_a/Q_w is both a measure of the efficiency of the spray and a design parameter. It is given as a function of the water pressure and flow number in Figure 15.157(b). It should be noted that in other work different units are quoted for the nozzle flow number.

In the original work, this correlation was validated in small scale experiments with $D = 0.3$ m and $Q_w < 1$ l/s. McQuaid (1977) has compared values predicted by the correlation with results from the larger scale work of Rasbash and Stark (1962), Eggleston, Herrera and Pish (1976), J.W. Watts (1976), Heskestad, Kung and Todtenkopf (1976) and Beresford (1977).

For design, McQuaid takes an air velocity V of 6 m/s. Then, given a water pressure P_w, the number of nozzles n



(a)

(b)

Figure 15.157 *Mitigation of gas dispersion by water spray barriers – water spray nozzle relationships (McQuaid, 1977): (a) and (b) air entrainment relationships.* $A = \pi V/4P_w^{1/2}$ *(Courtesy of HM Stationery Office)* and the required total air flow nQ_a, the water flow Q_w and hence the flow number F of the nozzles may be determined. There is some latitude in the choice of the number of nozzles, since this does not affect the efficiency Q_a/Q_w.

15.53.9 Water spray barriers: illustrative example

An illustrative example of the design of a water spray barrier is given by McQuaid (1980). This example is summarized in Table 15.67. The problem considered is the design of a barrier for the dilution of a continuous release of ethylene gas escaping at a rate of 1 kg/s and forming a plume with an angle of 35° and a height of 1 m. The table also treats the case of a steam curtain, as described below.

15.53.10 Water spray barriers: Moore and Rees model

P.A.C. Moore and Rees (1981) have given a model, or rather a set of models, for the forced dispersion of gases by water or steam curtains. The model is applied by the authors to dilute gas plumes and to dense gas plumes. The situation considered is that shown in Figure 15.158.

Following Bosanquet (1957), the authors consider an elemental slice of the gas cloud

$$\frac{d(\delta V)}{dt} = cSu \qquad [15.53.4]$$

where c is an entrainment parameter for the wind, S is the surface area of an elemental slice, u is the velocity of the gas and δV is the volume of the slice.

It is assumed that the cloud velocity u is equal to the wind speed w.

$$u = w \qquad [15.53.5]$$

Also

$$\frac{dx}{dt} = w \qquad [15.53.6]$$

where x is the distance along the plume.

The first model (model A) is for a downward pointing spray. The three regions (I–III) are considered in turn. For region I, the source has a volumetric rate of release Q. In time δt a volume $Q\delta t$ is emitted which at distance x is contained within the volume δV with radius r.

$$\delta V = \pi r^2 w \delta t \qquad [15.53.7]$$

The area S is

$$S = 2\pi r w \delta t \qquad [15.53.8]$$

By conservation of mass

$$Q\delta t = \pi r_o^2 w \delta t \qquad [15.53.9]$$

$$= C\pi r^2 w \delta t \qquad [15.53.10]$$

where C is the volumetric concentration and subscript o denotes the source. From Equations 15.53.4, 15.53.5, 15.53.7 and 15.53.8

$$\frac{d(r^2)}{dt} = 2crw \qquad [15.53.11]$$

Hence from Equations 15.53.6 and 15.53.11

$$\frac{dr}{dx} = c \qquad [15.53.12]$$

Integrating Equation 15.53.12 with respect to x over region I and at the boundary of the region

$$r = r_o + cx \qquad [15.53.13a]$$

$$r_1 = r_o + cx_1 \qquad [15.53.13b]$$

where subscript 1 denotes the end of region I. In region II

$$\frac{d(\delta V)}{dt} c \cdot 2\pi r w \delta t \cdot w + c_s \cdot 2\pi r w \delta t \cdot v_a \qquad [15.53.14]$$

where c_s is an entrainment parameter for the spray and v_a is the velocity of the air entrained in the spray. In this equation the first term on the right-hand side represents the entrainment of air by the wind and the second term

Table 15.67 *Illustrative calculation for a water spray barrier for dispersion of a dense gas plume (after McQuaid, 1980)*

A Scenario

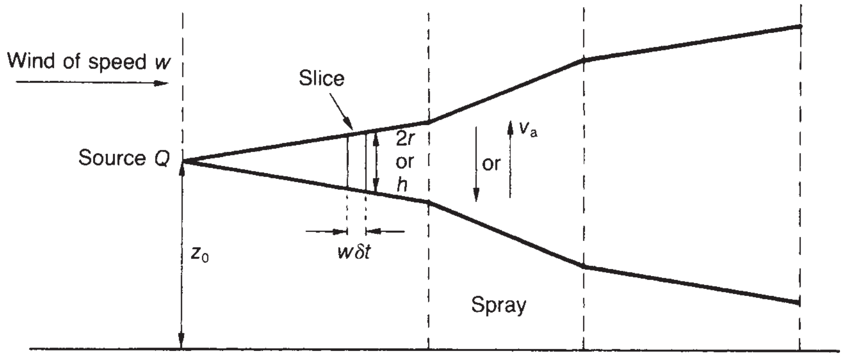
Release of ethylene (MW = 28; LFL = 2.7%)
Mass rate of release from source = 1 kg/s
Angle of plume = 35°
Distance between source and barrier = 16 m
Width of plume at barrier = 10 m
Height of plume at barrier = 1 m
Gas loading at barrier = 1/10 = 0.1 kg/s m

B Water spray barrier

Water pressure = 700 kPa
Spacing between nozzles = 1.15 m
Height of nozzles = 2 m
Angle of spray cone = 60°
Distance from nozzle to top of plume = 2 − 1 = 1 m
Mass flow of air required = 0.1 × (29/28) × (1/0.027)
  = 3.8 kg/s m
Density of air = 1.2 kg/m^3
Diameter D of spray cone at plume top = 1.15 m
Volumetric flow of air required per unit length
  = 3.8/1.2 = 3.2 m^3/s m
Volumetric flow of air required per nozzle = 3.2D m^3/s
  = 3.2 × 1.15 m^3/s = 3.7 m^3/s
Velocity of entrained air at top of cloud = 6 m/s
Ratio Q_a/Q_w (from Figure 15.157) = 2 m^3/1
Water flow Q_w = 3.7/2 = 1.85 1/s

C Steam curtain

Mass flow of air required = 3.8 kg/s m
Steam flow S required (from Equation 15.53.26)
  = (0.1 × 2 × 3.8)/200 = 0.0385 kg/s m



Distance	0	x_1	x_2	x
Radius of slice (A,B)	r_0	r_1	r_2	r
Height of slice (C)	h_0	h_1	h_2	h
Vertical velocity (A)	0	0	0	0
(B,C)	0	0	v_2	v

Region	I	II	III
Entrainment from:	Wind	Wind and spray	Wind
Width of slice (A)	$w\delta t$	$w\delta t$	$w\delta t$
(B,C)	$w\delta t$	$w\delta t$	$\sqrt{v^2+w^2}\delta t$
$\frac{1}{S}\bullet\frac{d(\delta V)}{dt}$ (A)	cw	$cw+c_s v_a$	cw
(B,C)	cw	$cw+c_s v_a$	$c\sqrt{v^2+w^2}$

Figure 15.158 *Mitigation of gas dispersion by water spray barriers – elevation view of dense gas cloud passing through a water spray barrier (P.A.C. Moore and Rees, 1981) (Courtesy of the Institution of Chemical Engineers)*

represents the entrainment by the spray. Proceeding as before yields

$$\frac{dr}{dx} = c + \frac{c_s v_a}{w} \tag{15.53.15}$$

and integrating gives

$$r = r_1 + \left(c + \frac{c_s v_a}{w}\right)(x - x_1) \tag{15.53.16a}$$

$$r_2 = r_1 + \left(c + \frac{c_s v_a}{w}\right)D \tag{15.53.16b}$$

with

$$D = x_2 - x_1 \tag{15.53.17}$$

where D is the width of the spray and subscript 2 denotes the end of region II. In region III, a similar procedure yields

$$r = r_o + \frac{c_s v_a D}{w} + cx \tag{15.53.18}$$

From Equation 15.53.10

$$C = \frac{Q}{\pi r^2 w} \tag{15.53.19}$$

The effectiveness of dilution is given in terms of a factor FD defined as the ratio

$$\mathrm{FD} = \frac{C_{\mathrm{ND}}}{C_{\mathrm{FD}}} \tag{15.53.20}$$

where C_{ND} is the concentration with natural dilution, C_{FD} is the concentration with forced dispersion by the spray and FD is the forced dispersion effectiveness factor. For region III without spray Equation 15.53.13a applies. Then utilizing Equation 15.53.19 with Equation 15.53.13a to obtain C_{ND} and with Equation 15.53.18 to obtain C_{FD} in Equation 15.53.20:

$$\mathrm{FD} = \left[1 + \frac{c_s v_a D}{w(r_o + cx)}\right]^2 \tag{15.53.21a}$$

$$= \left(1 + \frac{c_s v_a D}{cwx}\right)^2 \quad cx \gg r_o \tag{15.53.21b}$$

Bosanquet gives a value of $c = 0.13$. The authors also derive from Katan's formula a value of $c = 0.14$.

The two other models (models B and C) are for an upward pointing spray. Taking model B, it is assumed that in region II the elemental slice gains a vertical velocity v in the spray and that in region III the horizontal velocity is given by

$$u = (w^2 + v^2)^{1/2} \tag{15.53.22}$$

This model contains an additional equation for dv/dx. The result for FD is

$$\mathrm{FD} = \left(\frac{r_2}{r_1 + cx}\right)^2 \left\{\left[\left(\frac{v_2^2}{w^2} + 1\right)^{1/2} + \frac{c(x - x_2)}{r_2}\right]^4 - \frac{v_2^2}{w^2}\left(\frac{v_2^2}{w^2} + 1\right)\right\}^{1/2} \tag{15.53.23}$$

Model C is similar but treats a cloud from a line source. Moore and Rees describe field trials conducted to validate their models using water spray barriers and steam curtains.

The trials included a continuous release of propane gas at 2 kg/min, a spill of some 60 kg of liquid propane and a continuous release of liquid propane at 10 kg/min. The barrier was generally located 1 m downwind of the source. The first of these three sources gave a propane concentration at the barrier of 10% and the other two concentrations of 100%. The concentration was measured at 15 m downwind. Other experiments were conducted with argon and sulphur hexafluoride at much lower flows and different downwind measurement distances. For downward-pointing nozzles the FD factors were in the range 1.1–3.3 and for upward-pointing nozzles they were in the range 2.5–6.3; the upward-pointing nozzles were more effective. The results of the experiments were used to obtain empirical values of c_s/c in the model and the predictions of the model were then compared with the results of the experiments.

15.53.11 Water spray barriers for dense gases: HSE field trials

Experimental work by the HSE on the dispersion of a dense gas plume from a continuous source has been described by Moodie (1981, 1985) and McQuaid and Moodie (1983). Three configurations of water spray barrier were used: sprays pointing vertically downward, sprays pointing downward but angled forward at 45° and sprays pointing vertically upward. The downward-pointing nozzles were at a height of 3 m and were spaced at 0.33 m intervals along a 17 m pipe; the upward-pointing nozzles were at the same interval on an 18 m long pipe. Solid cone, hollow cone and flat fan sprays were investigated. The distance between the barrier and the source was varied, one distance quoted being 5 m. The gas released was carbon dioxide at release rates of 2 and 4.2 kg/s in wind speeds of 0.6–11 m/s and with water consumptions at the barrier of 0.4–7.61/(sm). Wind speeds were measured at, and quoted for, 1.25 m.

Figure 15.159 shows the variation of the entrained air and of the concentration of carbon dioxide across the barrier. The results are correlated in terms of the momentum of the spray. Moodie (1985) defines a momentum flow number M_N as

$$M_N = KF_N \qquad [15.53.24]$$

where F_N is the flow number (l/(min bar$^{1/2}$)), M_N is the momentum flow number (N s/(s bar)) and K is a constant. The value of the constant K is 0.236. Use is also made of the momentum flow M of the barrier (N s/(s m)).

The results are presented as a concentration ratio CR, defined as the ratio of the concentration with the water sprays off to that with the sprays on. Figure 15.160 shows the variation of CR with wind speed with specific momentum as the parameter. Values of CR are mainly in the range 1–4. The ratio increases with the momentum of the spray and decreases with wind speed.

Compared with the sprays pointing vertically downwards, those angled at 45° showed no apparent improvement in performance, but the upwards-pointing sprays did, being some 17% more effective at a wind speed of 2 m/s.

For upwards-pointing barriers only, and for the range of parameters studied, the authors give the following correlation:

$$M = u_{1.25}^2[0.65 \exp(0.5CR) - 0.23]^2 \qquad [15.53.25]$$

where M is the specific momentum flow (N s/(s m)) and $u_{1.25}$ is the wind speed at 1.25 m height (m/s).

McQuaid and Moodie (1983) have reviewed the implications of this work for the design of a water spray barrier. The barrier should be located near the source, though not so near as to promote increased evaporation of any liquid pool. A barrier near the source gives a considerable reduction in gas in the first few tens of metres downwind, but this effect decays quite rapidly. It is most effective at low wind speeds (<3–4 m/s).

Water consumption at a water pressure of 700 kPa is about 1.61/(s m). A standard fire tender giving 60 l/s can thus supply a 35 m length of barrier.

15.53.12 Water spray barriers for dense gases: HSE modelling studies

McQuaid and Fitzpatrick (1981, 1983) of the HSE have described the modelling of the dispersion of a dense gas plume by a water spray barrier. One question addressed was the extent to which the effect of the water spray barrier falls off with downwind distance. For a dense gas cloud the

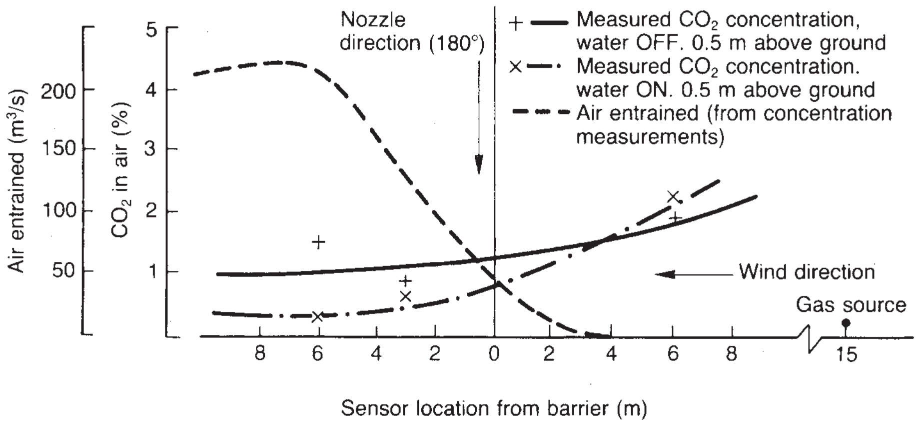


Figure 15.159 Mitigation of gas dispersion by water spray barriers – variation of entrained air and concentration of carbon dioxide across barrier in HSE trials (Moodie, 1981) (Courtesy of the Institution of Chemical Engineers)

effect of the density difference is to increase the area of the cloud top by lateral spreading, but to reduce vertical mixing. As far as concerns entrainment of air, the former effect tends to outweigh the latter so that the net effect is to increase entrainment and to shorten the length of the plume to a given concentration. A water spray barrier gives an addition of air and hence an immediate dilution, but it also gives a reduction of density and hence in lateral spread. Another question considered was the effect of the distance between the source and the barrier. If a barrier is close to the source it can be made smaller, but it will reduce the density of the cloud just at the point where this density is most effective in promoting entrainment.

The dispersion of a dense gas from a continuous release was modelled using CRUNCH. The experimental work showed that the entrained air mixes with the gas cloud within a distance roughly equal to the width of the spray. This effect was therefore modelled by assuming that the entrainment of the air at the barrier effects a change both in the geometry of the cloud and in its concentration. The plume modelled was a continuous release of 2 kg/s of carbon dioxide, representative of the sources used in the experiments of Moodie (1981). Some predictions given by the model are shown in Table 15.68 and Figure 15.161(a)–(d), which illustrate, respectively, the effect on plume height and concentration of the stability category, the wind speed, the downwind distance of the barrier and the specific air entrainment rate. The plume widths at the barrier vary, but it is assumed that they are not altered by passage through the barrier and that the only effect of this is to alter plume height. The results show that a water spray barrier gives a higher dilution if located close to the source, that a barrier with high specific air entrainment rates gives higher dilutions and that a barrier is particularly effective in stability category F conditions. The large air flows in this case are due to the large plume widths. The results also show that the effect of the barrier decays and that some distance downwind it disappears altogether.

As just described, the assumption in Figure 15.161(a)–(d) is that the effect of the barrier is to change the height of the plume but to leave its width unaltered. Figure 15.161(e) and (f) illustrate the results of the alternative assumption that it is the plume width which changes whilst the height remains unaltered. They show that it is

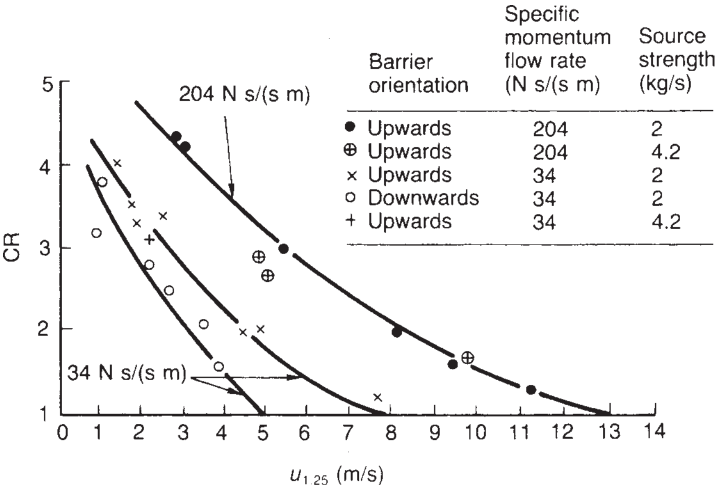

Figure 15.160 *Mitigation of gas dispersion by water spray barriers – effect of wind speed and specific momentum on concentration ratio (CR) for carbon dioxide in HSE trials (Moodie, 1985). Plume width maintained constant through barrier in (a)–(d) and plume height maintained constant in (e)–(f). The key to all six figures is given in graph (f) (Courtesy of the Institution of Chemical Engineers)*

much more effective to change the plume width. Quite how as a practical matter this may be effected is not obvious, but the general message is clear that any outward movement which can be imparted to the plume is highly beneficial.

These HSE field trials have also been modelled by Deaves (1983b, 1984) using HEAVYGAS. Figure 15.162 shows a comparison of the observed and predicted concentration profiles in one experiment. Other results from the model show that the gas, which had been hugging the ground, is lifted up and mixed by an upwind recirculation of the entrained air.

15.53.13 Water spray barriers for dense gases: Goldfish and Hawk trials

The Goldfish field trials at the NTS in 1986 on the dispersion of hydrogen fluoride included three trials involving the use of forced dispersion barriers. The main natural dispersion trials (trials 1–3) were described in Section 15.37 and the forced dispersion trials (trials 4–6) are described here. Accounts of these latter trials have been given by Blewitt, Yohn, Koopman and Brown (1987) and Blewitt, Yohn, Koopman, Brown and Hague (1987). The work constitutes an investigation of the case of dilution of a gas cloud due to absorption of the gas as well as entrainment of air into the cloud.

Trial 5 utilized an upwards-pointing water spray barrier and trial 6 a downwards-pointing one. A barrier with the water spray atomized by air was used in trial 4. The general conditions of the trials were described in Section 15.37. In trial 5 the flow of liquid hydrogen fluoride was 32.5 US gal/min with a wind speed of 3.8 m/s and stability category C/D, and trial 6 was essentially similar but with a wind speed of 5.4 m/s. The ambient temperature was 21°C in all three tests. In none of these three tests was any liquid collected on the spill pad.

The interpretation of trials 5 and 6 was complicated by shifts in wind direction during both trials, but the use of mass balances as well as concentration measurements allowed an estimate to be made of the proportion of hydrogen fluoride removed. The reduction in maximum hydrogen fluoride concentration 300 m downwind of the barrier was estimated as between 36 and 49%; the concentration at this point in trial 5 before the spray was turned on was 2028 ppm. The atomized water spray used in trial 4 was not effective in the form tested.

As already mentioned, a further set of field trials, the Hawk series, was performed at the NTS in 1988 under the auspices of ICHMAP. The gas dispersion aspect of these trials was considered in Section 15.37 and the vapour barrier work was described in Section 15.53.4. An account of the work on water spray barriers is given here.

A total of 87 trials were performed to investigate the effect of various parameters on the removal of hydrogen fluoride by a water spray barrier. The water/HF liquid volume ratio was found to be the dominant factor. Hydrogen fluoride removal efficiencies of 25 to >90% were achieved at water/HF liquid volume ratios of 6 : 1 to 40 : 1.

Of the other factors, the liquid droplet size also had some influence. Upward-pointing sprays were rather more effective than downward-pointing ones. The pressure and temperature of the hydrogen fluoride had little effect and the same applied to the atmospheric humidity and wind speed. Little difference was observed in removal efficiency of the spray as between hydrogen fluoride and alkylation unit acid.

Trials were done with the water augmented by various additives, including sodium bicarbonate, sodium hydroxide, calcium chloride and surfactant, but the only benefit was a marginal increase in removal efficiency when using sodium hydroxide.

It was found that fire monitors were virtually as effective in removing hydrogen fluoride as were fixed barriers. The best results were obtained using coarse droplets aimed directly at the release point from a short distance, as opposed to a wide angle fog or a jet directed from a distance. Tests were conducted to check on the risk of damage from jets from such monitors. The most severe of these involved a flow of 6000 US gal/min applied as a narrow jet at a distance of 7 ft from the target; damage was minimal.

15.53.14 Water spray barriers for dense gases: physical modelling

A wind tunnel investigation of the effect of water spray barriers on dense gas dispersion has been described by Blewitt *et al.* (1991). Tests were performed simulating continuous releases of hydrogen fluoride at flows in the range 11–96 kg/s and wind speeds in the range 3–10 m/s and with barrier configurations with water pressure 172 psi and flow 33,000 US gal/min with nozzle spacings of 0.46–1.83 m and orientations vertically downwards, angled, horizontal

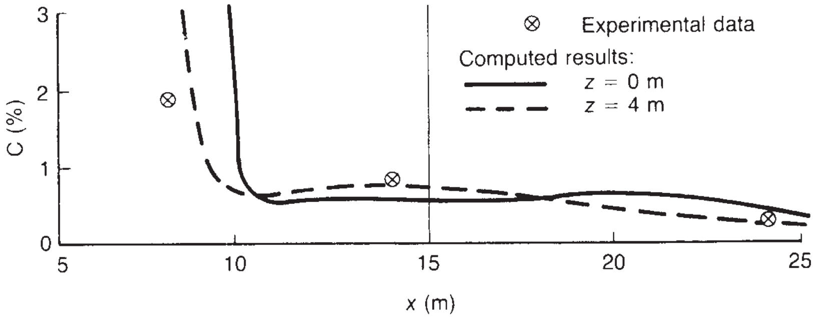

Figure 15.162 *Mitigation of gas dispersion by water spray barriers – predictions of HEAVYGAS for concentrations of carbon dioxide across barrier for HSE trials (Deaves, 1984). Nozzles pointing into wind and at an angle of 45° to horizontal. (Courtesy of Springer Verlag)*

and vertically upwards. The most effective dilution was good mixing with nozzles spaced as far apart as 1.83 m, the widest spacing studied. The authors discuss the principles of scaling water sprays in wind tunnel work.

15.53.15 Water spray barriers for dense gases: SPRAY65

The work of Meroney (1991) on the use of models of dense gas dispersion at vapour barriers was mentioned earlier. He has also reported work on models for dense gas dispersion at water spray barriers using the model SPRAY65.

This model was used to simulate the Goldfish field trials on the dispersion of a continuous release of hydrogen fluoride by a water spray barrier. Figure 15.163(a) shows for Goldfish trial 1 the effect of the water spray barrier location on the height of the cloud, and Figure 15.163(b) shows the effect on the downwind concentration. The water spray barrier is more effective in diluting the gas cloud if located near the source. The effects decay with distance and eventually disappear.

15.53.16 Water spray barriers: leak containment

The use of a water spray barrier by a works fire brigade to deal with escapes of gas has been described by Beresford (1981). The approach adopted is to hold the gas cloud inside a 'chimney' formed by a set of four mobile water spray barriers. These form a barrier to the passage of the gas, entrain air and dilute the gas, and impart to it upwards momentum so that it rises and disperses harmlessly. It is possible to see inside the chimney and for personnel to enter to effect valve isolation.

Two monitors are placed some 30 ft apart and arranged to give an inverted V some 40–50 ft above ground. At this point the water spray feathers and heavy drops fall to ground. Two fan-shaped sprays are set at right angles to the monitor curtains to give a vertical water curtain some 40 ft wide × 40 ft high. The overall effect is to surround the gas with an upward-moving wall of water so creating the chimney effect. The gas disperses some 50 ft or more above ground. The monitors are 250–1200 UK gal/min and the fan sprays 180–200 Ukgal/min devices and the water pressure used is 150 psig.

This technique is suitable for quite serious leaks but not for catastrophic failures. It may be used for flammable or toxic releases. It requires that the equipment be set up rapidly. Ignition of a flammable vapour cloud, for example, is liable to occur within 3–5 min of the start of the leak. It is necessary to consider the drainage of the water if application is likely to be prolonged.

Beresford gives examples of a number of escapes handled by this method. They include a leak of propylene from a 2 in. diameter drain line at 400 psig discharging at a rate of about 100 te/h which could not be isolated for several hours; one of ethylene gas from a flanged joint on a 14 in. diameter pipe at 500 psig which lasted some 50 minu; one of methane escaping at about 50 te/h for 30 min from a fracture on a 6 in. diameter pipe at 60 psig; and various other leaks of benzene, ethylene, ethylene oxide, naphtha and hydrocarbon solvents.

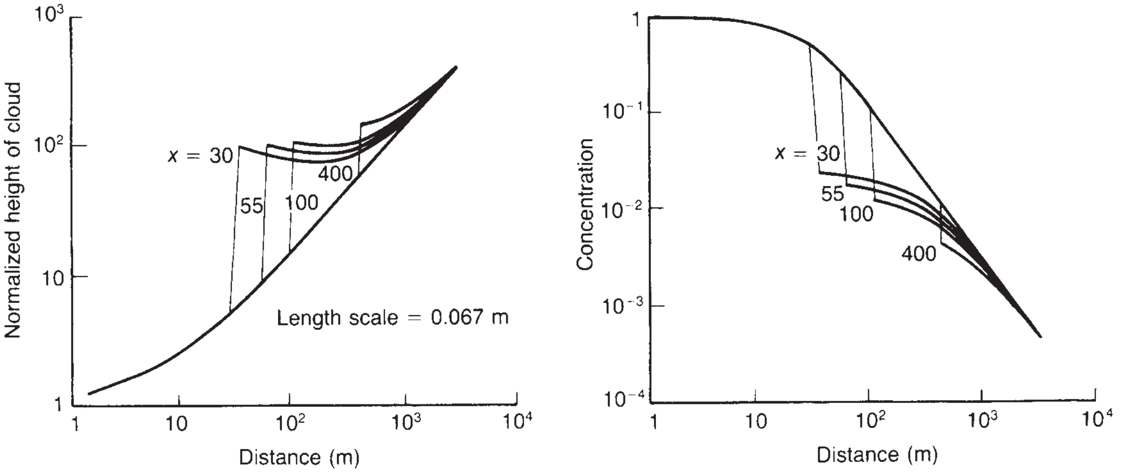
15.53.17 Water spray barriers: enclosed spaces

Work on the use of water sprays to promote entrainment into, or act as a barrier to, instantaneous and continuous leaks of gas in an enclosed space has been described by van Doom and Smith (van Doom and Smith, 1980; J.M. Smith and van Doom, 1981).

15.53.18 Steam curtains

A steam curtain is used as a permanent installation to contain and disperse leaks of flammable gas heavier than air. A steam curtain system has been described by Cairney and Cude (1971) and Simpson (1974).

The arrangement is that the plant is surrounded by a solid but lightly constructed wall. A horizontal steam pipe with a row of small holes is mounted near the top of the



(a)

(b)

Figure 15.163 *Mitigation of gas dispersion by water spray barriers – predictions of SPRAY65 for dispersion of hydrogen fluoride across barrier for Goldfish trial 1 (Meroney, 1991): (a) effect on plume height; and (b) effect on centreline concentration, x is the downward distance of the water spray (m) (Courtesy of the American Institute of Chemical Engineers)* wall. The pipe is divided into sections which are individually supplied with steam from distribution mains with remotely controlled, quick-acting valves. The associated monitoring of leaks is carried out by the flammable gas detector system, as described in Chapter 16. In the system described by the authors mentioned, Sieger diffusion-type detectors are used.

The wall constitutes an initial barrier to the cloud and thus serves both to provide a time delay during which the detection system can operate and to spread the gas along the length of the curtain. The relative spacing of the potential sources of escape, the detectors and the wall are chosen with these factors in mind. The wall is 1.5 m high, which is sufficient to check a heavy vapour cloud, but does not prevent dispersal of small leaks by natural air movement.

The steam pipe is designed so that the individual jets combine to form a planar jet which entrains sufficient air to dilute the vapour cloud below its lower flammability limit. The division of the pipe into sections allows steam to be supplied only to those sections near the leak. The activation of the system is controlled by the process operators.

The steam curtain was designed to dilute heavy flammable vapours. It is possible, in principle, to apply it to the dispersion of toxic gases, but in this case it is necessary to effect dilution to much lower concentrations.

The use of steam jets, particularly jets containing wet steam, can create a hazard of ignition by static electricity. Therefore particular care is taken that all pipework and other metal objects near the jets are properly earthed.

A method for the design of a steam curtain has been given by McQuaid (1980). The quantity of steam required is determined from the relation

$$S = \frac{G + 2Q_a}{200} \qquad [15.53.26]$$

where G is the mass flow of gas, Q_a is the mass flow of air and S is the mass flow of steam. The equation is based on conservation of momentum, a wind velocity of 2 m/s and a steam velocity equal to the velocity of sound in steam of 400 m/s. The illustrative example given in Table 15.67 also covers the case of a steam curtain.

P.A.C. Moore and Rees (1981), in the work already described, also conducted experiments on steam curtains and obtained empirical correlations for the FD value.

The generation of static electricity in steam curtains and in water curtains has been investigated by Napier (1974b). He concluded that a degree of static electricity hazard exists both with steam and with water curtains.

15.53.19 Water spray barriers vs steam curtains

Several authors have compared the use of water spray barriers and steam curtains. A detailed comparison of the two devices has been made by McQuaid (1980), as illustrated in Table 15.68. For the water spray barrier the water flow required is 1.6 kg/(s m) and the steam flow is 0.0385 kg/(s m). The ratio of the required mass of water to that of steam is therefore some 40 : 1.

P.A.C. Moore and Rees (1981) state that in their experimental work the FD value for steam curtains was less than 4, whereas for upwards-pointing water spray barriers it was in the range 4–16.

15.54 Vapour Cloud Mitigation: CCPS Guidelines

The CCPS has published guidance on the mitigation of vapour clouds and this is now described.

15.54.1 Guidelines for Vapor Release Mitigation

The CCPS *Guidelines for Vapor Release Mitigation* (the CCPS *Vapor Release Mitigation Guidelines*) (1988/4) cover a wide range of approaches to mitigation. Prugh (1985–, 1987b,c) has given a number of accounts of vapour release mitigation which foreshadow the Guidelines.

The main headings of the *Guidelines* may be summarized as

(1) Overview;
(2) Inherently safer design;
(3) Engineering design;
(4) Process safety management;
(5) Early vapour detection and warning;
(6) Cuntermeasures;
(7) On-site emergency response;
(8) Off-site emergency response;
(9) Selection of measures.

The interpretation of the concept of mitigation in the *Guidelines* is a broad one and covers both prevention and protection. It constitutes, but is more than, a comprehensive checklist of measures. Many of the topics listed above are dealt with in other parts of the present text. Table 15.69 gives an indication of the chapters or sections in which these topics are treated here.

The *Guidelines* give as a base case a system consisting of an unloading rail tank car, pump transfer, storage vessel, pump transfer and reactor. This system is then used throughout the text to illustrate the various points under consideration.

It starts with a discussion of the broad features of a vapour release: the forms which a release may take; the features of a flashing release; the causes of release; and the consequences of release. The different types of release are exemplified and categorized and an appendix is given which contains a checklist of release scenarios.

The principles of inherently safer design treated are: limitation of inventory; substitution of less hazardous materials; substitution of a less hazardous process; and siting. Consideration is given to both on-site and off-site exposure. There is an appendix on the properties of hazardous materials.

The contribution of engineering design is considered under the headings of plant integrity, process integrity, and emergency control. There is a fairly extensive treatment of the latter, dealing with emergency relief disposal, abort systems, isolation systems, material transfer, and spill containment. Emergency relief disposal covers active and passive scrubbers, stacks and flares, catchtanks, incinerators, and absorbers, adsorbers and condensers. There is an appendix on catchtank design and another on vendors of emergency equipment.

The treatment of management in the *Guidelines* concentrates on: operating procedures; training for emergencies; audits and inspections; equipment testing; maintenance programmes; plant and process modifications; methods of stopping a leak; and security.

Early warning is treated in terms of detectors for flammable and toxic gases, including their response time

Table 15.69 *Some principal topics treated in the CCPS Vapor Release Mitigation Guidelines and their treatment in this text*

8 Off-site Emergency Response	4, 24
9 Selection of Measures	9

and positioning, detection by personnel, and alarm systems.

Countermeasures against vapour releases are water sprays, water, steam and air curtains, deliberate ignition, and ignition source control, whilst those against liquid releases are dilution, neutralization, and liquid, foam and solid covers, together with the method of application and avoidance of actions which may aggravate vaporization.

On-site emergency response embraces: on-site communications; emergency shut-down equipment and procedures; site evacuation; havens; escape; personal protective equipment; medical treatment; and emergency plans, procedures, training and drills. There is an appendix on the capacity of a haven.

Off-site emergency response as such is not the direct responsibility of the company, and the account is confined to those aspects which are its responsibility: alerting systems; roles and lines of communication; and information to be communicated.

The approach described to the selection of mitigation measures is based on a formal system of hazard identification and assessment, by which the scenarios for loss of containment and potential Countermeasures are identified and the nature of the hazards and the effectiveness of the Countermeasures are assessed.

15.55 Fugitive Emissions

Process plants have numerous potential sources of leaks and, although the emission rate from any one source may be small, the cumulative effect of these leaks may be such as to require action. One effect of such emissions is to raise the concentration of toxic chemicals in the plant and thus make it difficult to meet the workplace limit values set. Another effect is to increase the level of pollutants outside the plant. There is also a cost due to the loss of the chemicals.

Some of the emissions from the plant are attributable to particular sources or operations such as combustion and solvents handling, storage and terminal operations, process vents and stacks. The others are classed as fugitive emissions and consist of leaks from flanges, valves, pump and compressor seals, pressure relief valves, and so on.

An account of fugitive emissions is given in *Fugitive Emissions of Vapours from Process Equipment* by the British Occupational Hygiene Society (BOHS) (the *BOHS Guide*) (1984 TG3), *Health Hazard Control in the Chemical Process Industry* (Lipton and Lynch, 1987), *Fugitive Emissions and Controls* (Hesketh and Cross, 1983) and *Handbook of Health Hazard Control in the Chemical Process Industry* (Lipton and Lynch, 1994). There have been a number of publications by the Environmental Protection Agency (EPA) (1973, 1978a,b, 1982b, 1984c). Other accounts include those by Rosebrook (1977), Bierl and co-workers (Bierl *et al.*, 1977; Bierl, 1978, 1980; Bierl and Kremer, 1978), T.W. Hughes, Tierney and Khan (1979), M.J. Wallace (1979) and Wetherold *et al.* (1983). Selected references on fugitive emissions are given in Table 15.70.

Estimates of sources of emission in a typical refinery and in chemical plants are given in Tables 15.71 and 15.72, respectively.

15.55.1 Regulation of fugitive emissions

In the United States, early work on the control of fugitive emissions was the Los Angeles County project in 1958. Los Angeles has a particular problem of smog to which hydrocarbons are a main contributor.

A study was carried out of fugitive emissions in 11 refineries in the Los Angeles area in which measurements were made of the emission factors for various types of equipment. These constituted the original data for the compilations of emission factors produced by the EPA and were published as AP-42, which then became the basis for regulatory controls.

The EPA subsequently commissioned a number of studies, including in 1979 studies by the Radian Corporation and by Monsanto. The Radian project covered total emissions on refineries, but fugitive emissions received particular attention. The Monsanto project covered similar ground for chemical plants. The EPA has issued a number of documents giving emission factors.

The EPA has promulgated as amendments to the Clean Air Act 1970 regulations limiting fugitive emissions from refineries and chemical plants. These controls are concerned mainly with pollution rather than occupational exposure.

In the Federal Republic of Germany the Federal authorities maintain a register of emission factors (Bierl, 1980), which are used by the inspectorate of the States. In Nord Rhein-Westfalen, for example, these emission factors are incorporated in the local regulations.

In the United Kingdom, there is no specific requirement on emission factors as such. Fugitive emissions are regulated as an aspect of pollution and of the control of toxic concentrations in the workplace.

15.55.2 Measurement of fugitive emissions

The existence of a leak may be detected using the soap bubble method. However, this method is not generally regarded as suitable for quantitative measurement. The concentration at the point of leak may be used as a measure of the leak rate, but the values obtained are highly dependent on factors such as the size of leak, the wind conditions, the plant geometry, etc.

In the Radian study, the maximum concentration obtained around an emission source was termed the 'screening value.' The EPA has attempted to relate screening values to mass emission rates, but the correlation shows appreciable scatter.

The two principal methods of measuring emission rates both involve enclosing the source in a container. In the bag method the bag is placed around the source, air is passed through the bag and the outlet steady-state concentration of the chemical in the air stream is measured. In the box method there is no air flow and the measurement taken is the rate of rise of concentration of the chemical in the air in the box.

15.55.3 Monitoring of fugitive emissions

The arrangements for monitoring emissions depend on the purpose of the monitoring. If the aim is to reduce pollution outside the works, periodic spot checks on emission sources may be sufficient. The control of toxic concentrations in the atmosphere of the workplace normally requires additional measures. In the latter case it is necessary to implement continuous sampling of the atmosphere. The data obtained by such sampling must then be interpreted statistically. A discussion of sampling and interpretation of sampled data is given in the BOHS *Guide*.

15.55.4 Emission factors for equipment

The contribution of the various sources of fugitive emissions to the total plant emission has been the subject of several studies. Table 15.73 shows the fugitive emission sources assigned in a hypothetical refinery in an EPA study. Table 15.74 gives the actual sources in the Monsanto study (T.W. Hughes, Tierney and Khan, 1979).

Information on emission factors is available from several sources. Mention has already been made of the Los Angeles County study and of the studies commissioned by the EPA. The California Resources Board has carried out a project involving six refineries to check the 1958 data. Rockwell International has carried out a study for the American Petroleum Institute on oil production operations.

Table 15.75 lists emission factors from the Los Angeles County project as given in the 1973 edition of the EPA publication AP-42. Tables 15.76 and 15.77 show emission factors obtained in the work by Radian (Wetherold, Rosebrook and Tichenor, 1981) and by Monsanto (T.W. Hughes, Tierney and Khan, 1979).

Work by Bierl (1978, 1980) at BASF is shown in Table 15.78. The literature values referred to in this table are those from earlier work by Schwaneke (1965, 1968, 1975). Bierl expresses his own measured values as percentages of these published ones.

A composite set of emission factors given by Schroy (1979), based mainly on those of AP42 and Bierl, are shown in Table 15.79.

The spread of emission rates is illustrated by the data for valves in light liquid service given by A.L. Jones (1984) and shown in Table 15.80.

Table 15.74 *Fugitive emission sources in four chemical plants (after T.W. Hughes, Tierney and Khan, 1979) (Courtesy of the American Institute of Chemical Engineers)*

Source	*Plant type*							
	Monochloro-benzene		*Butadiene*		*Dimethyl terephthalate*		*Ethylene oxide/glycol*	
	(ton/year)	(%)	(ton/year)	(%)	(ton/year)	(%)	(ton/year)	(%)
Pumps	1	3.1	96	8.6	8		2	
Valves	0.2	0.6	1000	90.0	?		?	
Flanges	29	91.0	0	0	?		?	
Other	1.7	5.3	16	1.4	7.9		8.6	
Total	31.9	100.0	1112	100.0				

The effect of maintenance on emission rates is shown in the data in Table 15.81 given by Kunstmann. In this a set of valves was selected at random and the leak rates were measured, the average value being 2.37 g/h. Some 80% of the total emission was attributable to the valves with leak rates greater than 2 g/h. The leak rates of these valves were reduced by maintenance and their leak rates were remeasured with the result that the average leak rate for all the valves was reduced to 0.44 g/h.

API Bull. 2521: 1966 Use of Pressure-Vacuum Vent Valves for Atmospheric Pressure Tanks to Reduce Evaporation Loss
API Bull. 2522: 1967 Comparative Test Methods for Evaluating Conservation Mechanisms for Evaporation Loss
API Bull. 2523: 1969 Petrochemical Evaporation Loss from Storage Tanks

These publications give equations for the estimation of evaporation losses.

Extensive work has been done on emissions from floating roof tanks. The background to this work is discussed by Zabaga (1980), by Hanzevack, Anderson and Russell (1983) and by Laverman (1984).

Table 15.81 *Effect of maintenance of emission rates of valves (after Kunstmann, 1980)(Courtesy of Elsevier Sequoia SA)*

Valves tested No.	 (%)	Emission rate (g/h)

2	5	10–50
0	0	>50
B Valves after maintenance		
36	92	0–2
3	8	2–10
0	0	10–50

15.55.6 Control of fugitive emissions

The information on emission factors given above indicates that for a given type of emission source there is a wide variability in emission rates but also that for almost all types the technology exists to reduce the emission rate to a low level. A detailed review of the methods of obtaining leak tight plant is given in the BOHS Guide. A further account is given by Bierl *et al.* (1977). The BOHS *Guide* describes the following types of seal:

(1) static seals
  (a) gasketed joints (full faced flanges, narrow faced flanges),
  (b) automatic face seals;
(2) dynamic seals
  (a) contact seals,
  (b) clearance seals (bushing seals, labyrinth seals);
(3) miscellaneous seals
  (a) O-rings,
  (b) flexible lip seals.

The *Guide* also gives a detailed account of packed glands (stuffing boxes) and mechanical seals.

For flanges, the *Guide* describes the elements of good practice necessary to reduce leakage. Its principal proposal for cases where high leak-tightness is required is the elimination of flanges by the use of all-welded pipe.

For valves, leakage of the rising stem may be reduced by the use of 100% graphite packing. For high leak-tightness use may be made of bellows-sealed or diaphragm-sealed valves. Bellows-sealed valves were developed for use in the nuclear industry. The *Guide* gives the following emission rates for rising stem valves:

	Emission rate (μg/s)
Regular packing	
<20 bar	100
>20 bar	2
100% graphite packing	
<20 bar	12
>20 bar	0.2

For pumps, the *Guide* gives the following emission rate index:

Seal type	*Shaft emission rate index*
Regular packing	100
Regular packing with lantern ring	10
100% Graphite packing	10
Single mechanical seal	1.2
Double mechanical seal	0.004

For bellows seal pumps, diaphragm pumps and canned pumps the index is zero. Details of the seal arrangements are given in the *Guide*. A further discussion of packed glands is given by Hoyle (1978).

For agitators, the *Guide* states that the pump data may also be used as a guide to the relative effectiveness of the different seal types. A discussion of agitator seals is given by Ramsey and Zoller (1976).

The sealing of centrifugal or reciprocating compressors is appreciably more difficult than the sealing of pumps. Labyrinth seals are commonly used on both types, but leakage rates are high, being typically 1–2% of the flow through the compressor. Carbon seals give lower leak rates, but for a more positive seal the *Guide* suggests oil film seals or mechanical seals with oil flush. A further discussion of centrifugal compressor seals is given by W.E. Nelson (1977).

15.55.7 Economics of emission control

Several studies have been published on the economics of emission losses and of control measures, including those by Kittleman and Akell (1978), Wetherold *et al.* (1983) and Rhoads, Cole and Norton (1984). The cost of control measures is also considered by Kunstmann (1980). These studies tend to be concerned with the costs of reducing leaks and with minimization of these costs rather than with savings obtained by leak elimination. The general conclusion is that effort should be concentrated on individual sources with a high leak rate, the outliers, and that thereafter the law of diminishing returns sets in strongly.

15.56 Leaks and Spillages

Leaks and spillages are main causes of fire and explosion in chemical plants. They may give rise to a local fire or explosion, a wider flash fire or a large vapour cloud explosion. Some of the situations which can give rise to leaks and spillages have been described by Kletz (1975b). They include:

(1) leaks from pump glands and seals;
(2) leaks from joints, valves and fittings;
(3) spillages from drain valves;
(4) spillages occurring during maintenance work;
(5) spillages from road and rail tankers.

Leaks have occurred not infrequently on pumps handling cold liquid ethylene. In some cases vapour clouds have been formed, while in others the leak has ignited, apparently due to static electricity.

On pumps handling C_3 and C_4 hydrocarbons at ambient temperature and moderate pressure there is little trouble with seal leakages, but failures have occurred on high pressure injectors.

Joints, valves and fittings are common sources of leakage due to features such as loose bolts, ruptured gaskets, failed instrument connections.

Another fertile source of spillage is drain valves. Typically a drain valve blocks due to ice or hydrate formation, the blockage is cleared in some way, but it then proves impossible to shut the valve off.

The disaster at the Rhone Alps refinery at Feyzin in 1966 (Case History A38) began with blockage in a drain line from a propane storage sphere which was almost certainly caused by ice or hydrate. The drain line was a vertical pipe below the sphere and had two valves on it. The standing instruction was to drain by opening the top valve and controlling the flow with the lower one so that, if necessary, the former could be used to shut the flow off. But the operator in fact turned the bottom valve wide open and controlled draining from the top one. When this latter valve blocked, he opened it further, the blockage gave way and a jet of propane came out full bore through the 2 in. line, struck the ground, rebounded into the operator's face and knocked the handle off the valve. Attempts to replace the handle on the top valve or to shut the bottom one failed. There was a massive escape of propane, the vessel was engulfed by fire and 18 people were killed.

Maintenance work sometimes gives rise to spillages. This is usually the result of failure to ensure isolation of equipment. Isolation procedures are described in Chapter 21. Failures of connecting hoses on road and rail tankers at filling terminals are not unusual. These are discussed in Chapter 22.

The volume of vapour generated by a liquid spillage can be very large. Moreover, only a small percentage of vapour is needed to give a flammable mixture. Thus one volume of liquid can become 10,000 or more volumes of a flammable vapour–air mixture. Leaks of liquefied flammable gas (LFG) of different sizes are discussed in the ICI LFG Code (ICI/RoSPA 1970 IS/74).

Small leaks such as those from pump and valve glands or pipe joints are quite probable, but usually involve little risk, provided that the leak is discovered quickly, the gas is dispersed rapidly and there is no nearby source of ignition. Dispersion is assisted by ventilation and may be promoted by steam from a steam lance.

Medium leaks are defined as those large enough to go beyond the plant boundaries. The leak should be isolated if possible. Isolation by the use of hand valves near the leak may be hazardous and the use of remotely operated isolation valves is preferable if the latter are available. It may be noted that excess flow valves do not operate at lower leakage rates.

Attempts should also be made to disperse the leakage and to prevent it finding a source of ignition. Use may be made of steam curtains, if installed, or of mobile water curtains. A leak of LFG which is water soluble can be dealt with by diluting it with large amounts of water.

Major leaks are defined as those of 1 ton/h or more. The methods just described are appropriate, but a major leak usually gives rise to a large pool of liquid. There is typically a rapid flash-off of vapour followed by slower vaporization from the pool. It is necessary, therefore, to decide how the liquid is to be handled. One method is to assist vaporization and dispersion, another is to suppress vaporization and to dispose of the liquid. Vaporization may be suppressed by laying foam on the surface. In some cases the formation of an ice layer effects complete suppression.

Leaks are also discussed by J.R. Hughes (1970) who states that a leak of more than 1 UK gal/h (4.5 l/h) would be regarded as unusual on a modern pump seal and would not be allowed to continue, and that experiments on this size of leakage with motor gasoline have shown that in the open air the concentration of vapour produced is so small that a flammable concentration exists only within a few inches of the leakage point.

Hughes also describes experiments involving the spillage of two pints (1 l) of gasoline. In a light wind of 2 mile/h (3.2 km/h) the vapour cloud floated downwind and gave a flammable concentration near the ground at 20 ft (6 m) downwind, but at a few inches above ground the concentration was undetectable. For spillage near a low wall the distance at which the cloud gave a flammable concentration increased to 30 ft (9.1 m).

Leaks in confined spaces, such as an enclosed and poorly ventilated compressor or pump house, are another matter and can easily build up to flammable concentrations, giving rise in due course to a fire or explosion.

15.57 Notation

Bo	Bowen ratio
Fr	Froude number
Gr	Grashof number
Ma	Mach number
Nu	Nusselt number
Pe	Peclet number
Pr	Prandtl number
Re	Reynolds number
Ri	Richardson number
Ro	Rossby number
Sc	Schmidt number
Sh	Sherwood number
St	Stanton number
We	Weber number
c_p	specific heat
g	acceleration due to gravity
g'	reduced gravity
M	molecular weight
P	absolute pressure
R	universal gas constant
t	time
T	absolute temperature
γ	ratio of gas specific heats
Δ	reduced density
μ	viscosity
ρ	density
$\Delta\rho$	density difference

Superscript

$\cdot$	time derivative

Subscripts

max	maximum
r or ref	reference

Note:

(a) Some of these variables have different local definitions, for example; P (probability), R (radius of cloud), T (time interval), γ (edge entrainment coefficient).

(b) There are different definitions of the reduced gravity g'.

Section 15.1

A_o	cross-sectional area of orifice (m^2)
C	constant defined by Equation 15.2.95
C_D	coefficient of discharge
D	diameter of cylinder (m)
g	acceleration due to gravity (m/s^2)
h	height of liquid above bottom of vessel (m)
h_o	height of orifice, or hole, above bottom of vessel (m)
h_p	equivalent liquid height (m)
H	height of vessel (m)
L	length of horizontal cylindrical vessel (m)
ΔP	pressure difference between liquid surface and atmosphere, imposed pressure (Pa)
Q	outflow through orifice (m^3/s)
t	time (s)
V	volume of vessel (m^3)
x	dimensional hole height
θ	half-angle of cone of vertical conical vessel (°)
ρ	density of liquid (kg/m)
τ	dimensionless drainage time

Section 15.2

A	cross-sectional area of pipe
C	parameter defined by Equation 15.2.47
C_D	coefficient of discharge
d	diameter of pipe
f	friction factor
F	friction loss
G	mass velocity
h	specific enthalpy
k	slip ratio
l	distance along pipe, length of pipe
n	polytropic index
$\mathrm{d}P_a/\mathrm{d}l$	pressure drop due to acceleration
$\mathrm{d}P_f/\mathrm{d}l$	pressure drop due to friction
$(\mathrm{d}P_f/\mathrm{d}l)_g$	pressure drop which would occur if gas phase were flowing alone in pipe

$(\mathrm{d}P_\mathrm{f}/\mathrm{d}l)_\mathrm{go}$	pressure drop which would occur if whole fluid were flowing alone in pipe
$(\mathrm{d}P_\mathrm{f}/\mathrm{d}l)_\mathrm{l}$	pressure drop which would occur if gas fluid were flowing as liquid in pipe
$(\mathrm{d}P_\mathrm{f}/\mathrm{d}l)_\mathrm{lo}$	pressure drop which would occur if whole fluid were flowing as liquid in pipe
$\mathrm{d}P_\mathrm{g}/\mathrm{d}l$	pressure drop due to gravitational forces
Q	volumetric flow
R_o	shear stress at wall
S	perimeter of pipe
u	velocity
v	specific volume
W	mass flow
x	mass fraction of vapour, or quality
X	parameter defined by Equation 15.2.41
z	vertical distance, height
α	fraction of volume occupied by vapour, void fraction, or voidage; parameter defined by Equation 15.2.3
β	vapour phase volumetric flow fraction; parameter defined by Equation 15.2.4
Γ	parameter defined by Equation 15.2.42
η	critical pressure ratio
λ	parameter defined by Equation 15.2.1
σ	surface tension
ϕ	parameter used in Equations 15.2.40–15.2.43
ψ	parameter defined by Equation 15.2.2

Subscripts

a	air
c	critical
E	equilibrium
g	gas
go	gas only
h	homogeneous
l	liquid
lo	liquid only
L	all liquid condition
m	two-phase mixture
o	stagnation
s	two-phase
w	water

Section 15.3

A_a	cross-sectional area of aperture
A_p	cross-sectional area of pipe
c_l	specific heat of liquid
C	specific heat of liquid
C'_a	modified cavitation number
C_D	coefficient of discharge
C_DM	modified coefficient of discharge
d	diameter of pipe
f	friction factor
f^*	friction factor (two-phase flow)
f_m	average friction factor
F	flow correction factor
F'	friction loss
G	mass velocity
k	slip ratio
K	coefficient of discharge
l	distance along pipe, length of pipe
l_e	equilibrium, or relaxation, length
n	polytropic index
N	non-equilibrium parameter
P	absolute pressure
P^*	absolute effective downstream pressure
ΔP	pressure drop
P_a	absolute atmospheric pressure
P_c	absolute back pressure in choked flow
P_o	absolute stagnation pressure
P_v	absolute vapour pressure
R_g	fraction of cross-sectional area occupied by vapour
s	specific entropy
U	average velocity
v	specific volume
x	mass fraction of vapour, or quality
α	void fraction
β	parameter defined by Equation 15.3.12
ζ	parameter defined by Equation 15.3.34
η	parameter defined by Equation 15.3.16
ρ_l	density of liquid
ρ_m	average density

Subscripts

b	downstream
c	critical
E	equilibrium
ERM	equilibrium rate model
f	liquid
fg	transition from liquid to vapour
g	vapour
h	constant enthalpy
l	liquid
m	two-phase mixture
n	two-phase annular
t	throat

Section 15.4

C_f	specific heat of liquid
D	diameter of pipe
f	friction factor
Fi	flow inclination number
h	specific enthalpy
G	mass velocity
G^*	dimensionless mass velocity
G_o	mass velocity through nozzle
L	length of pipe
N	pipe resistance factor
s	specific entropy
v	specific volume
x	mass fraction of vapour, or quality
α	void fraction
η	pressure ratio
θ	angle between pipe axis and vertical

Subscripts

c	critical
f	liquid
fg	transition from liquid to vapour
lm	limiting
o	stagnation
r	reduced
s	saturation

Section 15.5

a	parameter defined by Equation 15.15.53
A	area of vent (m^2)
A_x	cross-sectional area of vessel (m^2)
C_0	distribution parameter
D	diameter of vessel (m)
F	geometric factor
h_{fg}	latent heat of vaporization (kJ/kg)
H	height of liquid (m)
H^*	dimensionless liquid height
H_{BL}	height of interface below which there is no vapour carryunder (m)
H_o	height of liquid without swell (m)
H_x	height of vessel (m)
j	total volume flux, or superficial velocity (m/s)
j_g	superficial velocity of gas (m/s)
j_{gl}	superficial velocity of gas phase relative to liquid phase, drift flux (m/s)
j_l	superficial velocity of liquid (m/s)
j_{lg}	superficial velocity of liquid phase relative to gas phase, drift flux (m/s)
$\mathrm{j}_{g\infty}$	vapour superficial velocity (m/s)
J_o	dimensionless heat flux constant
L	length of vessel (m)
m	index
n	index
q	heat input per unit mass (kW/kg)
Q_{ex}	external heat input flux (kW/m^2)
S	volumetric source strength (m^3/s)
U	velocity (m/s)
U_c	downward liquid recirculating velocity (m/s)
U_g	area average velocity of gas (m/s)
U_l	area average velocity of liquid (m/s)
U_s	upward liquid superficial velocity (m/s)
U_∞	bubble rise velocity (m/s)
V_l	volume of liquid (m^3)
x_e	mass fraction of vapour at vent
z	vertical distance from bottom of vessel (m)
α	void fraction
α_o	initial void fraction, or freeboard
δ	thickness of boundary layer (m)
ϵ	geometric factor
ρ	parameter density (kg/m^3)
σ	surface tension (N/m)
ψ	dimensionless source strength, dimensionless velocity
Ω	ratio of vessel area to vent area

Superscript

¯	average

Subscripts

c	continuous phase
g	gas
l	liquid
∞	rise

Section 15.6

See Section 15.4 plus

A	cross-sectional area of valve (m^2)
A_{in}	cross-sectional area of inlet pipe (m^2)
A_2	cross-sectional area of outlet pipe (m^2)
C_f	specific heat of liquid (J/kg K)
D_{in}	diameter of inlet pipe (m)
D_2	diameter of outlet pipe (m)
f	Fanning friction factor
g	acceleration due to gravity (m/s^2)
G	mass velocity ($kg/m^2\,s$)
h	specific enthalpy (J/kg)
H	change in elevation (m)
K	valve discharge coefficient
L_2	length of outlet pipe (m)
L_{in}	length of inlet pipe (m)
ΔP_{in}	total pressure difference across inlet pipe (Pa)
P	absolute pressure
P_b	absolute back pressure at orifice (Pa)
P_c	absolute critical pressure (Pa)
P_o	absolute stagnation pressure in vessel (Pa)
P_s	absolute saturation pressure of liquid (Pa)
T	absolute temperature (K)
v	specific volume (m^3/kg)
$\bar{v}_{in}$	average specific volume in inlet pipe (m^3/kg)
W	mass flow (kg/s)
x	mass fraction of vapour, or quality
α	void fraction
η	pressure ratio defined by Equation 15.6.5
ρ	density (kg/m^3)
$\bar{w}$	parameter

Subscripts

act	actual
c	critical
f	liquid
fg	liquid–vapour transition
g	vapour
s	stagnation
req	required
s	saturation
1	upstream end of outlet line
2	downstream end of outlet line

Section 15.7

a	velocity of sound in gas at choke (m/s)
A	cross-sectional area of choke (m^2)
C_D	coefficient of discharge
H	enthalpy (J/kg)
P	absolute pressure (Pa)
P_{ms}	absolute pressure at which metastability is no longer supported (Pa)
P_s	absolute saturated vapour pressure of liquid (Pa)
P_x	absolute orifice pressure (Pa)
R	universal gas constant (kJ/mol K)
S	entropy (kJ/kg K)
T	absolute temperature (K)
T	absolute temperature upstream of orifice (K) (Equation (15.7.7)
T_c	absolute critical temperature of liquid (K)
V	volume of vessel (m^3)

W	mass flow from vessel (kg/s)
Π	depressurization rate (N/m^2 s)
ρ	density of gas (kg/m^3) (Equations 15.7.1–15.7.6); density (Equations 15.7.7 and 15.7.8)
σ	surface tension of liquid (N/m)

Subscripts

c	choke
d	downstream
g	gas
I	vessel
l	liquid
o	initial
s	isentropic
u	upstream

Section 15.8

Subsection 15.8.1

h	height of liquid in vessel
h_b	height reached by liquid on depressurization
h_0	initial height of liquid
h_v	height of vessel
ΔH_v	latent heat of vaporization
K	ratio of vent area to vessel cross-sectional area
m	mass
ΔT	superheat
δ	diameter of vapour nucleus
ρ	density
σ	surface tension

Subscripts

l	liquid
nb	nucleate boiling
o	initial
onb	onset of nuclear boiling
r	retained
sat	saturation value
v	vapour

Subsection 15.8.2

A_1	area of aperture
A_2	area of cloud perpendicular to direction of expansion at end of second stage (Hardee and Lee model)
c	constant
h	height of cloud; specific enthalpy (Equation 15.8.4)
r	radius, radial distance
s	specific entropy
u	velocity
V	volume of cloud
W	initial mass of fluid
ρ	density
ψ	momentum of cloud

Subscripts

a	air
d	dump
f	liquid
v	vapour
1, 2	initial and final states

Subsections 15.8.3 and 15.8.4

a	radius of initial cloud formed on completion of bursting process
c	concentration
l	mixing length
r	radial distance
u'	fluctuating velocity
V_g	effective volume of vapour
w	propagation velocity of cloud boundary
X_c	parameter characterizing mass fraction of gas in core
ϵ	eddy diffusion coefficient
τ	dimensionless time

Subscripts

c	core concentration
g	core radius
ign	within flammable limits
o	initial cloud

Subsection 15.8.5

c	concentration at transition
M	initial mass of liquid
N	transition criterion
r	distance
t_g	time to transition
t_v	volume of vapour released
w	radial velocity
α	momentum per unit mass
Δ	buoyancy term
ρ	density

Subscripts

a	air
v	vapour

Section 15.9

A	cross-sectional area of pipeline
d	diameter of pipeline
f	friction factor
f_D	Darcy friction factor
l	length of pipeline
m	mass flow from pipeline
N	correction factor
u	velocity
v	specific volume
W	mass hold-up in pipeline
Y	void fraction
z	distance along pipeline from rupture point
τ_1, τ_2	time constants
ϕ_g	parameter defined by Equation 15.9.14
ψ	parameter defined by Equation 15.9.7a

Subscripts

e	exit
f	liquid
fs	superficial value for liquid
g	vapour
i	two-phase interface

o	initial
s	sound

Section 15.10

Subsections 15.10.1–15.10.3

a	albedo
A_p	area of pool
C_BM	logarithmic mean concentration difference
C_T	total concentration
d	pool diameter or, more generally, characteristic length
D	diffusion coefficient
h	heat transfer coefficient
ΔH_v	latent heat of vaporization
j_h	j factor for heat transfer
j_m	j factor for mass transfer
k	thermal conductivity
k_m	mass transfer coefficient
m_v	mass vaporization rate per unit area
p	partial pressure
p°	vapour pressure
q	heat flow per unit area
q_cd	heat flow per unit area by conduction from ground to pool
q_cn	heat flow per unit area by convection from atmosphere to pool
q_r	net heat flow per unit area by radiation from pool
q_ra	heat flow per unit area by radiation from atmosphere to pool
q_rI	heat flow per unit area by radiation from pool to atmosphere
q_rs	heat flow per unit area by solar radiation to pool
q_v	heat required per unit area for vaporization
Q	total heat transferred per unit area
Re_x	point Reynolds number
u	velocity
w	mass of liquid
z	vertical distance down into soil
α	thermal diffusivity
ϵ	emissivity
θ	temperature above datum, or soil, temperature
λ	constant
σ	surface tension (Equation 15.10.4); Stefan–Boltzmann constant (Equations 15.10.35 and 15.10.36)
ϕ	fraction of liquid vaporized, flash fraction
ψ	solar constant

Subscripts

a	air, atmosphere
b	normal boiling point
d	drop
i	initial
l	liquid
o	initial
s	soil
v	vapour
∞	atmosphere beyond influence of pool

Equations 15.10.10 and 15.10.11:

k	constant
M_i	molecular weight of component i
M_To	initial mass of liquid
n_T	moles of liquid
$p_{i\mathrm{s}}$	vapour pressure of component i
$x_{i\mathrm{o}}$	initial mol fraction of component i in liquid

Subsection 15.10.4

a	constant defined by Equation 15.10.41
D	diffusion coefficient of vapour in air ($\mathrm{cm^2/s}$)
E	evaporation rate (g/s)
f_1, f_2	parameters defined by Equations 15.10.45 and 15.10.46
k	von Karman constant
K	constant defined by Equation 15.5.39
K'	constant defined by Equation 15.5.40
M	molecular weight
n	diffusion index
p°	vapour pressure of liquid ($\mathrm{dyn/cm^2}$)
r	radius of pool (cm)
R	universal gas constant (erg/gmol K)
T	absolute temperature (K)
u	wind speed (cm/s)
u_1	wind speed at height z_1 (cm/s)
x_0	downwind length of pool (cm)
y_0	crosswind width of pool (cm)
z	height (cm)
z_1	height at which wind speed u_1 is measured (cm)
λ	parameter ($\mathrm{cm^2/s}$)
v	kinematic viscosity of air ($\mathrm{cm^2/s}$)
χ_o	concentration ($\mathrm{g/cm^3}$)

Equations 15.10.50 and 15.10.51
As for Subsection 15.10.4, but with SI units plus

a, a'	constants

Subsection 15.10.5

C_D	drag coefficient
u	wind speed
ρ_g	density of gas at 10 m from pool
ρ_sg	saturation density of gas at ambient conditions

Subsection 15.10.6

c	specific heat
C	constant
h	heat transfer coefficient
j_m	j factor for mass transfer
k	constant
k_m	mass transfer coefficient
N	mass transferred per unit area
p	partial pressure
q_cn	heat flow per unit area by convection from atmosphere to pool
u	wind speed
x	diameter of pool

Subscripts

a	air, atmosphere
l	liquid

v	vapour
∞	atmosphere beyond influence of pool

Subsection 15.10.7

c	constant
C	constant
C_L	constant (for land)
C_W	constant (for water)
f	constant
F	friction term
F_g	gravity force
F_i	inertia force
h	height of pool
r	radius of pool
s	shape factor
u	velocity of pool edge
V	volume of pool
β	shape factor
Δ	buoyancy term
ν	kinematic viscosity

Subscripts

l	liquid
w	water

Subsection 15.10.8

As Subsections 15.10.1–15.10.3 plus:

A_v	vaporization parameter

Equation 15.10.75

t	time (s)
v	vaporization, or regression, rate of liquid surface (cm/s)

Subsection 15.10.9

As Subsections 15.10.1–15.10.3 plus

A	volume of liquid for instantaneous spill
k_3	constant
m	total mass vaporized
r	radial distance
v	vaporization, or regression, rate of liquid surface

Equations 15.10.77 and 15.10.78

E_i	mass vaporized per unit area within 1 min (g/cm^2)
E_s	steady-state mass vaporization rate per unit area (g/cm^2/s)
ΔH_v	latent heat of vaporization (cal/g)
k_1, k_2	constants

Equation 15.10.79

m_v	mass vaporization rate per unit area
q_w	heat flow per unit area from water to spill
ΔT	temperature difference between substrate and spill
β	coefficient of cubical expansion (Equation 15.10.79)
ν	kinematic viscosity

Subscript

w	water

Equation 15.10.80

m_v	mass vaporization rate per unit area (kg/m^2/s)
t	time (s)

Subsection 15.10.10

A	volume of liquid for instantaneous spill
A_p	area of pool
B	volumetric flow of liquid for continuous spill
ΔH_v	latent heat of vaporization
k	thermal conductivity
m	total mass vaporized
M_s	mass of spill liquid
r	radius of pool
v	vaporization, or regression, rate of liquid surface
V	volume of pool
X	surface roughness factor
α	thermal diffusivity
β_1	constant defined by Equation 15.10.102
β_2	constant defined by Equation 15.10.106
θ	parameter defined in Equation 15.10.98

Subscripts

b	normal boiling point
e	end of evaporation
o	initial
s	soil
1, 2	at time t_1, t_2

Subsections 15.10.11 and 15.10.12

A_o	area of confined spill
c	specific heat
ΔH_v	latent heat of vaporization
k	thermal conductivity
L	characteristic length
m_v	mass vaporization rate per unit area
q	heat flux per unit area
r	radial distance
S	parameter defined by Equation 15.10.114
t_{ch}	characteristic evaporation time
t_{cr}	time for transition from instantaneous to continuous spill, crossover time
t_o	time for spill to cover confined area
ΔT	temperature difference between liquid at distance r_1 and soil
v	vaporization, or regression, rate of liquid surface
V	volume of pool
V_c	volumetric flow of liquid into continuous spill
V_i	volume of liquid in instantaneous spill
α	thermal diffusivity
ξ	dimensionless maximum spread
τ	dimensionless time

Subscripts

e	end of evaporation
l	liquid

s	soil
sp	spill duration
1	value at radial distance r_1

Subsection 15.10.13

p	fraction which dissolves in water, partition coefficient
r_e	final evaporation radius (ft)
t_e	final evaporation time (s)
v	regression rate (ft/s)
V	volume spilled (US gal)
Δ	buoyancy term defined by Equation 15.10.63

Subsections 15.11–15.66

C_E	slumping coefficient
x, y, z	distances in downwind, crosswind, vertical directions
u	wind speed
u, v, w	wind velocity components in down wind, crosswind, vertical directions
u_*	friction velocity
x_i	mixed layer height
z_0	roughness length
Γ	dry adiabatic lapse rate
$\sigma_u, \sigma_v, \sigma_w$	standard deviations of wind velocity in downwind, crosswind, vertical directions
$\sigma_x, \sigma_y, \sigma_z$	standard deviations, or dispersion coefficients, in downwind, crosswind, vertical directions
χ	concentration (mass per unit volume)

Subscripts

a	air
cl	centreline
cr	critical
mgl	maximum ground level
tr	transition
x, y, z	in x, y, z directions

Section 15.11

h	height of cloud
p	index

Section 15.12

Subsection 15.12.4

f	Coriolis force
p	pressure
X, Y	accelerations in downwind, crosswind directions representative of forces not due to pressure and gravity
ϕ	latitude
ω	angular velocity of earth

Subsections 15.12.5–15.12.28 and 15.12.32–15.12.34

a	constant
c	constant
c_g	drag coefficient
c_p	specific heat of air
d	zero plane displacement, displacement height
E	vertical flux of water vapour, evaporation rate
f	Coriolis force
F_s	vertical flux
h'	scale height of neutral atmospheric boundary layer
H	vertical heat flux, sensible heat flux
i_y, i_z	intensities of lateral, vertical turbulence
k	von Karman constant
K	coefficient of exchange, turbulent exchange coefficient
K_H	coefficient of exchange for heat, eddy thermal diffusivity
K_M	coefficient of exchange for momentum, eddy diffusivity for momentum, eddy viscosity
K_{Mo}	adiabatic value of K_M
K_w	coefficient of exchange for water vapour, eddy diffusivity
l	mixing length
L	Monin–Obukhov length
L_e	latent heat of vaporization
L_w	latent heat of water vapour
n	index
p	index (Subsection 15.12.8 and 15.12.25); absolute pressure (Subsection 15.12.13)
p_o	absolute pressure at surface
P_u	P value
P_θ	P value
q	concentration of water vapour, or specific humidity
Q_0	surface heat flux
Ri_B	bulk Richardson number
Ri_F	flux Richardson number
Ri_{mod}	modified Richardson number
s	environmental stability
S	non-dimensional windshear (Equation 15.12.25); mean quantity of property per unit mass of air (Equation 15.12.55)
S^*	scale parameter
T_o	absolute average temperature of mixed layer
u_g	geostrophic wind speed
U_R	wind speed ratio
u, v, w	wind speeds in downwind, crosswind, vertical directions
$\bar{v}, \bar{u}, \bar{w}$	mean wind speeds in downwind, crosswind, vertical directions
u', v', w'	wind speed fluctuations in downwind, cross–wind, vertical directions
$\bar{v}'^2, \bar{u}'^2, \bar{w}'^2$	variances of wind speed in downwind, crosswind, vertical directions
w^*	convective velocity
X	parameter defined by Equation 15.12.108
z	height
α	Monin–Obukhov coefficient
α_1, α_2	constants
β	ratio of specific heats of air; constant (Equation 15.12.49b)
ϵ	mean height of roughness elements (Subsection 15.12.12); eddy dissipation rate (Subsection 15.12.28)

θ	potential temperature
ζ	Monin–Obukhov parameter
μ	Kazanski–Monin parameter
ν	kinematic viscosity of air
ρ	density of air
$\Delta\rho$	density difference between cloud and air
σ_A	standard deviation of azimuth
σ_E	standard deviation of elevation
σ_θ	standard deviation of horizontal direction of wind
σ_ϕ	standard deviation of inclination to horizontal of wind
τ	mean momentum flux per unit area, Reynolds stress
ϕ_H	similarity factor for heat flux
ϕ_M	similarity factor for momentum flux
ϕ_s	similarity factor for property s
ϕ_W	similarity factor for water vapour flux

Subscripts

s	property specified
1, 2	at height 10 and 5 m, respectively

Equation 15.12.40

H	sensible heat flux (W/m^2)
S	incoming solar radiation (W/m^2)

Equation 15.12.80

p	index
t	sampling period

Equations 15.12.112–15.12.114

A, B	constants
Q_m	maximum surface heat flux
Z_{im}	maximum mixed layer height
τ	time after sunrise

Subsection 15.12.29

i	intensity of turbulence
r	radius of eddy
t_E	Eulerian time scale
t_L	Lagrangian time scale
β	ratio of Lagrangian to Eulerian time scales
ω	tangential velocity

Subsections 15.12.30 and 15.12.31

$R(x)$	correlation coefficient
$R(\tau)$	correlation coefficient
t	time
u	velocity
u'	component of velocity
x	distance
σ_x	standard deviation in downwind direction
τ	time

Subscripts

1, 2	points 1, 2

Sections 15.14 and 15.15

Subsection 15.14.1

K	diffusion coefficient (m^2/s)
K_x, K_y, K_z	diffusion coefficients in downwind, cross-wind, vertical directions (m^2/s)
r	radial distance (m)
t	time (s)
u, v, w	wind speeds in downwind, crosswind, vertical directions (m/s)
x, y, z	distances in downwind, crosswind, vertical directions (m)
χ	concentration (kg/m^3)

Subsection 15.14.5

D	diffusion coefficient, diffusivity
k	thermal conductivity
l	characteristic dimension
u	velocity
ν	kinematic viscosity

Section 15.16

Subsections 15.16.1, 15.16.2 and 15.16.5

As Subsection 15.14.1 plus

C	diffusion parameter (m$^{(1/2)n}$)
C_x, C_y, C_z	diffusion parameters in downwind, crosswind, vertical directions (m$^{(1/2)n}$)
h	height of source (m)
H	height of source (m)
K	diffusion coefficient (m^2/s)
K_0	modified Bessel function of second kind
n	diffusion index
p	index
Q	continuous mass rate of release (kg/s)
Q'	continuous mass rate of release per unit length (kg/ms)
Q^*	mass released instantaneously (kg)
y_o, z_o	cloud bondary in y, z directions (m)
$\sigma_x, \sigma_y, \sigma_z$	standard deviations, or dispersion coefficients, in downwind, cross wind, vertical directions (m)

Subsection 15.16.3

C	ground level concentration (units/m^3)
C_c	ground level concentration axis of plume for elevated source (units/cm^3)
C_0	ground level concentration axis of plume (units/m^3)
d	distance in downwind direction (km)
d'	half-distance for development of uniform vertical concentration profile (km)
F_1	stack correction factor
F_2	off-axis correction factor
h	vertical spread (m)
h'	limiting vertical spread (m)
H	height of stack (m)
Q	mass rate of release (units/min)
x	downwind distance (m)
u	mean wind speed (m/s)
β	deviation from axis (°)

θ	lateral spread (°)
σ_{y}	standard deviation of concentration in crosswind direction (m)
σ_{θ}	standard deviation of wind direction (°)
σ_{ϕ}	standard deviation of wind inclination (rad)
ϕ	wind inclination (rad)

Subsections 15.16.6–15.16.8

As sections 15.16.1–15.16.4 plus

D	dosage
D_{tid}	total integrated dosage
e	base of natural logarithms
L	load
n	index (Equation 15.16.67)

Subscripts

cb	cloud boundary
cc	cloud centre
ex	extinction

Subsection 15.16.9

C	volumetric concentration (v/v)
V_1	distance between first virtual source and actual source (m)
V_2	distance between second virtual source and actual source (m)
V	volume of gas released (m^3)
x	downwind distance (m)
x_{b}	distance between actual source and works boundary (m)
x_{s}	distance between actual source and point of interest (m)
x_{v1}	distance between first virtual source and works boundary (m)
x_{v2}	distance defined by Equation 15.16.72

Subsections 15.16.7 and 15.16.8

K	parameter
m, n	indices
t_{e}	time for total discharge or evaporation

Section 15.17

Subsection 15.17.1

Q_{a}	mass rate of release per unit area
Δx	incremental length
ξ_{a}	concentration above mixed layer height
ξ_{b}	concentration upwind of city, background concentration

Subsection 15.17.3

As Sections 15.16.1–15.16.4 plus

a	radius of hill
$D_{\mathrm{y}}, D_{\mathrm{z}}$	parameter defined by Equations 15.17.5a and 15.17.5b
h	actual stack height
Δh	plume rise
h_{e}	equivalent stack height
h_0	effective stack height
h_1, h_2	height of hills 1 and 2
h_{p}	local height of plume
ζ	parameter defined by Equation 15.17.7
η	parameter defined by Equation 15.17.6
ψ	stream function

Subscripts

f	flat terrain
o	effective source height

Subsection 15.17.4

D_{l}	larger of dimensions height h and width w
D_{s}	smaller of dimensions height h and width w
h	height of building
h_{s}	height of source
l	alongwind length of building
R	scaling factor
w	crosswind width of building

Equations 15.17.11–15.17.15

h_{c}	height of roof cavity
l_{c}	length of roof cavity
x	downwind distance
Z_{II}	upper boundary of high turbulence layer
Z_{III}	upper boundary of roof wake

Equations 15.17.6 and 15.17.17

A	characteristic area
A_{v}	vent area
K	dimensionless concentration
Q	mass rate of release
w_{o}	effluent velocity

Equations 15.17.18 and 15.17.19

h	actual stack height
h'	effective stack height after downwash
h_{d}	downwash
h_0	effective plume height

Equations 15.17.20–15.17.22

A, B	parameters defined by Equations 15.17.21, 15.17.22
$x_{\mathrm{r}}, y_{\mathrm{r}}, z_{\mathrm{r}}$	length, width, height of wake cavity

Equations 15.17.23–15.17.26

A	cross-sectional area of building normal to wind
c	constant
D_{A}	atmospheric dilution factor
D_{B}	building dilution factor
D_{tot}	total dilution factor
Q	mass rate of release
x	downwind distance
$\sigma_{\mathrm{y}}, \sigma_{\mathrm{z}}$	dispersion coefficients in crosswind, vertical directions

Equations 15.17.27–15.17.44

C	mean concentration
H	parameter defined by Equation (15.17.28)
k	constant
k_{f}	characteristic energy of free stream turbulence
l_{f}	characteristic length of free stream turbulence
Q	source strength
S	dimension of block

u	mainstream air velocity
V	volume of wake bubble
X	length of wake bubble
Λ	free stream turbulence parameter

Equations 15.17.33–15.17.44

A	frontal area of building
b	crosswind breadth of building
C_w	average concentration in near-wake region
F	flow out of wake
h	height of building
L_r	length of recirculation region
Q	source strength
S	surface area of near-wake region
t_r	residence time in near-wake region
u_h	wind speed at building height in undisturbed flow
V	volume of near-wake region
α	flux constant
β	wake shape parameter
λ_r	dimensionless length of recirculation region
τ_r	dimensionless residence time in recirculation region
χ_w	dimensionless average concentration in near-wake region

Section 15.18

H	height of 'lid'
Q	mass rate of release

Section 15.19

Subsection 15.19.1

As Subsections 15.16.1–15.16.4 plus

f_1, f_2	universal functions
$R(\tau)$	autocorrelation coefficient
t_L	Lagrangian time scale
T_i	dispersion time
T_y, T_z	time scales for lateral, vertical dispersion
δ	delta function
σ_θ	standard deviation of wind direction

Subsection 15.19.3

As Section 15.16.3 plus

d	distance
h	vertical spread
θ	lateral spread

Subsection 15.19.6

As Sections 15.16.1–15.16.4 plus

a, c, f, h	constants
b, d, g, j	indices
$F(z_0, x)$	roughness length correction factor
P	P value
T	duration of release (h)
u_{10}	wind speed at 10 m height (m/s)
σ_y	dispersion coefficient in crosswind direction (m)
σ_{yt}	turbulent diffusion term (m)
σ_{yw}	wind direction fluctuation term (m)
σ_θ	standard deviation of horizontal wind direction (rad)

Subsection 15.19.7

As Sections 15.16.1–15.16.4 plus

Equation 15.19.25

a, c	constants
b, d	indices

Equation 15.19.26

a, b, c	constants
σ	dispersion coefficient

Subsection 15.19.8

As Sections 15.16.1–15.16.4

Subsections 15.19.9–15.19.11

As Sections 15.16.1–15.16.4 plus:

p	index
R	reference distance
α, β	indices

Subsection 15.19.12

As Sections 15.16.1–15.16.4 plus

c_1, c_2, c_3	constants
ϵ	eddy dissipation rate
σ	dispersion coefficient
σ_o	initial size of puff

Subscripts

o	initial
plume	plume
puff	puff

Section 15.20

d_o	diameter of outlet
r_o	radius of outlet

Subscripts

e	exit
o	outlet

Subsections 15.20.2–15.20.3

u	velocity of gas

Equations 15.20.1–15.20.23

b_0	half-width of slot
c	volumetric concentration
d	width of slot
k	constant
k_1–k_7	constants
m	mass flow
M	momentum flux
r	radial distance
r_p	radius of pipe (for radial jet)
u	velocity of gas
w	wind speed
x	distance along axis of jet
β	half angle of jet
θ	air–fuel mass ratio

Subscripts

m	centre line, and hence maximum
tr	transition (from jet to plume)
x	mean value at axial distance x

x_o	centre line
xr	at axial distance x and radial distance r

Equations 15.20.24–15.20.37

D	diameter
M	mass flow
u	velocity of gas

Subscripts

a	atmospheric
E	exit, or outlet
N	nozzle, or outlet
s	shock plane
v	vessel

Equations 15.20.38–15.20.46

b_1–b_3	constants
d_{eq}	equivalent diameter
j	volumetric concentration
x	distance along axis of jet
x'	distance between virtual source and outlet
x''	distance defined by Equation 15.15.41
y	radial distance
$\rho_{ga'}$	normalized density of gas at atmospheric conditions
$\rho_{go'}$	normalized density of gas at outlet
$\rho_{oeq'}$	normalized density of gas at equivalent diameter

Subscripts

m	centre line, hence maximum
xy	at point x, y

Equations 15.20.47–15.20.62

A	cross-sectional area of flow
c_D	coefficient of discharge
d	diameter
k	compressible eddy coefficient
k'	eddy viscosity coefficient
m	mass fraction
N	pressure ratio
r	radius
$r_{0.5}$	radius at which velocity is half centre line value
u	velocity of gas
x_c	dimensionless core length
z	distance along axis of jet
z_b	barrel length
z^*	modified axial distance

Subscripts

eq	equivalent
m	centre line, hence maximum
v	vessel

Subsection 15.20.4

a	radius of outlet
c	constant
d	diameter of outlet
k	constant representing air resistance
l	height of outlet
x	distance in horizontal direction
u	horizontal velocity of liquid
z	distance in vertical direction
Z	breakup length
α	angle between jet and horizontal (Equations 15.20.63–15.20.78); constant (Equations 15.20.79–15.20.86)
δ	amplitude of disturbance
δ_o	initial amplitude of disturbance
σ	surface tension

Subsection 15.20.6

c	volumetric concentration
F	buoyancy flux
k_4 and k_5	constants
l	characteristic length
M	momentum flux
Q	volumetric flow
r	radial distance
u	velocity of gas in jet or plume
x	distance along axis
β	coefficient of cubical expansion
$\Delta\rho_o$	density difference

Subscripts

lt	transition (from laminar to turbulent)
xr	at axial distance x and radial distance r

Subsection 15.20.7

As Sections 15.16.1–15.16.4

Subsection 15.20.8

C	constant
F	buoyancy flux
M	momentum flux
u	velocity of gas
z_{max}	maximum plume rise

Subscripts

l	ambient fluid

Subsection 15.20.9

A	time parameter (defined by Equation (15.20.105))
D_c	drag coefficient
$F_1(x_1)$	function expressing change in density of plume due to dilution by air
h_{pl}	total effective height of plume
H	height of outlet (m)
i	rise of fall of plume at distance wt_1
J	volumetric flow from outlet referred to ambient temperature (m^3/s)
k_1, k_6–kc_8	constants
l	height of jet (above outlet)
m_a	mass flow of air
m_l	mass flow of gas-air mixture at distance l
m_o	mass flow at outlet
M	molecular weight of gas
M_a	molecular weight of air
N	volumetric flow from outlet
Q	volumetric flow at outlet

p_a	concentration along axis at distance x (mole fraction)
p_{mgl}	maximum ground level concentration at distance x (mole fraction)
r	radial distance from axis
t_1	arbitrary chosen time interval
u	velocity of gas
u_b	buoyancy velocity
u_σ	velocity of plume along axis of falling plume from virtual source to ground
v	velocity at outlet
w	wind speed
x	downwind distance, downwind distance from virtual source
x_{max}	downwind distance from virtual source at which maximum rise of plume occurs
x_{mgl}	downwind distance to maximum ground level concentration
x_0	downwind distance of transition point from virtual source
x_1	downdwind distance from virtual source at which plume axis reaches ground
x_1	distance defined by Equation (15.20.106)
x_θ	distance from virtual source to point where plume reaches ground measured along axis of plume
z	vertical distance above transition point
z_{max}	maximum plume rise
θ	angle between axis of falling plume and horizontal
ρ_g	density of gas at outlet
ρ_l	mean density of gas–air mixture at distance l
ϕ	angle between axis and edge of plume, half-angle of plume
ψ	momentum flux in still air
ψ_w	momentum flux in windy conditions

Subscripts

g	gas at outlet
trw	transition in windy conditions
w	windy conditions

Subsection 15.20.10

C_1, C_2	constants
e	base of natural logarithms
F	buoyancy flux
h_e	effective stack height
h_s	stack height
Δh	plume rise (above stack outlet)
H	surface buoyancy flux
k	von Karman's constant
m	molecular weight
M	momentum flux
Q	mass rate of release
r	radius
s	environmental stability
s'	modified stability
S	ratio of effective area influenced by plume momentum to cross-sectional area of so-called thermal plume
u	wind speed
V	volumetric flow
w	velocity in vertical direction
w'	parameter defined by Equation (15.20.180)
z	vertical distance above stack outlet; height of jet or plume
z_{max}	maximum plume rise
α	constant
β	constant
ϵ	ambient eddy dissipation rate
η	constant
σ	dispersion coefficient

Subscripts

c	critical
eff	effective
en	environment
eno	initial environment
eq	equilibrium
fb	fallback
p	plume
po	initial plume

Section 15.21

Subsection 15.21.1

ϵ	constant

Subscripts

sat	saturation
sh	shattering

Subsection 15.21.2

A	cross-sectional area of jet
C	concentration (mass per unit volume)
G	mass flow in jet
R	radius of jet
u	velocity of jet
z	distance downstream from source
α	entrainment coefficient
β	half-angle of jet

Subscripts

d	end of deposition zone
∞	asymptotic value

Subsection 15.21.3

A	cross-sectional area of jet
B	buoyancy flux
C	concentration of contaminant
f	momentum flux
L	length scale
p	dimensionless variable defined by Equation 15.21.32
q	dimensionless variable defined by Equation 15.21.33
R	radius of jet
u	velocity of jet
u_E	entrainment velocity
U	velocity scale
x	downstream distance
α	entrainment coefficient
ϕ	ratio of density of jet to that of air

Subsection 15.21.4

A	cross-sectional area of jet
e	entrainment rate
E_o	entrainment coefficient
h	specific enthalpy
P	pressure in jet
R	radius of jet
u	velocity of jet
x	vapour fraction, or quality
z	distance along jet axis

Subscripts

a	at end of depressurization zone
b	at orifice
bp	boiling point
f	liquid
fg	liquid–vapour transition
g	vapour
o	stagnation conditions
tp	two-phase
∞	atmospheric conditions

Section 15.24

Subsections 15.24.6–15.24.9

k	van Karman constant
K	eddy diffusivity
L	Monin–Obukhov length
p	index
z	height
Δ	reduced density difference defined by Equation 15.24.3
Δ'	reduced density difference (alternative formulation, defined by Equation 15.24.5)
$\Delta\rho$	absolute density difference
ϵ	energy dissipation rate
κ	turbulence energy
ψ	profile function

Subsection 15.24.10

C_f	friction factor
G	mass velocity
h	heat transfer coefficient
j_H	j factor for heat transfer
k	thermal conductivity
L	characteristic dimension
St_h	Stanton number for heat transfer
ΔT	temperature difference for heat transfer
u	velocity of cloud
β	coefficient of thermal expansion

Subscripts

t	film
gr	between ground and cloud

Subsection 15.24.11

c	velocity of wave
h	height of dense fluid
n	symmetry index
u	velocity of dense fluid
x	distance

Subsection 15.24.12

B	negative buoyancy
H	height of cloud
R	radius of cloud
u_e	top entrainment velocity
V	volume of cloud
w_e	edge entrainment velocity

Section 15.25

As Sections 15.16.1–15.16.4 plus

c	volumetric concentration
c_p	specific heat of gas in source cloud
E	heat source in cloud
H	height of cloud
L	width of source
m	mass of gas in source cloud
R	radius of cloud
u_e	top entrainment velocity
V	volumetric rate of release
W_v	velocity of vapour source
x_v	distance of virtual source upwind of actual source
ϵ_v	heat released by condensation and freezing of water vapour
ϵ_w	surface heat flux

Subscript

i	initial

Section 15.26

A, B	constants
B	rate of buoyancy destruction of turbulent energy
c_1	constant
c_t	constant
C	volumetric concentration
D	rate of dissipation of turbulent energy into internal heat
F_a	force due to reaction of ambient fluid to outward radial acceleration of cloud edge
F_d	drag force on cloud edge due to presence of quiescent ambient fluid
F_s	static pressure force due to negative buoyancy of cloud
F_v	force due to vertical acceleration in cloud and reaction of ambient fluid
G	rate at which gravity transforms potential energy into mean kinetic energy
H	height of cloud
$\mathrm{H_f}$	height of fluid front
I_E	internal heat
K_E	kinetic energy of mean radial and vertical motions
L	half-width of plume
M_{rd}	radial momentum integral of cloud
P_E	potential energy
Q	volumetric rate of release
R	radius of cloud
$\mathrm{Ri_t}$	bulk turbulent Richardson number
s	profile shape parameter
S	cross-sectional area of plume from continuous release

	(Equations 15.26.19–15.26.18); rate of shear production of turbulent energy (Equations 15.26.30 and 15.26.31)
T_E	turbulent kinetic energy
u_e	top, or vertical, entrainment velocity
u_f	velocity of fluid front
u_y	cloud velocity in crosswind direction
u_t	bulk turbulent velocity
V	volume of cloud
w_e	edge, or horizontal, entrainment velocity
W_o	volumetric flow from source
γ	edge entrainment coefficient
Δ	reduced density difference
Δ'	reduced density difference for cloud
ρ_1, ρ_2	density of fluid behind, ahead of wavefront
$\bar{\rho}_c$	mean density of cloud
$\Delta\rho_c$	mean density difference of cloud
$\Delta\rho_o$	mean density difference of cloud

Superscript

$\bar{}$	average

Subscripts

c	cloud
o	time zero, hence source
u	transition

Subsection 15.26.4

Subscripts

c	continuous
i	instantaneous

Section 15.27

C_d	drag coefficient
C_f	friction factor
c_{pc}	specific heat of cloud
D	drag force on cloud
f	wind speed coefficient
F	friction force
h	specific enthalpy
h_{grn}	heat transfer coefficient between ground and cloud by natural convection
H	height of cloud
k_E	spreading constant
l	turbulence length scale
l_{vs}	width of virtual source
L	half-width of cloud
m	total mass in cloud
m	mass of component in cloud (with subscript)
m_e	mass of air entrained at edge of cloud
m_t	mass of air entrained at top of cloud
Q	continuous mass rate of release
Q^*	mass released instantaneously
Q_e	volumetric flow of air entrained at edge of cloud (total value for instantaneous release; value per unit downwind distance for continuous release)
Q_{gr}	heat flux from ground to cloud
Q_t	volumetric flow of air entrained at top of cloud (total value for instantaneous release; value per unit downwind distance for continuous release)
$r(n)$	distance downwind from source η
R	radius of cloud
S^*	parameter defined by Equation 15.27.20
u'	magnitude of vector sum of slumping and wind velocities
u_{av}	average wind speed cloud height
u_c	velocity of cloud
u_e	top, or vertical, entrainment velocity
u_h	wind speed at cloud height H
u_r	wind speed at reference height (normally 10 m)
u_l	longitudinal turbulence velocity
V	volume of cloud per unit distance downwind (total value for instantaneous release; value per unit downwind distance for continuous release)
w_e	edge, or horizontal, entrainment velocity
α	top entrainment coefficient
β	limiting value of group (u_e/u_l)
γ	edge entrainment coefficient
σ	dispersion coefficient
τ	shear stress

Subscripts

c	cloud
gr	ground
l	liquid
o	source
v	vapour
wl	water liquid
wv	water vapour
y	crosswind

Section 15.28

C^*	constant
g_{gr}	heat transfer coefficient between ground and cloud
H	height of cloud
l	turbulence length scale
k	constant
k	thermal conductivity (with subscript)
m	total mass in cloud
m_a	mass of air
m_g	mass of gas
Q_{gr}	heat flux between ground and cloud
R	radius of cloud
ΔT_a	temperature difference between air and cloud
ΔT_{gr}	temperature difference between ground and cloud
u_c	velocity of cloud
u_e	top, or vertical, entrainment velocity
u_r	wind speed at reference height (normally 10 m)
u_l	longitudinal turbulence velocity
V	volume of cloud
w_e	edge, or horizontal, entrainment velocity

x_{vy}	distance downwind of virtual source for horizontal dispersion
x_{vz}	distance downwind of virtual source for vertical dispersion
X	parameter defined by Equation 15.28.61
z_τ	reference height (normally 10 m)
Z	parameter defined by Equation 15.28.11
β	coefficient of volumetric expansion
γ	edge entrainment coefficient
Δ	reduced density difference
$\Delta\rho$	density difference

Subscripts

c	cloud
f	fluid film
g	gas, material release
gr	ground
H	Hosker scheme
o	initial
vy	virtual source for crosswind effects
vz	virtual source for vertical effects

Subsection 15.28.1

A, B, C	parameters
L	characteristic dimension of cloud

Subsection 15.28.2

A, B, C	parameters
A'	parameter defined by Equation 15.28.62
L	half-width of cloud

Section 15.29

c	concentration (mass fraction)
C_d	drag coefficient
h	specific enthalpy
H_{min}	height at breakup
K_h, K_v	horizontal, vertical eddy diffusivities
l	turbulence length scale
L_o	latent heat of water
$\dot{m}$	mass rate of evaporation
$\dot{m}_{min}$	mass rate of evaporation at breakup
p	pressure
p_s	pressure at surface
p_t	pressure at top
q	heat flux
t_{max}	time at breakup
U	heat transfer coefficient
W	mass of water vapour per unit mass of air
π	parameter defined by Equation 15.29.7
σ	dimensionless pressure coordinate
$\dot{\sigma}$	substantial derivative in x, y, σ, t coordinates
σ_ϵ	standard derivation of wind direction
τ_o	shear stress at surface
ϕ	geopotential height
ω	substantial pressure derivative

Subscripts

c	cloud
g	gas
l	liquid
s	surface

Section 15.30

b	cloud shape parameter
B	cloud width parameter
C	volumetric concentration
C_1, C_2	concentration functions
h	cloud height parameter
k	von Karman constant
K_a	ambient vertical diffusion coefficient
K_h	horizontal diffusion coefficient
K_v	vertical diffusion coefficient
K_ρ	dense-layer diffusion coefficient
K^m	eddy diffusion tensor for momentum
K^θ	eddy diffusion tensor for energy
K^ω	eddy diffusion tensor for mass fraction
Q_{gr}	heat flux between ground and cloud
p	pressure deviation from an adiabatic atmosphere at rest
ρ'	index
S	temperature source term
u_c	velocity of cloud
u_e	vertical entrainment velocity
u_o	velocity of material at source
u_y	velocity of cloud in crosswind direction
u_{*c}	cloud friction velocity
u	velocity tensor
w_e	horizontal entrainment velocity
w_{*c}	cloud 'convection velocity'
β	cloud shape parameter
β^*	constant
θ	potential temperature deviation from an adiabatic atmosphere
ρ_h	density corresponding to pressure p
ϕ	profile function
ω	mass fraction of material released

Subscripts

c	cloud
g	material released
o	source

Section 15.31

A_i	half-area of source for observer i
b	half-width of middle part
B	half-width of gas blanket
B_{eff}	effective half-width of plume
B_p	half-width of pool
B_s	half-width of source
B_{si}	half-width of source for observer i
B'_{si}	local half-width of source for observer I
c	concentration in mass per unit volume
c_A	ground level concentration on centre line
c'_A	corrected ground level concentration on centre line
c_{gr}	concentration at ground level
C_f	friction factor
H	height of cloud
H_b	height of 100% gas blanket
H_e	surface heat flux
H_{eff}	effective height of cloud
i	counter for observer i

k	von Karman constant
K	eddy diffusion coefficient
K_o	constant
K_o^*	vertical eddy diffusion coefficient at reference height z_r acting on concentration profile of width 2B
L	length of gas blanket
L_p	length of pool
L_s	length of source
L_{si}	length of source for observer i
Q_{gr}	heat flux between ground and cloud
Q_p	*total mass rate of evaporation*
Q''	*mass rate of take-up into atmosphere per unit area*
Q_i''	mass rate of take-up into atmosphere per unit area for observer i
Q''_{max}	mass rate of take-up into atmosphere per unit area
Q_o''	mass rate of evaporation per unit area
Q_p''	mass rate of evaporation per unit area
r	shape factor for crosswind concentration profile
R	radius of source
R_b	radius of gas blanket
R_1	radius of spreading pool
Ri_*	Richardson number defined by Equation 15.31.34
Ri_{*I}	internal Richardson number defined by Equation 15.31.65
s	shape factor for vertical concentration profile
S	dispersion parameter
t_s	specified time
t_{1i}, t_{2i}	times when observer i passes upwind, downwind edges of source
u	wind speed; gas velocity (Equation 15.31.58)
u_e	top entrainment velocity
u_{eff}	effective local cloud velocity
u_A	effective air velocity
u_B	bulk cloud velocity
u_i	velocity of observer i
u_{*I}	internal velocity scale
w_e	edge entrainment velocity
W_b	half-width of concentration profile
x_i	downwind distance of observer i at time t
x_{tr}	downwind distance of transition point
x_v	downwind distance of virtual source
y_{Ls}	limit of integration of y
y_{w3}	mole fraction of surface water vapour
α_T	thermal diffusivity
α'	index
β_c	coefficient of volumetric expansion of cloud
β'	constant
γ	edge entrainment coefficient
γ'	constant
δ'	constant
v	kinematic viscosity
ρ_E	density at emission conditions
ρ_{gr}	density downwind
τ_{gr}	shear stress acting on downwind ground surface
τ_o	shear stress acting on upwind ground surface
ϕ	profile function

Subscripts

c	cloud
g	material released
gr	ground, ground level
i	observer i

Section 15.32

As Section 15.24.10 and Section 15.31 plus

H	height
k	von Karman constant
Ri_*	modified Richardson number
u_e	vertical entrainment velocity
α	index
ϕ	profile function

Section 15.33

c_o	constant or function
p	pressure
S_o	function
u	velocity
x	distance
Γ_o	function
ϵ	energy dissipation
κ	turbulence energy
ϕ	scalar quantity

Subscripts

i, j	i, j direction

Section 15.34

A	constant given in Figure 15.85(b)
B	constant given in Figure 15.87(b)
C	volumetric concentration
$\bar{C}_m$	maximum time mean volumetric concentration on the centre line
C_o	volumetric concentration at initial release
D	characteristic dimension of source
g_m'	reduced gravity corresponding to maximum concentration
g_o	reduced gravity of initial release
G	source geometry
h	measure of plume height
h_c	height of crest
H	height of cloud
l_b	buoyancy length scale
l_i	length scale of turbulence in the atmospheric boundary layer
L_h	half-width of plume
L_{ho}	half-width of plume at source
L_u	upwind extent of plume
L_v	height of plume
n	fraction of initial concentration ($= \bar{C}_m/C_0$); index (Equation 15.34.42)
q_o	volumetric rate of release
Q	volume of cloud
Q_o	volume of material released
R	radius of cloud
R_o	initial radius of cloud

t_a	arrival time of leading edge of cloud
t_c	time between arrival time t_a and departure time t_d
t_d	departure time of trailing edge of cloud
x_c	distance of leading edge
x_n	distance at which the fraction of initial concentration is n
y_c	half-width of cloud
u_{ref}	characteristic mean velocity
ρ_a	density of air
ρ_o	density characteristic of material released
ϕ	stability parameter
ψ	stability parameter

Subsections 15.34.4 and 15.34.5

T_o	duration of release

Subsection 15.34.7

T_a	absolute temperature of air
T_o	absolute temperature of initial volume
V_a	volume of air
V_o	non-isothermal initial volume

Subscripts

I	isothermal
ni	non-isothermal

Section 15.35

a_1–a_3	parameters
C	concentration
C_m	ground level centre concentration
F_h	parameter defined by Equation 15.35.5
F_v	parameter defined by Equation 15.35.6
L_s	Monin–Obukhov length scale
s	parameter
x'	relative coordinate
X	downwind coordinate of cloud centre
w	parameter
Z	vertical coordinate of cloud centroid
ζ	measure of skewness of cloud
ξ	downwind coordinate relative to skewed cloud

Section 15.36

C	volumetric concentration
$\hat{h}$	normalized height of cloud
H	height of cloud
$\hat{r}$	normalized radius of cloud
r	radius of cloud
$\hat{t}$	normalized time
t_o	initial time scale
u_E	edge entrainment velocity
u_f	cloud front velocity
u_T	top entrainment velocity
$\hat{v}$	normalized volume of cloud
V	volume of cloud
α	parameter defined by Equation 15.36.13a
β	parameter defined by Equation 15.36.14a

Superscript

Λ	normalized value

Subscript

o	initial

Section 15.39

A_o	area of source
D	diffusivity
f	Coriolis parameter
L	characteristic length scale
q_o	volumetric release rate
Q_o	volume released
u	characteristic velocity
u_o	source velocity
α	ground slope
κ	thermal conductivity
μ	viscosity of atmosphere
μ_o	viscosity of source gas
v	kinematic viscosity
ρ	density of atmosphere
ρ_a	density of air
ρ_o	density of source gas
$\Delta\rho/\rho$	potential density difference

Subscript

o	source gas

Subsection 15.39.5

D	plume dimension
Q	volumetric release rate

Subsection 15.39.7

c	volumetric concentration
l_b	buoyancy length scale
l_q	length scale
Q	volumetric release rate

Section 15.40

Equations 15.40.1–15.40.9

C_D	drag coefficient
E	entrainment coefficient
g'_o	reduced gravity
h	height of following flow
Q	volumetric flow per unit width
S_1, S_2	parameters
x	downhill distance
u	mean velocity of following flow
u_f	velocity of front
u_s	velocity on a defined streamline
α	parameter defined by Equation 15.40.4
θ	angle of incline to horizontal

Subscripts

n	normal
1, 2	less, more dense fluid

Equations 15.40.10 and 15.40.11

C_D	form drag coefficient
f	friction factor
H	height of cloud
R	radius of cloud
u	velocity downhill
θ	angle of slope

Subscripts

b	bottom of cloud
g	gas
t	top of cloud

Equations 15.40.12 and 15.40.13

A_o	initial cross plume area of plume element
A_p	final cross plume area of plume element
g'_o	initial reduced gravity
u	wind speed at ground level
z	height from source to target
θ	potential temperature

Subscript

p	plume

Subsection 15.40.2

As Section 15.34.4 plus

C_g	maximum volumetric concentration at ground level
C_o	volumetric concentration at initial release
h	height of dense fluid layer
Δh	head difference
h_w	height of obstacle
$h_{0.5}$	height at which concentration is half ground level value
H	height of fence
H_b	ratio of heights defined by Equation 15.40.29
H_w	ratio of heights defined by Equation 15.40.20
q_o	volumetric rate of release
q^*_o	volumetric release rate per unit width
u	velocity of fluid
u_w	velocity over obstacle
U	velocity of wave travelling upstream (hydraulic jump)
W	plume width

Subscripts

f	with fence
f	without fence
1	upstream
2	space between upstream moving wave and obstacle

Subsection 15.40.5

A	frontal area of building
B	dimensionless buoyancy flux
C_o	time mean ground level concentration
C_L	concentration in lower layer
C_o	volumetric concentration at source
C_U	concentration in upper layer
D	diameter of source orifice
F_A	flow of air into wake
F_{LU}	flow from lower layer to upper layer
F_{UL}	flow from upper layer to lower layer
g'_o	reduced gravity at source
h	height of building
h_L	height of lower layer
h_U	height of upper layer
h	dimensionless height of lower layer
h	dimensionless height of upper layer
H	height of obstacle
l	length of building
l_w	length of recirculation region, or wake
L_B	buoyance length scale
q_o	volumetric rate of release
q	volumetric rate of release per unit length
Q	release rate, source strength
$\bar{Q}$	dimensionless release rate
Ri_o	initial Richardson number before mixing
Ri_T	transition Richardson number
S_L	lateral spread of cloud
S_U	updwind spread of cloud
S_w	surface area of wake
u	wind speed; mean velocity at obstacle height

Equation 15.40.60

V_W	volume of wake
w	width of building
α_I	mixing coefficient
α_M	mixing coefficient
α_o	constant
α_W	dimensionless length of wake
ρ	density of cloud
ρ_a	density of air

Superscript

-	normalized

Subsection 15.40.6

a	ratio of areas defined by Equation 15.40.73
A	area of opening
A_i,	area for inflow
A_o	area for outflow
b	constant
C	pressure coefficient
C_i	pressure coefficient for inflow opening
C_o	pressure coefficient for oulflow opening
f	vapour fraction
h	height of inlet opening
n	ratio of molar flows
N	number of moles
$\bar{N}_G$	dimensionless quantity defined by Equation 15.40.72
P'	pressure drop between atmospheric pressure and internal pressure
ΔP	pressure difference between outside and inside
P_o	atmospheric pressure
q_G	flow of gas
$\bar{q}_\alpha$	dimensionless flow of gas
Q	volumetric flow
Q_A	volumetric air flow of air
T	absolute temperature of air–gas mixture
T_A	absolute temperature of air
u	wind speed
V	volume of space

τ	time for concentration of gas to reach steady state if outflow is neglected
$\bar{\tau}$	ratio defined by Equation 15.40.78

Subscripts

A	air
G	gas

Section 15.42

D^*	density of cloud
R^*	air/HF ratio of cloud
T^*	absolute temperature of cloud

Section 15.43

Subsection 15.43.2

b	characteristic width of plume
c	concentration
r	radius of plume
s	distance along axis of plume
u	velocity along axis of plume
u'	entrainment velocity
U_a	mean wind velocity
θ	angle between axis of plume and horizontal
ρ	density of plume
ρ_a	density of air
ρ_{ao}	density of atmosphere at stack outlet
$\alpha_1-\alpha_3$	entrainment coefficients
ϕ_i	set of functions defined by Equation 15.43.2
ψ_i	set of functions used in Equation 15.43.1

Subsection 15.43.3

C	concentration
Δh	maximum initial plume rise
h_s	height of stack
R	radius of plume
s	distance along plume axis
u_s	velocity along plume axis
w	velocity of plume
x	downwind distance
$\alpha_{1,2}$	entrainment coefficients
θ	angle of plume axis to horizontal

Subscripts

m	maximum
o	initial
td	touchdown

Subsection 15.43.4

A_1-A_6	constants
b	width of plume (m)
B	initial buoyancy flux (m^4/s^3)
C	constant
C_1-C_6	constants
d_o	diameter of outlet (m)
g	acceleration due to gravity (m/s^2)
g'	(reduced gravity (m/s^2)
h_s	stack height (m)
l_m	length scale, related to source (m)
l_Q	length scale, related to transition from momentum to buoyancy control (m)
m	ndex
M	initial momentum flux (m^4/s^2)
Q	initial volumetric flow (m^3/s)
u, v, w	wind velocities in downwind, crosswind, vertical directions (m/s)
u_o	outlet velocity (m/s)
U	wind speed (m/s)
w_*	entrainment velocity (m/s)
x, y, z	distances in horizontal, crosswind and vertical directions (m)
x_{TD}	horizontal distance from virtual source of final plume to touchdown point (m)
x^*_{TD}	horizontal distance from stack to touchdown point (m)
x_{tr}	horizontal distance from stack to jet transition point (m)
x_v	horizontal distance from stack to virtual source of final plume (m)
z_B	length scale, related to effect of crossflow on plume (m)
z_{effB}	effective stack height with strong crossflow (m)
z_{effv}	effective stack height with weak crossflow (m)
z_m	length scale, related to effect of crossflow on jet (m)
z_{max}	maximum rise (m)
z_s	vertical coordinate of jet or plume axis (m)
z_v	distance of virtual source of jet below stack outlet (m)
α	entrainment coefficient
θ	relative density difference

Subscripts

o	Source
v	virtual source

Subsection 15.43.5

H	height of cloud
I_o	momemtum flux (Equations 15.43.34); excess momentum flux (Equations 15.43.35)
k_1, k_2	constants
Q_a	flow of entrained air
R	half-width of cloud
u_w	wind speed
v	velocity of jet
$\Delta\rho$	density difference between cloud and air

Subsection 15.43.8

D	diameter
w	velocity of plume

Subscript

o	initial

Section 15.44

A	cross-sectional area of plume
Buoy	buoyancy function
c	concentration (mass per unit volume)
C_D	spreading coefficient

D	diameter of circle, major axis of ellipse
Drag	drag function
e	eccentricity of ellipse
e_{at}	coefficient
e_{gr}	coefficient
e_{jet}	entrainment coefficient
$e_{\mathrm{u,cr}}$	coefficient
$e_{\mathrm{e,cr}}$	coefficient
e_x, e_z	unit vector in horizontal (wind aligned), vertical direction
$\dot{E}$	excess energy flux
Ener	energy function
Entr	entrainment function
Foot	reactive pressure force function
h	plume height; specific enthalpy (Equation 15.44.12)
k	slumping coefficient
l	width of 'footprint' of plume
l_y, l_z	turbulence length scales in crosswind, vertical directions
L	Monin–Obukhov length
$\dot{m}$	mass flux
$\dot{P}_x$	excess horizontal momentum flux
$\dot{P}_z$	excess vertical momentum flux
r	polar radius coordinate of cross-section of airborne plume
Ri_*	bulk Richardson number
s	distance along axis of plume
Shear	shear force function
T_{gr}	absolute temperature of ground
T_*	$\mathrm{u}_*\mathrm{T}_*$ = ground to air heat flux
u	mean flow velocity
x, z	horizontal, vertical distance of centroid
z_{c}	vertical distance of centre
ϵ	dissipation rate of turbulent kinetic energy
η	parameter defined by Equation 15.44.16
η_{c}	parameter defined by Equation 15.44.17
η_ρ	parameter defined by Equation 15.44.34
θ	polar angle coordinate of cross-section of airborne plume
ζ	parameter
κ	von Karman constant
ϕ	angle of inclination of airborne plume
$\Phi(\mathrm{Ri}_*)$	heavy gas entrainment function
ψ_{T}	temperature function
ψ_{u}	velocity function

Subscripts

at	atmospheric turbulence
c	centre
cw	crosswind
fs	free surface
g	material released
gs	gravity slumping
hg	heavy gas
jet	jet
pot	potential
∞	ambient conditions at centroid height

Section 15.45

M	mean value of concentration
P	peak value of concentration

Subsections 15.45.1–15.45.7

c	instantaneous deviation of concentration
$\bar{c}_2$	variance of concentration (see text)
c	concentration
C	mean concentration
C_{max}	maximum concentration
C_{med}	median concentration
C_{p}	peak concentration
$\bar{C}$	time mean concentration
$F(C)$	probability distribution function of concentration C
i	intensity
M	mean value of concentration
p	index
p	peak value of concentration
$P(C)$	probability that concentration exceeds C
t	sampling time
t_{m}	sampling time for mean value M
t_{p}	time during which concentration is non-zero (Equation 15.45.2); sampling time for peak value P (Equations 15.45.6–15.45.9)
t_{s}	total sampling time
T_{I}	integral time scale
γ	intermittency
μ	mean of concentration
σ	variance of concentration
σ_1	standard deviation (logarithmic)

Subsection 15.45.8

As Sections 15.16.1–15.16.4 plus

D_y, D_z	crosswind, vertical standard deviations attributable to meandering
Q	continuous mass rate of release
Y	crosswind standard deviations attributable to fluctuations about centre line
Z	crosswind standard deviations attributable to fluctuations

Subscripts

i	instantaneous
m	mean
p	peak

Subsection 15.45.9

C^*	concentration in sphere
C_τ	maximum concentration which can occur over time period τ
$\bar{C}$	time mean concentration
k	constant
x	downwind distance
β	constant
γ	intermittency
λ	index
σ	standard deviation of instantaneous concentration
τ	time period

ψ	parameter defined by Equation 15.45.29

Subscript

τ	limiting value

Subsection 15.45.10

As Subsections 15.16.1–15.16.4 plus

c	concentration
c'	concentration fluctuation about mean
$\bar{c}$	mean concentration
$\bar{c}'_2$	concentration variance
c_{mp}	condition median concentration
c_o	mean concentration on centre line
c'_p	conditional concentration fluctuation
$\bar{c}_p$	conditional mean concentration
c_{p2}	conditional concentration variance
d	diameter of source
F_c	cumulative distribution function for concentration
F_m	height correction
F_v	height correction
G_m	crosswind distance correction
G_v	crosswind distance correction
h	height of source
h_v	effective height of variance source
H	height of neutrally stable atmospheric boundary layer
i	intensity
i_p	conditional intensity
i_p	conditional intensity on centre line with negligible surface interaction
$p(c)$	probability density function for concentration
$p_p(c)$	probability density function for conditional concentration
q	variance source strength
q_p	conditional variance source strength
Q	mass rate of release
u_c	advection velocity of plume
z_e	scale height
α	sink strength
δ	delta function
γ	intermittency
λ	normalized downwind distance
λ_o	virtual origin of variance source
σ_1	standard deviation (log-normal)
ϕ	location parameter for variance source

Subscript

p	conditional

Subsection 15.45.11

$c(x, t)$	concentration fluctuation about mean
$\bar{c}(x, t)$	mean value of concentration fluctuations $c(x, t)$
$\bar{c}^2(x, t)$	variance defined by Equation 15.45.76
$C(x, t)$	mean value of ensemble of concentrations $\bar{\Gamma}(x, t)$
$\bar{C}$	mean concentration
i	intensity
I	intensity
$p(\theta, x, t)$	probability density function for θ
P	probability that concentration θ lies between lower and upper flammability limits
$R(C)$	intensity parameter
$\gamma(x, t)$	intermittency
$\Gamma(x, t)$	concentration from a single experiment
$\bar{\Gamma}(x, t)$	mean value of (x,t)
Δ	delta function
ϵ	constant
θ	(x, t) particular value of (x, t)
θ_L	lower limit of flammability
θ_0	limiting value of θ
θ_U	upper limit of flammability

Subsection 15.45.14

k_2–k_5	constants

Section 15.46

Subsection 15.46.1

As Sections 15.16.1–15.16.4 plus

F	mass of flammable gas at maximum hazard
H	height of source
Q^*	mass of gas released instantaneously
Q^*_e	mass of gas within flammable range
r	radial distance
v	ratio of upper to lower flammability limit
v_1, v_2	parameters defined by Equations 15.46.15b and 15.46.15c
W	mass of flammable gas
σ	dispersion coefficient

Subscripts

cc	cloud centre
L	lower flammability limit
m	at maximum hazard
U	upper flammability limit
1, 2	inner, outer

Equations 15.49.16–15.49.19

F_c	weighting function
L	number of moles of oxygen reacting with one mole of fuel
n_a	number of moles of air in rich mixture
n_c	number of moles of fuel consumed
n_p	number of moles of fuel present
V_{LS}	volume of cloud between lower flammability limit and stoichiometric concentration (m^3)
V_{SU}	volume of cloud between stoichiometric concentration and upper flammability limit (m^3)
W_F	mass of fuel available for combustion (kg)

Subsection 15.46.2

a, c	constants
b, d	indices
D	constant
f	index
m_o	mass rate of release
Q	mass of gas released
Q_e	mass of gas within flammability limits

Q_{FL}	mass of gas within flammability limits
x_L, x_U	distances to lower, upper flammability limits

Subsections 15.46.3–15.46.5

c	concentration (volume fraction)
d_o	effective diameter of discharge (m)
D	constant
f	index
g	acceleration due to gravity (m/s^2)
G	parameter defined by Equation 15.46.41
k_1–k_6	constants
$\dot{m}_o$	mass rate of release (kg/s)
M	molecular weight
$\bar{M}$	mean molecular weight of gas mixture at distance z
Q_{FL}	mass of flammable material in cloud between flammability limits (kg)
r	radial distance from axis (m)
T	absolute temperature (K)
u	wind speed (m/s)
$\dot{v}$	volumetric flow (m^3/s)
V_{FL}	volume of cloud between flammability limits (m^3)
w	velocity (m/s)
z	axial length or vertical height (m)
α	ratio of number of moles of unreacted and reacted gas
Γ	dry adiabatic lapse rate (°C/m)
$\Delta\rho_o$	density difference between gas and air
χ	concentration (kg/m^3)

Subscripts

F	flame
L	lower flammability limit
o	original discharge
s	stoichiometric mixture
U	upper flammability limit

Subsection 15.46.7

M	mass of vapour (t)
R	radius of cloud (m)

Subsection 15.46.9

f	lower flammability limit (%)
P	operating pressure (bar)
t	time span (s)
W	mass flow (kg/s)
W_{lr}	mass flow per unit area (kg/m^2)

Section 15.47

Subsections 15.47.1–15.47.3

C	concentration
C_p	concentration over time f_p
k_1, k_2	constants
L	toxic load
n	index
P	probability of injury
T	exposure time
Y	probit
γ	intermittency

Subscripts

pe	exposure
s	sampling

Equations 15.47.8-15.47.10

As	Subsection 15.45.9 plus
ω	enhancement factor

Subsection 15.47.4

c	concentration
F_c	probability that concentration will not exceed c
n	index
N_b	number of breaths
$S(T_e)$	probability that concentration will not exceed c over exposure time T_e
T_e	exposure time
V_c	probability that concentration will exceed c

Subsection 15.47.5

C	concentration
D	dosage
$\bar{D}$	mean dose
D^*	effective dose
D_{50}	median fatal dose
k	constant
k_1, k_2	constants
n	index
$N[\,]$	normal distribution
Y	probit
δ	standardized log dosei mean standardized log dose
δ^*	effective standardized log dose
θ	probability of fatality
$\mu(C)$	mean of concentration
$\sigma(C)$	standard deviation of concentration
ϕ	distribution function

Section 15.48

Subsection 15.48.4

D	internal diameter of stack (m)
Δh	plume rise (m)
u	wind speed (m/s)
v_s	velocity of stack gas (m/s)

Subsection 15.48.5

D	diameter of vent tip (ft)
E	number of dilutions to lower flammability limit
h_s	height of vent above exposure level (ft)

Subsection 15.48.6

C_1–C_4	constants
D	internal diameter of stack (m)
h	height of stack (m)
Δh	plume rise (m)
Q	mass rate of release (g/s)
u	wind speed (m/s)
v_s	stack gas outlet velocity (m/s)
ρ	density of gas mixture (kg/m^3)

χ	critical ground level concentration (μg/m^3)

Subscripts

s	stack gas

Subsection 15.48.8

A	parameter
C_m	maximum permissible value of touchdown concentration of contaminant (%v/v)
C_s	concentration of contaminant in stack gas (%v/v)
D	internal diameter of stack (mm)
h_s	height of stack (m)
L	lower flammability limit (%v/v)
M_w	molecular weight of stack gas mixture
s	stack gas specific gravity relative to air
T_a	absolute temperature of ambient air (K)
T_s	absolute temperature of stack gas (K)
u	wind speed (m/s)
v_s	velocity of stack gas (m/s)
β	peak/mean concentration ratio

Section 15.49

Subsection 15.49.1

As Sections 15.16.1–15.16.4

Subsection 15.49.2

Equation (15.49.7)

k	constant
k_1–k_3	constants
M	mass released (te)
R	downwind range (km)
X	distance to maximum width (km)

Equations 15.49.8–15.49.18

h	height of cloud (m)
k	constant
L	distance/dimension (m)
M	mass released (te)
n	index
R	downwind distance (m)
R_c	radius of cloud (m)
R_{cr}	range transition criterion (m)
R_{LFL}	downwind range to lower flammability limit (m)
R_{UFL}	downwind range to upper flammability limit (m)
X_1	downwind dimension (m)
Y	crosswind distance at downwind distance R (m)
Y_{max}	maximum crosswind range of lower flammability limit (m)
Y_1	crosswind dimension (m)
U_{LFL}	upwind range to lower flammability limit (m)

Equations 15.49.15–15.49.18

I	inventory (kg)
k	constant
k^*	constant
L	distance/dimension (m)
$\dot{m}_v$	mass rate of release of vapour (kg/s)
n	index
R	downwind distance (m)
T_a	arrival time (s)
T_d	duration of release (s)
u	wind speed (m/s)
Y	crosswind distance at downwind distance R (m)

Equations 15.49.19 and 15.49.20

q_o	volumetric rate of release
Q_o	volume released
x	downwind distance

Section 15.50

Subsections 15.50.1–15.50.3

As Sections 15.16.1–15.16.4 plus

F	depletion factor
H	height of source
Q_o	initial source strength
Q_x	effective source strength
r	radius of particle
r_e	equivalent radius
$t_{1/2}$	half-life of concentration
x_G	distance defined by implicit Equation 15.50.23
v_d	deposition velocity
v_g	fall velocity
v_t	terminal velocity of particle
V_p	volume of particle
α	dynamical shape factor (Equation 15.50.6); reflection coefficient (Equations 15.50.21 and 15.50.22)
μ	viscosity of air
ρ_p	density of particle
τ_c	chemical decay time constant
ω	deposition rate

Subscripts

n	non-spherical
s	spherical
1, 2	standard value, other value

Subsections 15.50.5 and 15.50.6

A_s	cross-sectional area of drop
E	collection efficiency
F_w	flux of pollutant to surface
J_o	equivalent rainfall rate
k	concentration of pollutant in rainwater (mass per unit volume)
k'	concentration of pollutant in rainwater (mass per unit mass)
N_s	number of drops
s	diameter of drop
v_w	wet deposition velocity
v_s	velocity of drop
w	interphase transport rate
W_r	washout ratio
W_r'	washout ratio (alternative formulation)
Z_W	height of wetted plume
Λ	washout coefficient, scavenging coefficient

ρ_a	density of air
ρ_w	density of water
χ	concentration of pollutant in air
χ_e	effective concentration over height of wetted plume

Subscripts

o	reference height
s	drop

Section 15.51

c	concentration (various units)
D	toxic dose (units h)
k	mixing efficiency factor
L	toxic load (units−h)
n	index
R	ratio of indoor to outdoor toxic loads
t	time (h)
t_o	duration of finite outdoor concentration (h)
λ	ventilation rate, ventilation constant (h^{-1})
λ'	effective ventilation rate (h^{-1})

Equation 15.51.18

A	area of aperture (m^2)
k_1	constant
Q	volumetric flow of air (m^3/s)
Δ_p	pressure drop (N/m^2)
ρ_o	density of ambient air (kg/m^3)

Equations 15.51.19−15.51.24

$k_2 - k_5$	constants
m	number of open casement windows
n	number of open top-vent windows
ΔT	temperature difference between outdoors and indoors (°C)
u	wind speed (m/s)
λ	ventilation rate (h^{-1})
λ_b	ventilation rate due to buoyancy (m^3/h)
λ_s	ventilation rate measured at standard conditions (h^{-1})
λ_w	ventilation rate due to wind (m^3/h)

Subscripts

i	indoors
o	outdoors

D	initial diameter of plume
u_o	velocity of release

Section 15.53

Subsection 15.53.1

As	Section 15.10.8

Subsection 15.53.8

D	diameter of spray cone (m)
F_N	flow number of nozzle (l/s). $(kN/m^2)^{1/2}$
P_w	pressure of water at nozzle (kN/m^2) (gauge)
Q_a	volumetric flow of air (m^3/s)
Q_w	volumetric flow of water (l/s)
V	velocity of entrained air (m/s)

Subsection 15.53.10

c	entrainment parameter
c_s	entrainment parameter for spray
C	volumetric concentration
c_{FD}	concentration with forced dispersion
c_{ND}	concentration with natural dilution
D	width of spray
FD	forced dispersion effectiveness factor
Q	volumetric rate of release
r	radius of plume
S	surface area of elemental slice of plume
u	velocity of plume
v	vertical velocity in spray
v_a	velocity of air entrained in spary
δV	volume of elemental slice of plume
w	wind speed
x	downwind distance

Subscripts

o	source
1, 2	end of region I, II

Subsection 15.53.11

CR	concentration ration
F_N	flow number (1/ (min bar$^{1/2}$))
K	constant
M	specific momentum flow (m^2/s^3)
M_N	momentum flow number (N s/(s bar))
$u_{1.25}$	wind speed at 1.25 m height (m/s)

Subsection 15.53.18

G	mass flow of gas
Q_a	mass flow of air
S	mass flow of stream

FIRE

Contents

The first of the major hazards in a process plant is fire. Fire in the process industries causes more serious accidents than explosion or toxic release, although the accidents in which the greatest loss of life and damage occur are generally caused by explosion. Fire is normally regarded as having a disaster potential less than explosion or toxic release. One of the worst explosion hazards, however, is usually considered to be that of an explosion of a vapour cloud that has drifted over a populated area, and in this case the difference in the number of casualties caused by a flash fire rather than an explosion in the cloud may be relatively small.

Fire is, therefore, a serious hazard. The Second *Report* of the Advisory Committee on Major Hazards (ACMH) (Harvey, 1979b) refers in particular to vapour cloud fires and to the description of fires given by V.C. Marshall (1977a):

> It can be said that such clouds will start to burn around their outer envelopes and will 'lift off' to form fireballs. Such fires are dangerous in the extreme. When formed of hydrocarbons, they are luminous and radiate heat which can cause fatal burns to bystanders and ignite wood and paper; for example, they have been known to set fire to the interior of office blocks. As fireballs rise they produce mushroom clouds, in the stalks of which are formed violent upward convection currents that can suck up and ignite debris, and scatter burning brands over a wide area. Such an occurrence can clearly cause damage far beyond the normal safety distance of what are termed conventional fires.

Vapour cloud, or flash fires and fireballs radiate intense heat that can be lethal. Another lethal effect is the depletion of oxygen in the atmosphere caused by a flash fire. Although the Flixborough disaster was primarily a vapour cloud explosion, a large flash fire in part of the cloud also accompanied the latter and this fire was responsible for some of the deaths that occurred. Flash fires can also do considerable damage to the plant. In buildings, fire is the main threat and can cause great damage as well as loss of life.

In the United Kingdom there are a number of bodies concerned with fire and fire protection. These include the fire services and organizations such as the British Fire Services Association, the professional institutions such as the Institution of Fire Engineers (IFE), the insurance organizations such as the Fire Offices Committee, the research establishments such as the Fire Research Station (FRS) and the educational institutions such as the Fire Protection Association (FPA) and the Department of Fire Engineering at Edinburgh University.

In the United States of America the relevant bodies include: in insurance, the National Board of Fire Underwriters, the Industrial Risk Insurers (IRI) (formerly the Factory Mutual Engineering Corporation (FMEC); in research, the Underwriters Laboratories (UL), the Bureau of Mines (BM) and the Combustion Institute; and in the formulation of codes and research, the National Fire Protection Association (NFPA).

There is a voluminous literature on fire and fire protection. Only a few selected items particularly relevant to process plants can be instanced here. These are *Safety in Petroleum Refining and Related Industries* (Armistead, 1959), *Chemical Fires and Chemicals at Fires* (IFE, 1962), *Fire Protection Handbook* (Vervalin, 1964a, 1973a), *Handbook of Industrial Loss Prevention* (FMEC, 1967), *A Guide to Fire Prevention in the Chemical Industry* (BCISC, 1968/7), *Storage and Handling of Petroleum Liquids: Practice and Law* (Q.R. Hughes, 1970), *Background Notes on Fire and its Control* (FPA, 1971/14), *Heat Transfer in Fires* (Blackshear, 1974), *Manual of Firemanship* (Home Office, 1974–), *An Introduction to Fire Dynamics* (Drysdale, 1985) and *Fire Protection Handbook* (NFPA, 2003).

Information on numerous aspects of fire and fire protection is given in the FPA *Compendium of Fire Safety Data Sheets* (1974–), which covers the following topics. Volume 1: (1) organization of fire safety and (2) management of fire risks. Volume 2: (3) industrial and process fire safety and (4) occupancy fire safety. Volume 3: (5) housekeeping and general fire precautions and (6) nature and behaviour of fire. Volume 4: (7) information sheets on hazardous materials. Volume 5: (8) fire protection equipment and systems, (9) security precautions and (10) arson. Volume 6: (11) design guides and (12) building products.

A relevant standard is BS 5908: 1990 *Code of Practice for Fire Precautions in Chemical Plant*. This contains the following sections:

(1) general;
(2) legal requirements;
(3) principles of initiation, spread and extinction of fire;
(4) site selection and layout;
(5) buildings and structures;
(6) storage and movement of materials;
(7) design of process plant;
(8) operation of process plant;
(9) maintenance of process plant;
(10) fire prevention;
(11) fire defence;
(12) works fire brigades;
(13) classification of fires and selection of extinguishing media;
(14) fixed fire fighting systems;
(15) portable and transportable appliances;
(16) organization of emergency procedures.

Most of these aspects are considered in the present chapter, but some are dealt with elsewhere, notably legal aspects, plant siting and layout, storage, maintenance and emergency procedures, which are treated in Chapters 3, 10, 22, 21 and 24, respectively.

US codes include the National Fire Codes of the NFPA. A selection of the codes relevant to process plant is given in Appendix 27.

Selected references on fire, prevention, protection and control are given in Tables 16.1 and 16.2, respectively. In addition, many of the publications listed in Appendices 27 and 28 are concerned with fire.

16.1 Fire

16.1.1 The combustion process

Fire (or combustion) is a chemical reaction in which a substance combines with oxygen and heat is released. Usually, fire occurs when a source of heat comes into contact with a combustible material. If a combustible liquid or solid is heated it evolves vapour and if the concentration of vapour is high enough, it forms a flammable mixture with oxygen in the air. If this flammable mixture is then heated further to its ignition point, combustion starts. Similarly, a

Laminar diffusion flames: Burke and Schumann (1928a,b); Savage (1962)

Turbulent diffusion flames: F.R. Steward (1970); Brzustowski (1973); Kent and Bilger (1973); Chigier and Strokin (1974); Brzustowski, Collahalli and Sullivan (1975); Markstein (1976); Lockwood (1977); Tamanini (1977); Becker and Liang (1978); Becker and Yamazaki (1978); Pergament and Fishburne (1978); Heskestad (1983a); Nguyen and Pope (1984); Bilger (1989); Annaruma, Most and Joulain (1991); D.A. Smith and Cox (1992); Blake and McDonald (1993)

Turbulent jet diffusion flames: Baron (1954); Sunivala, Hulse and Thring (1957); Bilger (1976); Onuma and Ogasawara (1977); Peters and Williams (1983); Kalghatgi (1984); Pitts (1989); Delichatsios (1993b)

Buoyant diffusion flames! P.H. Thomas, Webster and Raftery (1961); Putnam and Grinberg (1965); P.H. Thomas, Baldwin and Heselden (1965); Masliyah and Steward (1969); Steward (1970); Delichatsios and Orloff (1985)

Flame regime intermediate between premixed and diffusion conditions: Talley (1992)

Radiant heat transfer, fire spread

BRE (n.d./2–4, 1974 CP 29/74, CP 72/74); FRS (Appendix 28, F3, F4, Fire Res. Special Rep. 2, 1961 F1, 1963 Fire Res. Tech. Pap. 5, 1966 F6, F8, 1972 Fire Res. Note 921); Lawson and Simms (1952a,b); McAdams (1954); Eckert and Drake (1959); Kreith (1962); Sparrow (1962); Sparrow and Cess (1966, 1978); Law (1969); Hearfield (1970, 1974); FPA (1971/14); Langdon-Thomas (1972); Siegel and Howell (1972, 1991); Sirignano (1972); P.H. Thomas and Law (1972, 1974); Blackshear (1974); L.E. Brown, Wesson and Welker (1974a,b, 1975); Fernandez-Pello and Williams (1974, 1977); W.A. Gray and Muller (1974); Kovacs and Honti (1974); Alpert (1975); Eisenberg, Lynch and Breeding (1975); Feng, Williams and Kassoy (1975); Craven (1976); Groothuizen and Romijn (1976); Klootwijk (1976); Nakakuki (1976); Rasbash (1976c); R.B. Robertson (1976b); Feng and Sirignano (1977); Straitz and O'Leary (1977); Yumoto (1977); HSE (1978b); Modak (1979); D.C. Bull *et al.* (1980); Carrier, Fendell and Feldmann (1980); F.R.S. Clark (1981); Anon. (1984 LPB 56, p. 11); Harmathy (1985); Modest (1993)

Flame radiation: Hottel and Mangelsdorf (1935); Hottel and Smith (1935); Hottel and Egbert (1941, 1942); Daly and Sutherland (1949); Hottel, Williams and Satterfleld (1949); Cassel, liebman and Mock (1957); Foster and McGrath (1960); D.K. Edwards (1963); Siddall and MacGrath (1963); Echigo, Nishiwaki and Hirata (1967); Hottel and Saroflm (1967); R.K. Smith (1967); Tien (1968); Beer and Howarth (1969); Dalzell and Saroflm (1969); Godridge and Hammond (1969); Masliyah and Steward (1969); Sato *et al.* (1969); Dalzell, Williams and Hottel (1970); Leckner (1971, 1972); Lowes and Newall (1971); J.M. Jones and Rosenfeld (1972); Thring and Lowes (1972); Felske and Tien (1973, 1974a,b); C.S. Kelly (1973); N.K. King (1973); Cess (1974); Markstein (1974, 1976, 1977, 1985, 1989); P.B. Taylor and Foster (1974, 1975); C.K. Lee (1975); W.A. Gray, Kilham and Muller (1976); Yuen and Tien (1977); Fishburne and Pergament (1979); Orloff, Modak and Markstein (1979); de Ris (1979); Wagner (1979); Calcote (1981); Ganapathy (1981); Grosshandler and Modak (1981); Orloff (1981); Vervisch, Puechberty and Mohamed (1981); Becker and Liang (1982); Tien and Lee (1982); Coppalle and Vervisch (1983); Frenklach, Taki and Matula (1983); Vervisch and Coppalle (1983); Gill and Olson (1984); Brosmer and Tien (1986); Raparotte and Brzustowski (1986); E.B. Cohen and Taylor (1987); MHAP (1988 LPB 82); Mudan (1989b); Hamins *et al.* (1991); Orloff, de Ris and Delichatsios (1992)

Radiant heat factor: A.F. Roberts (1981/82); Hymes (1983 SRD R275)

Soot: Mie (1908); Arthur and Napier (1955); Schalla and McDonald (1955); Tesner, Robinovitch and Rafalkes (1962); A. Thomas (1962); Yagi and lino (1962); Bonne, Homann and Wagner (1965); Narasimhan and Foster (1965); Homann (1967); Kunugi and Jinno (1967); McLintock (1968); Fenimore and Jones (1969); J.B. Howard (1969); Columbo and Thring (1972); Feugier (1972); Wersborg, Howard and Williams (1973); Muller-Dethlefs and Schlader (1976); Becker and Yamzaki (1977); Prado *et al.* (1977); Orloff, Modak and Markstein (1979); Wagner (1979); Classman and Yaccarino (1981); S.C. Lee and Tien (1981); Pong Chung and Smith (1982); Sen and Ludford (1982); Homan (1983); Santoro, Semerjian and Dobbins (1983); Senkan, Robinson and Gupta (1983); Takahashi and Classman (1984); Hirschler (1985); Kent and Wagner (1985); K.Y. Lee, Zhong and Tien (1985); R.S. Levine (1985); Markstein (1985, 1989); Pagni and Okoh (1985); Santoro and Semerjian (1985); Delumyea *et al.* (1986); Kent and Honnery (1987, 1991); Classman (1989); Giilder (1989); McCaffrey and Harkleroad (1989); Megaridis and Dobbins (1989); J.B. Moss (1989); Honneiy and Kent (1990, 1992); I.M. Kennedy, Kollman and Chen (1990); Leung, Lmstedt and Jones (1991); C.D. Stewart, Syed and Moss (1991); Syed, Stewart and Moss (1991); Fairweather *et al.* (1992); Smedley, Williams and Bartle (1992); Coppalle and Joyeux (1993); Chamberlain (1994)

View factor: Hottel (1930, 1931, 1954); Hamilton and Morgan (1952); McGuire (1953); McAdams (1954); Coulson and Richardson (1955–, 1977–); Rogers and Mayhew (1957); Eckert and Drake (1959); Bird, Stewart and Lightfoot (1960); Chandrasekhar (1960); C.O. Bennett and Myers (1962); Sparrow (1962); Sparrow, Miller and Johnson (1962); Dunkle (1963); Kourganoff (1963); Feingold (1966); Sparrow and Cess (1966, 1978); Hottel and Sarofim (1967); Grier (1969); Rein, Sliepcevich and Welker (1970); Chung and Sumitra (1972); Merriam (1972); Siegel and Howell

(1972); Ozisik (1973); Raj and Kalelkar (1974); Minning (1977); Becker (1980a,b); Chung and Naraghi (1981); Howell (1982); Mecklenburgh (1985); Tune and Venart (1984/85a,b); Crocker and Napier (1986, 1988a,b); Napier and Roopchand (1986); Mudan (1987, 1989b); Wong and Steward (1988); B.C. Davis and Bagster (1989–); Bagster and Davies (1990); Beard *et al.* (1993); CPD (1992a); CCPS (1994/15)
Atmospheric transmissivity: R.O. Parker (1974); Glasstone and Dolan (1980); Horvath (1981); Lihou and Maund (1982); Hymes (1983 SRD R275); Considine (1984 SRD R297); Simpson (1984 SRD R304); Babrauskas (1986b); R.C. Henry (1987); V.C. Marshall (1987); Wayne (1991); CPD (1992a) CCPS (1994/15)

Flames on pools, pool fires

Rasbash (1956); Blinov and Khudiakov (1957); Hottel (1958); Rasbash, Rogowski and Stark (1960); Burgess, Strasser and Grumer (1961); Fons (1961); Magnus (1961); Welker and Sliepcevich (1965, 1966); Agoston (1962); Burgess and Grumer (1962); Burgess and Zabetakis (1962 BM RI 6099); Spalding (1962); P.H. Thomas (1963); P.H. Thomas, Pickard and Wraight (1963); Pipkin and Sliepcevich (1964); Akita and Yumoto (1965); Atallah (1965); Welker, Pipkin and Sliepcevich (1965); Corlett and Fu (1966); A.F. Roberts (1966, 1971b); Corlett (1968, 1970); Classman and Hansel (1968); Canfield and Russell (1969); Classman, Hansel and Eklund (1969); Huffman, Welker and Sliepcevich (1969); Masliyah and Steward (1969); B.D. Wood and Blackshear (1969); Hearfield (1970); ICI/RoSPA (1970 IS/74); Murad *et al.* (1970); Akita and Fujiwara (1971); Hillstrom (1971); Torrance (1971); B.D. Wood, Blackshear and Eckert (1971); Yumoto (1971b); Chetty and Voinov (1972); A.R. Hall (1972); de Ris and Orloff (1972); Hertzberg (1973); C.S. Kelly (1973); Nakakuki (1973, 1974a,b, 1976); A.F. Roberts and Quince (1973); Dayan and Tien (1974); Duffy, Gideon and Puttnam (1974); Fu (1974); P. Nash (1974a); Dehn (1975); Escudier (1975); Hirano and Kinoshita (1975); Craven (1976); Dow Chemical Co. (1976); MITI (1976); Brotz, Schonbucher and Schable (1977); Modak (1977, 1981); Modak and Croce (1977); Yumoto, Takahashi and Handa (1977); Alger *et al.* (1979); NASA (1979); Raj, Moussa and Aravamudan (1979a,b); Anon. (1980d,k); Classman and Dryer (1980/81); Mizner (1981); Mizner and Eyre (1982); Dinenno (1982); Hsiang-Cheng Kung and Stavrianidis (1982); Kletz (1982h); Moorhouse (1982); Moorhouse and Pritchard (1982); Orloff and de Ris (1982); Pantony and Smith (1982); Sher (1982); Babrauskas (1983, 1986b); Cline and Koenig (1983); Mudan (1984c, 1989b); Santo and Delichatsios (1984); Shinotake, Koda and Akita (1985); Webber (1985 SRD R325); Croce and Mudan (1986); Crocker and Napier (1986); Frank and Moieni (1986); Uguccioni and Messina (1986); Brosmer and Tien (1987); Delichatsios (1987, 1988, 1993a,b); Fischer, Hardouin-Duparc and Grosshandler (1987); Nishio and Machida (1987); Fischer (1988); Koseki and Yumoto (1988); Adiga *et al.* (1989); Bagster and Pitblado (1989); Bouhafld, Vantelon, Soudil *et al.* (1989); Bouhafid, Vantelon, Joulain *et al.* (1989); Fischer and Grosshandler (1989); Koseki (1989); Koseki and Hayasaka (1989); J.B. Moss (1989); Schneider and Kent (1989); Seung Wook Back and Chan Lee (1989); Arpaci and Selamet (1991); Holen, Brostrom and Magnussen (1991); Koseki and Mulholland (1991); Pineau *et al.* (1991); Ditali, Rovati and Rubino (1992); Hayasaki, Koseki and Toshiro (1992); Inamura, Saito and Tagavi (1992); Klassen *et al.* (1992); Lautkaski (1992); Mangialavori and Rubino (1992); Schonbucher, Gock and Fiala (1992); Cetegen and Ahmed (1993)
LNG fires: HSE/SRD (HSE/SRD/WP 34); Welker, Wesson and Sliepcevich (1969); Hoult (1972a); Atallah and Raj (1973); Fay (1973); May and McQueen (1973); Welker (1973, 1982); Opschoor (1975a,b); Raj and Atallah (1975); Stannard (1977); Raj, Moussa and Aravamulan (1979); Schneider (1980); Blackmore, Eyre and Summers (1982); Ermak, Koopman *et al.* (1982); Mizner and Eyre (1982); Croce, Mudan and Wiersma (1986); Napier and Roopchand (1986); Rosenblatt and Hassig (1986); A.D. Johnson (1992)
LPG fires: Rasbash (1979/80); Blackmore, Eyre and Summers (1982); Mizner and Eyre (1982)
Pool fires on water: A.D. Little (1979); Mizner and Eyre (1983); Arai, Saito and Altenkirch (1990); Alramadhan, Arpaci and Selamet (1991)
Pool fires in enclosures: Tatem *et al.* (1986)
Fires on wicks: Burgoyne, Roberts and Quinton (1968); Toa and Kaviany (1991)

Trench fires

Welker (1965); Alger and Capener (1972); Gollahalli and Sullivan (1974); Mudan and Croce (1984); Croce, Mudan and Wiersma (1986); D.A. Smith (1992)

Fire engulfment, including directed jets

Chichelli and Bonilla (1945–); L.H. Russell and Canfield (1973); C. Anderson *et al.* (1974); Charles (1974); Charles and Norris (1974); Borgnes (1979a,b); Borgnes and Karlsen (1979); Birk and Oosthuize (1982); J.M. Wright and Fryer (1982); Heitner, Trautmanis and Morrissey (1983a,b); Hunt *et al.* (1983 SRD R240); A.F. Roberts, Cutler and Billinge (1983); Solberg and Borgnes (1983); Sousa and Venart (1983); Nylund (1984); Droste *et al.* (1984); Schulz-Forberg, Droste and Charlett (1984); Venart *et al.* (1984); Tune and Venart (1984/85a); Grolmes and Epstein (1985); Moodie, Billinge and Cutler (1985); Siddle (1986); Aydemir *et al.* (1988); Bainbridge and Keltner (1988); Beynon *et al.* (1988); Birk (1988, 1989); Droste and Schoen (1988); Moodie (1988); Moodie *et al.* (1988); Ramskill (1988); Venart *et al.* (1988); Venart *et al.* (1989); Dancer (1990); Hadjisophocleous, Sousa and Venart (1990); Tanaka *et al.* (1990); Bennet *et al.* (1991); Cowley and Pritchard (1991); Crespo *et al.* (1991); Verheif and Duijm (1991); Giselle and Krause (1992); Hernandez and Crespo (1992); Duijm (1994)

Fireballs, BLEVEs (*see also* Table 17.36)

Gayle and Bransford (1965); van Nice and Carpenter (1965); R.W. High (1968); Bader, Donaldson and Hardee (1971); Patterson *et al.* (1972); Hardee and Lee (1973, 1975, 1977–78); MLTI (1976); Fay and Lewis (1977); Hasegawa and Sato (1977, 1978); V.C. Marshall (1977a, 1987); Maurer *et al.* (1977); Hardee, Lee and Benedick (1978); HSE (1978b, 1981a); A. Baker (1979); Fay, Desgroseillers and Lewis (1979); Harvey (1979b); R.C. Reid (1979); Appleyard (1980); Gillette (1980); Mallory (1980); Aravamudan and Desgroseillers (1981); Kletz (1981n); A.F. Roberts (1981a,b, 1981/82, 1982); Considine, Grint and Holden (1982); Crawley (1982); Moorhouse and Pritchard (1982); Williamson and Mann (1981); Lihou and Maund (1982); Pantony and Smith (1982); Ursenbach (1983); Martinsen (1984); D.L.M. Hunt and Ramskffl (1985); Kohler (1985); Pietersen (1985); Tune and Venart (1984/5a,b); Blything (1986); Hirst (1986); Roper *et al.* (1986); Bagster and Pitblado (1989); J.B. Moss (1989); Buckmaster, Joulin and Ronney (1991); Pineau *et al.* (1991); Satyanarayana, Borah and Rao (1991); Buckmaster, Gessman and Ronney (1992); Buckmaster and Joulin (1993); Buckmaster, Smooke and Giovangigli (1993); Prugh (1994)

Vapour cloud fires, flash fires

Kletz (1971); Eisenberg, Lynch and Breeding (1975); Fay and Lewis (1975, 1977); Raj and Emmons (1975); A.D. Little (1979); Hogan (1982); Rodean *et al.* (1984); Roper, Arno and Jaggers (1991); Seshadri, Berlad and Tangirala (1992); CCPS (1994/15)

Jet flames

Hawthorne, Weddell and Hottel (1949); Hottel and Hawthorne (1949); Hottel (1953); Thring and Newby (1953); Goldburg and Sin-I Cheng (1965); Chervinsky and Manheimer-Timnat (1969); Hoehne, Luce and Miga (1970); Guruz *et al.* (1974); Lockwood and Naguib (1975); Becker and Yamazaki (1978); Becker (1980a,b); Kalghatgi (1983); Peters and Williams (1983); Hirst (1984, 1986); Sonju and Hustad (1984); Tune and Venart (1984/85b); Delichatsios and Orloff (1985); de Faveri *et al.* (1985); Hustad and Sonju (1986); McCaffrery and Evans (1986); M.T.E. Smith *et al.* (1986); Beychok (1987b); Chamberlain (1987, 1989); D.K. Cook, Fairweather, Hammonds and Hughes (1987); D.K. Cook, Fairweather, Hammonds and O'Brien (1987); Delichatsios (1987, 1993a); Leahey and Schroeder (1987); Crocker and Napier (1988b); Bagster and Pitblado (1989); Birch *et al.* (1989); Greenberg (1989); Grint (1989); Loing and Yip (1989); J.B. Moss (1989); Mudan (1989b); Tarn and Cowley (1989); Turns and Lovett (1989); J. Cook, Bahrami and Whitehouse (1990); Damiano (1990); R.W. Davis *et al.* (1990); D.A. Carter (1991); D.K. Cook (1991a); Cowley and Pritchard (1991); Fairweather *et al.* (1991); Peters and Gottgens (1991); Arnaud *et al.* (1992); Fairweather, Jones and Linstedt (1992); GollahaUe, Khanna and Prabhu (1992); Vfflermaux and Durox (1992); API (1990 RP 521); Coppalle and Joyeux (1993); Sivathanu and Gore (1993); Duijm (1994); A.D. Johnson, Brightwell and Carsley (1994); C.R. Kaplan *et al.* (1994)

Mist and spray fires

Godsave (1953); Burgoyne and Cohen (1954); J.A. Browning and Krall (1955); Hottel, Williams and Simpson (1955); Kobayasi (1955); Agoston, Wise and Rosser (1957); Bolt and Saad (1957); J.A. Browning, Tyler and Krall (1957); Eraser (1957); Kumagai (1957); F.A. Williams (1959); Reichenbach, Squires and Penner (1962); Rosser (1967); Aldred and Williams (1966); Eisenklam and Arunachalam (1966); Eisenklam, Arunachalam and Weston (1967); Faeth (1967, 1977, 1979, 1983); Polymeropoulos and Peskin (1969); Sioui and Roblee (1969); Lemott, Peskin and Levine (1971); Law and Williams (1972); Mizutani and Nakajima (1973); A.Williams (1973, 1976, 1990); Polymeropoulos (1974, 1984); Kapila, Ludford and Buckmaster (1975); Hayashi and Kumagai (1975); Law (1975); Miyasaki and Mizutani (1975); Polymeropoulos and Das (1975); Yuen and Chen (1976); Sangiovanni and Kesten (1977); Ballal and Lefebvre (1978, 1979, 1981a,b, 1983a,b); Anon. (1980h); Briffa (1981); K.N. Palmer (1983); Yule, Ereaut and Ungut (1983); Pindera and Brzustowski (1984); Sichel and Palinaswamy (1985); Polymeropoulos and Peskin (1989); P.J. Bowen and Shirvffl (1994a,b)

Flames on flares

Ludwig *et al.* (1968); Becker (1980a,b); de Faveri *et al.* (1985); Beychok (1987b); Chamberlain (1987); O.K. Cook *et al.* (1987); D.K. Cook *et al.* (1987); A.D. Johnson, Brightwell and Carsley (1994)

Flames on pipelines

Hoff (1983); Hirst (1984); Chamberlain (1987); D.A. Carter (1991)

Effect of fire on materials, buildings

Kashiwagi (1974, 1976, 1979a,b, 1981); C.S. Kelley (1975); Hymes (1984); J.L. Bryan (1986); Rasbash, Drysdale and Deepak (1986); van Loo and Opschoor (1989); Opschoor, van Loo and Pasman (1992).

Ignition and combustion of wood, cellulose: Bamford, Crank and Malan (1946); Hopkins (1952); E.K. Lawrence (1952); Lawson and Simms (1952a,b); Stout (1952); Garden (1953, 1959); C.C. Williams (1953); Hottel and Williams (1955); S. Martin (1956, 1964, 1965); Akita (1959); Simms (1960, 1961, 1962, 1963); Courteney (1962); A.F. Roberts and Clough (1963); Blackshear and Murty (1965); Weatherford and Sheppard (1965); Lipska (1966); Weatherford and Valtierra (1966); Koohyar (1967); Murty and Blackshear (1967); A.F. Roberts (1967a, 1971d); Simms and Law (1967); Rasbash and Langford (1968); Deverall and Lai (1969); Kosdon, Williams and Buman (1969); A.F. Roberts (1970); W.K. Smith and King (1970); Wesson (1970); Alvares and Martin (1971); Garg and Steward (1971); Panton and Rittmann (1971); Wesson, Welker and Sliepcevich (1971); Kanury (1972a–c); Kashiwagi (1974, 1979a,b, 1980, 1981); Ndubizu and Durbetaki (1978); EPRI (1979b, 1981a); Gelderblom (1980); Vovelle, Mellotee and Delbourgo (1982); Yoshizawa and Kubota (1982); Cullis *et al.* (1983a,b); Wichman and Atreya (1987); Janssens (1991)

Ignition of flammable liquids: Burgoyne and Roberts (1968a); Burgoyne, Roberts and Quinton (1968); Sirignano and Classman (1970); A.F. Roberts and Quince (1973); Kashiwagi (1980); Dorofeev *et al.* (1993)

Flame spread

Kinbari, Endo and Sega (1966); Baldwin (1968); de Ris (1969); Magee and McAlevy (1971); Kanury (1972a); W.J. Parker (1972); Akita (1973); Fernandez-Pello and Williams (1974, 1977); Hirano, Noreikis and Waterman (1974); Alvares (1975); Kashiwagi (1976); Fernandez-Pello (1977a,b, 1984); R. Friedman (1977); F.A. Williams (1977); Hirano and Tazawa (1978); Annamalai and Sibulkin (1979a,b); Fernandez-Pello and Mao (1981); Quintiere (1981); Fernandez-Pello and Hirano (1983); Ray and Classman (1983); Anon. Figure 16.1 *The fire triangle*

combustible gas or vapour mixture burns if it is heated to a sufficiently high temperature.

Thus there are three conditions essential for a fire: (1) fuel, (2) oxygen and (3) heat. These three conditions are often represented as the fire triangle shown in Figure 16.1. If one of the conditions is missing, fire does not occur; if one of them is removed, fire is extinguished.

Normally, the heat required is initially supplied by an external source and then provided by the combustion process itself. The amount of heat needed to cause ignition depends on the form of the substance. A gas or vapour may be ignited by a spark or small flame, while a solid may require a more intense heat source.

Ignition of a combustible gas or vapour mixture may occur in two ways. In the first, the energy for ignition is supplied by a local source such as a spark or small flame at a point within the mixture, as shown in Figure 16.2(a). In the second, the bulk gas mixture is heated up to its ignition temperature, as shown in Figure 16.2 (b).

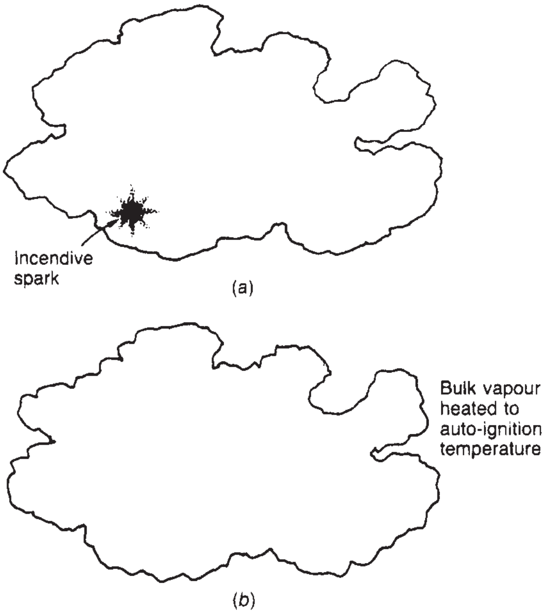

Figure 16.2 *Ignition of a flammable mixture: (a) local ignition and (b) bulk gas ignition*

The three conditions of the fire triangle indicate how fires may be fought. The first method is to cut off the fuel. This is particularly relevant for fires caused by leaks at a process plant. The second method is to remove heat. Putting water on the fire usually does this. The third method is to stop the supply of oxygen. This may be affected in various ways, including the use of foam or inert gas.

Fire is sustained only if there is a net release of heat. The heat comes from the combustion of fuel. If this fuel is liquid or solid, it must first be vaporized. With liquids or solids, fire usually involves a process of positive feedback. The heat evolved by the fire causes the vaporization of an increasing amount of fuel and the fire spreads.

Development of the fire depends on the situation of the fuel. This is commonly illustrated by considering the difference in modes of burning of a lighted match held upwards or downwards. Thus, the stacking of material in closely spaced vertical piles in a warehouse may tend to encourage fire spread.

Fire needs to be supported by the ignition source until it is self-sustaining. For this, duration may be more important than temperature. Thermite bombs, which reach about 1650°C for 15–20 s, have been found less effective in starting fires than napalm, which reaches about 1100°C for 10–15 min.

Different parts of a fire have different heat balances. In some parts, particularly near the edge of the fire, the heat balance may be only just positive. It is sometimes good sense, therefore, to direct fire extinguishant to those parts of the fire and attack it at its weakest points.

It is not necessarily essential to remove all the oxygen in order to extinguish a fire. Reducing the oxygen concentration below 12–16% can generally put out liquid fires. Solids fires may require a greater reduction of oxygen concentration – below about 5% for surface smoldering and as low as about 2% for deep-seated smoldering.

16.1.2 Fire growth and spread

Fire normally grows and spreads by direct burning, which results from impingement of the flame on combustible materials, by heat transfer or by travel of the burning material.

The three main modes of heat transfer are (1) conduction, (2) convection and (3) radiation. All these modes are significant in heat transfer from fires. Conduction is important particularly in allowing heat to pass through a solid barrier and ignite material on the other side.

Most of the heat transfer from fires, however, is by convection and radiation. It is estimated that in most fires, some 75% of the heat emanates by convection. The hot products of combustion rising from a fire typically have a temperature in the range of 800–1200°C and a density a quarter that of air. On open plant much of the heat is dissipated into the atmosphere, but in buildings it is transferred to the ceiling.

Radiation is the other main mode of heat transfer. Although it usually accounts for a smaller proportion of the heat issuing from the fire, radiated heat is transferred directly to nearby objects, does not go preferentially upwards and crosses open spaces. For these reasons it is generally the most significant mode of transfer on open plant.

An account of the modes of heat transfer is given in *Heat Transfer in Fire* (Blackshear, 1974). Radiant heat transfer is treated in *Thermal Radiation Heat Transfer* (Siegel and Howell, 1991).

The other way in which fire spreads is by travel of bulk materials, such as burning liquids or solid brands. With fires in buildings particularly, a stage is generally reached when the materials have been heated up to the point where they produce flammable vapours. The rapid spread of fire which occurs at this point is called 'flashover'.

16.1.3 Classification of fires

There are several classification systems for fires. In the United Kingdom, the BS classification is given in BS EN2: 1992 *Classification of Fires*. This classification is:

Class A	Fires involving solid materials, usually of an organic nature, in which combustion takes place with the formation of glowing embers.
Class B	Fires involving liquids or liquefiable solids.
Class C	Fires involving gases.
Class D	Fires involving metals.

BS EN2: 1992 replaces BS 4547: 1972.

In the United states, the NFPA classification is given in the NFPA Codes. NFPA 10: 2002 contains the following classification:

Class A	Fires in ordinary combustible materials, such as wood, cloth, paper, rubber and many plastics
Class B	Fires in flammable or combustible liquids, oils, greases, tars, oil-based paints, solvents, lacquers, alcohols and flammable gases.
Class C	Fires that involve energized electrical equipment.
Class D	Fires in combustible metals, such as magnesium, titanium, zirconium, sodium, lithium and potassium.

Class K	Fires in cooking appliances that involve combustible cooking media (vegetable or animal oils and fats).

This classification has obvious relevance to the extinguishing medium to be used. For a Class C fire, when electrical equipment is de-energized, extinguishers for Class A and B fires may be used.

Fires are also classified by size. The classification recommended by the Central Fire Brigades Advisory Council and given in the *Manual of Firemanship* by the Home Office (1974–) is:

Major fire	>20 jets
Large fire	8–19 jets
Medium fire	3–7 jets
Small fire	1–2 jets, or >3 hose reels
Minor fire	1–2 hose reels, or hand extinguishers

The classifications of combustible and flammable liquids given in Chapter 10 are also relevant.

16.1.4 Classification of fires: process industries

With regard to fires in the process industries specifically, fires may be classified broadly into the following categories:

(1) vapour cloud fires
  (a) fires with no explosion,
  (b) fires resulting from explosion,
  (c) fires resulting in explosion;
(2) fireballs;
(3) jet flames;
(4) liquid fires
  (a) pool fires,
  (b) running liquid fires;
(5) solids fires
  (a) fires of solid materials,
  (b) dust fires;
(6) warehouse fires;
(7) fires associated with oxygen.

Many major fires are vapour cloud fires. It is convenient to term the three categories of vapour cloud fire, or flash fire, as

Type 1	Fires with no explosion.
Type 2	Fires resulting from explosions.
Type 3	Fires resulting in explosions.

16.2 Flammability of Gases and Vapours

Combustion of a flammable gas–air mixture occurs if the composition of the mixture lies in the flammable range and the conditions exist for ignition. As already mentioned, ignition may result from either (1) bulk gas temperature rise or (2) local ignition.

The combustion of the mixture occurs if the bulk gas is heated up to its auto-ignition temperature (AIT) Alternatively, combustion occurs if there is a source of ignition that has sufficient energy to ignite the applied mixture.

Accounts of flammability characteristics and collections of flammability data are given in *Limits of Flammability of Gases and Vapours* (Coward and Jones, 1952 BM Bull. 503) and *Flammability Characteristics of Combustible Gases and Vapours* (Zabetakis, 1965 BM Bull. 627). A further description of flammability characteristics is given by Burgoyne (1965a). Flammability data are also given in the *Handbook of Industrial Loss Prevention* (FMEC, 1967) and the ICI *Electrical Installations in Flammable Atmospheres Code* (ICI/RoSPA, 1972 IS/91).

The discussion of flammability characteristics given below assumes, unless otherwise stated, that the flammable gas mixture is with air and that the pressure and temperature conditions are the initial values. Selected references on flammability and ignition characteristics are given in Table 16.3.

16.2.1 Flammability limits

A flammable gas burns in air only over a limited range of composition. Below a certain concentration of the flammable gas, the lower flammability limit (LFL), the mixture is too 'lean'; while above a certain concentration, the upper

flammability limit (UFL), it is too 'rich'. The concentrations between these limits constitute the flammable range. The LFLs and UFLs are also sometimes called, respectively, the lower and upper explosive limits (LELs and UELs). They are distinct from the detonability limits.

In general, the most flammable mixture corresponds approximately, but not exactly, to the stoichiometric mixture for combustion. It is frequently found that the concentrations at the LFLs and UFLs are roughly one-half and twice that of the stoichiometric mixture, respectively.

Flammability limits are affected by pressure, temperature, direction of flame propagation, gravitational field and surroundings. The limits are determined experimentally and the precise values obtained depend, therefore, on the particular test method.

Although there is no universally used equipment, one which has been utilized for the measurement of many flammability limit data is the BM apparatus, which is described by Coward and Jones (1952 BM Bull. 503) and which consists of a cylindrical tube 5 cm diameter and 1.5 m high. The tube is closed at the top but open at the bottom. Gas–air mixtures of different compositions are placed in the tube and a small ignition source is applied at the bottom. The lower and upper limit concentrations at which the flame initiated by the source of ignition just travels the full length of the tube are then determined.

The test is normally carried out with the mixture at atmospheric pressure and temperature and with upward flame propagation, but other conditions can be investigated such as different pressures and temperatures, downward flame propagation and/or addition of inert gases. Table 16.4 shows flammability limits of selected substances. It also gives other flammability characteristics that are described below.

For many organic substances the LFL, expressed in mass per unit volume, lies within a relatively narrow range. Burgoyne (1963) quotes data that show the limits as lying mainly in the range 0.04–0.10 g/l (or oz/ft^3). More specifically, he states that for saturated hydrocarbons the LFL is of the order of 0.045 g/l (oz/ft^3). For unsaturated hydrocarbons it is less and for oxygenated hydrocarbons it is more.

Flammability limits are affected by pressure. Normal variations of atmospheric pressure do not have any appreciable effect on flammability limits. The effect of larger pressure changes is not simple or uniform, but is specific to each mixture. A decrease in pressure below atmospheric can narrow the flammable range by raising the LFL and reducing the UFL until the two limits coincide and the mixture becomes non-flammable. This effect is illustrated for methane in Figure 16.3.

Conversely, an increase in pressure above atmospheric can widen the flammable range by reducing the LFL and raising the UFL. This effect is shown in Figure 16.4 for natural gas. It may be noted that the effect is more marked on the upper than on the LFL. In the case of higher hydrocarbons, increase in pressure causes an abnormal increase in the UFL with the creation of a region of cool flames (Hsieh and Townend, 1939b). Cool flames are considered further below. However, an increase in pressure does not always widen the flammable range; in some cases it can narrow it.

Flammability limits are also affected by temperature. An increase in temperature tends to widen the flammable range. This effect is shown for methane in Figure 16.5. The variation of the LFL of methane with temperature is illustrated in Figure 16.6. The limit values obtained experimentally fall fairly close to a straight line that passes through the lower limit at 25°C and through zero at the flame temperature of 1225°C.

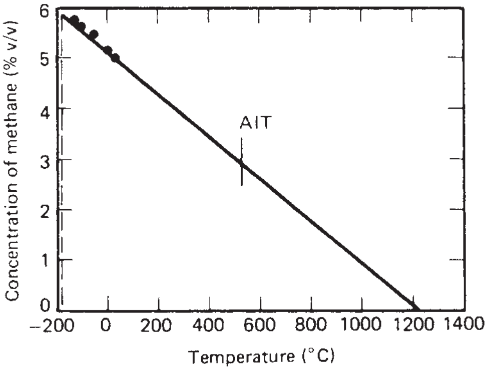

Figure 16.6 *Effect of temperature on low flammability limit of methane in air (Zabetakis, 1965 BM Bull. 627) (Courtesy of the Bureau of Mines)*

Similar results are obtained for the effect of temperature on the LFLs of other lower paraffinic hydrocarbons. For these the approximate flame temperature can be taken as 1300°C. Then for the first 10 members of the series from methane to decane

$$\frac{L_t}{L_{25}} = 1 - \frac{t-25}{1300-25} \qquad [16.2.1]$$

where L_t is the LFL at t°C (%v/v), L_{25} is LFL at 25°C (%v/v) and t is the temperature (°C).

The data may also be fairly well correlated by the modified Burgess–Wheeler law, suggested by Zabetakis, Lambiris and Scott (1959):

$$\frac{L_t}{L_{25}} = 1 - \frac{0.75(t-25)}{\Delta H_c} \qquad [16.2.2]$$

where ΔH_c is the net heat of combustion (kcal/mol). Likewise the modified Burgess–Wheeler law may correlate the effect of temperature on the UFL of these hydrocarbons, in the absence of cool flames:

$$\frac{U_t}{U_{25}} = 1 - \frac{0.75(t-25)}{\Delta H_c} \qquad [16.2.3]$$

where U_t is the UFL at t°C (%v/v), and U_{25} is the UFL at 25°C (%v/v).

The variation of flammability limits with temperature was studied by Bodurtha (1980), who obtained for the substances studied a value of 0.0008/°C both for the fractional decrease with temperature of the LFL and for the fractional increase with temperature of the UFL.

A more recent study of the effect of pressure and temperature on flammability limits is that of Gibbon, Wainwright and Rogers (1994), who investigated a limited number of solvents. Their work confirmed that an increase in temperature causes a decrease in the LFL and an increase in the UFL. They also found that the UFL increased with increase in pressure. Unexpectedly, the LFL also increased with increase in pressure.

In sum, the effect of pressure on the flammability limits is much less predictable than that of temperature. In particular, increase in pressure causes in some cases a decrease in the LFL and in others an increase.

It has been demonstrated that flammability limit measurements can be complicated by surface and vapour phase reactions that occur above the AIT. It has been shown, for example, that methane–air mixtures containing up to 5% v/v methane burn readily at 1000°C. The experiments were conducted with methane concentrations as low as 0.5% v/v (Burgoyne and Hirsch, 1954).

Flammability limits are also affected by the addition of an inert gas such as nitrogen, carbon dioxide or steam. This effect is shown for methane in Figure 16.7. Minimum inert gas contents for suppression of flammability of selected substances in air are shown in Table 16.5. In general, carbon dioxide causes a greater narrowing of the flammable range than does nitrogen. For many flammable gas–air systems, the mixtures can be rendered non-flammable by the addition of about 30% of carbon dioxide or about 40% of nitrogen.

The flammability limits described are those for mixtures of a flammable gas in air. There are also flammability limits for combustion in pure oxygen. In general, the LFL of a gas is almost the same in oxygen as in air, but the UFL is much greater in oxygen than in air. The flammable range in oxygen is thus wider than it is in air. The applicability of flammability limits is not confined, however, to air and oxygen. There are flammability limits for substances that burn in chlorine.

Flammability limits for a fuel mixture that contains several flammable gases may be calculated from the equation of Le Chatelier (1891). For the lower limit

$$L = \frac{1}{\sum_{i=0}^{n} (y_i/L_i)} \qquad [16.2.4a]$$

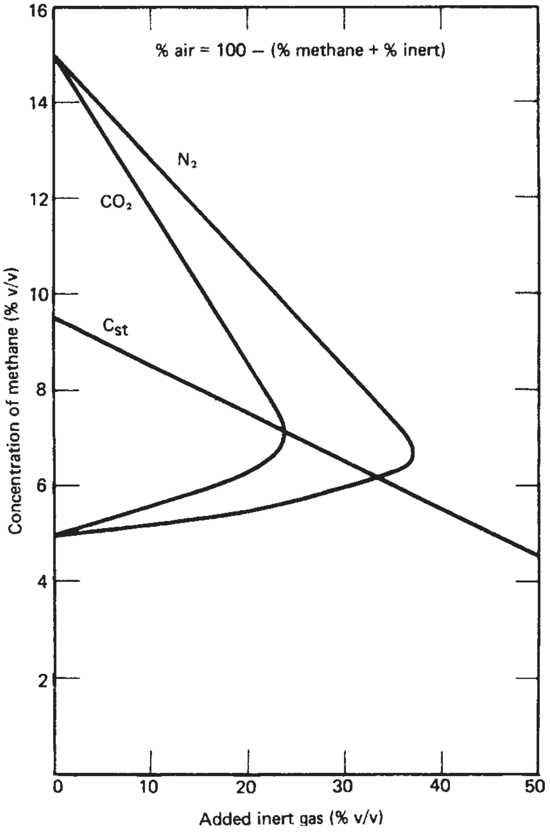

Figure 16.7 Effect of inert gases on flammability limits of methane in air (Zabetakis, 1965 BM Bull, 627) (Courtesy of the Bureau of Mines)

where L is the LFL of air-free fuel (%v/v), L_i the LFL of fuel component i (%v/v) and y_t is the concentration of fuel component i (mole fraction). For the upper limit

$$U = \frac{1}{\sum_{i=0}^{n} (y_i/U_i)} \qquad [16.2.4b]$$

where U is the UFL of air-free fuel (%v/v), and U_i, the UFL of fuel component i (%v/v).

Le Chatelier's equation is an empirical one and it is not universally applicable. Its limitations are discussed by Coward and Jones (1952 BM Bull. 503, p. 6). Further information on and examples of the calculation of the flammability limits of fuel mixtures are given in BS 5345: Part 1: 1976.

It is necessary to exercise care in using flammability limit data, since the limit may vary with pressure, temperature and other conditions. The LFL required to determine the amount of flammable gas–air mixture resulting from a plant leak can probably be obtained quite readily, because usually the data are available for ambient conditions and the accuracy called for is not high, but that required to maintain the concentration of a flammable gas–oxygen mixture entering a reactor just below the flammable range under other pressure and temperature conditions needs greater consideration, because the data may not be available so readily for these other conditions, but they must be accurate.

Table 16.5 *Minimum inert gas content for suppression of flammability of selected substances in air (after Burgoyne, 1965a) (Courtesy of the Institution of Marine Engineers)*

	Nitrogen (% v/v)	*Carbon dioxide* (% v/v)

n-Pentane	43	29
n-Hexane	42	29
Ethylene	50	41
Propylene	43	30
Benzene	45	32

16.2.2 Ignition temperature

If the temperature of a flammable gas–air mixture is raised in a uniformly heated apparatus, it eventually reaches a value at which combustion occurs in the bulk gas. For the range of flammable mixtures there is a mixture composition that has the lowest ignition temperature. This is the minimum spontaneous ignition temperature (SIT) or auto-ignition temperature (AIT).

The AIT for the first 10 paraffinic hydrocarbons are as follows (Zabetakis, 1965 BM Bull. 627):

	AIT (°C)		*AIT* (°C)
Methane	537	*n*-Hexane	223
Ethane	515	*n*-Heptane	223
Propane	466	*n*-Octane	220
n-Butane	405	*n*-Nonane	206
n-Pentane	258	*n*-Decane	208

It may be noted that there is a break between the AIT for *n*-butane and that for *n*-pentane and that the rate of decrease of these temperatures after *n*-pentane is low. Some substances have quite low AITs. The AIT of carbon disulfide, for example, is 90°C.

The AIT temperature is a property that is particularly liable to variations caused by the nature of hot surfaces. The values normally quoted are obtained in laboratory apparatus with clean surfaces. The AIT may be reduced by as much as 100–200°C for surfaces that are lagged or are contaminated by dust.

Auto-ignition temperatures of selected substances are given in Table 16.4.

16.2.3 Ignition time delay

Ignition of a flammable mixture raised to or above the temperature at which spontaneous ignition occurs is not instantaneous; there is a finite time delay before ignition takes place. This time delay decreases as the ignition temperature increases and the reduction has been correlated by Semenov (1959) using the equation

$$\ln \tau = \frac{k_1 E}{T} + k_2 \quad [16.2.5]$$

where E is the apparent activation energy, T is the absolute temperature, τ is the time delay before ignition, and k_1 and k_2 are constants. The time delay may be as little as a fraction of a second at higher temperatures or several minutes close to the AIT.

This effect may be of significance in flow systems where the fluid is a flammable mixture that comes in contact with a hot surface above the AIT, but for a short time only.

16.2.4 Flashpoint

The flashpoint of a flammable liquid is the temperature at which the vapour pressure of the substance is such as to give a concentration of vapour in the air that corresponds to the LFL.

There are two methods of measuring flashpoint, the closed cup test and the open cup test. Some standard test methods are:

Closed cup	Pensky Martens	ASTM D 93–61 BS 2839: 1969
	Tagliabue	ASTM D 56–61
Open cup	Cleveland	ASTM D 92–57

The open cup flashpoint is usually a few degrees higher than the closed cup flashpoint. The relationships between vapour pressure, flammability limits, flashpoint and AIT are illustrated in Figure 16.8.

A liquid that has a flashpoint below ambient temperature and can thus give rise to flammable mixtures under ambient conditions is generally considered more hazardous than one with a higher flashpoint. The flashpoint is a main parameter, therefore, in hazard classification of liquids and in government regulations based on these. Thus, in aviation there has been movement to replace fuel JP4 with JP1. The former is akin to petroleum and has a low flashpoint, while the latter is more like kerosene and has a higher flashpoint, which is therefore safer.

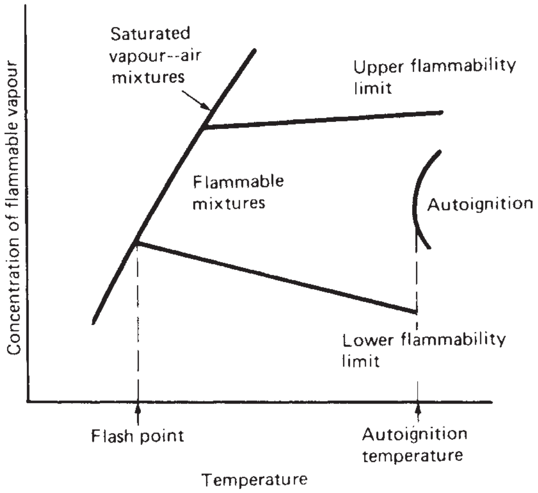

Figure 16.8 Relationships between vapour pressure, flammability limits, flashpoint and auto-ignition temperature (after Zabetakis, 1965 BM Bull. 627) (Courtesy of the Bureau of Mines)

Obviously, however, a higher flashpoint liquid also becomes more hazardous if it is heated up to a temperature above its flashpoint. The flashpoints of selected substances are given in Table 16.4.

16.2.5 Fire point

The fire point of a flammable liquid is the lowest temperature at which the liquid, when placed in an open container, will give off sufficient vapour to continue to burn once ignited. The fire point is usually a few degrees above the open cup flashpoint.

16.2.6 Ignition energy

If a flammable gas–air mixture is to be ignited by a local source of ignition, however, it is not sufficient (as it is with auto-ignition) to raise a volume of the mixture to a certain temperature for a certain time. There is also a minimum volume of mixture so treated that is required in order to give rise to a continuing flame through the rest of the mixture. It has been shown, for example, that to ignite a methane–air mixture in a cold container by means of a hot patch an area of 18 mm^2 is required at 1000–1100°C (Rae, Singh and Danson, 1964). There is in effect an ignition energy requirement.

Similarly, ignition of a flammable gas–air mixture by a local source of ignition by electrical discharge occurs only if the latter possesses a certain energy. The variation of ignition energy with composition is shown for hydrogen and for methane in Figure 16.9.

There is a minimum ignition energy (MIE), which usually occurs close to the stoichiometric mixture. Minimum ignition energies (MIEs) for selected substances are shown in Table 16.6.

16.2.7 Burning velocity

The burning velocity affects the rate of combustion of a flammable mixture. The burning velocity is a property of the mixture. It is in effect the velocity at which a gaseous fuel–air mixture issuing from a burner burns back on to the burner. The burning velocity of a fuel–air mixture is usually determined by measurement of a premixed bunsen burner flame in the laminar region. The burning velocity S_u is obtained by dividing the volumetric gas flow V by the area A of the flame front cone:

$$S_u = V/A \quad [16.2.6]$$

Alternatively, the burning velocity may be obtained from the velocity u of the gas and the half-angle α of the apex of the flame front cone:

$$S_u = u \sin \alpha \quad [16.2.7]$$

If the flame front cone has radius r, height h and slant height l, the area A of the cone surface and the area A' of the

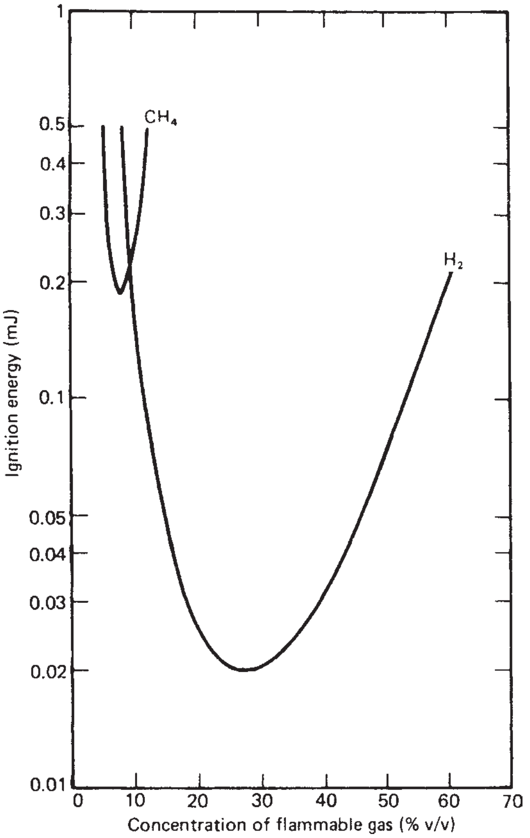

***Figure 16.9** Effect of mixture composition on electrical ignition energy of methane and of hydrogen in air (Factory Mutual Engineering Corporation, 1967)*

cone triangular cross-section are, respectively

$$A = \pi r l \qquad [16.2.8a]$$

$$= \pi r (r^2 + h^2)^{1/2} \qquad [16.2.8b]$$

$$A' = rh \qquad [16.2.9]$$

Also

$$A = \pi A' l / h \qquad [16.2.10]$$

The gas velocity u is

$$u = \frac{V}{\pi r^2} \qquad [16.2.11]$$

The flame front is usually not a perfect cone and, in consequence, the equations just quoted are subject to errors of varying size. The choice of equations for the calculation of burning velocity is discussed by B. Lewis and von Elbe (1961) and by Fells and Rutherford (1969). The maximum burning velocity obtained at atmospheric pressure and temperature is referred to as the maximum fundamental burning velocity.

n-Hexane	0.25
Ethylene	0.12
Benzene	0.22
Ammonia	up to >100

Sources: Burgoyne (1965a); FMEC (1967).

Burning velocities for methane in air and in oxygen are shown in Figure 16.10. In general, burning velocities for paraffinic hydrocarbons range from a few centimetres per second near the flammability limits up to about 45 cm/s near the stoichiometric mixture. For these hydrocarbons in oxygen the corresponding values are about 125 and 425 cm/s, respectively.

Burning velocities are affected by pressure and temperature. The effect of pressure changes is variable. A decrease in the burning velocity of stoichiometric methane–air mixtures has been found with increasing pressure in the range 0.5–20 atm, but with stoichiometric methane–oxygen mixtures an increase in pressure in the range 0.2–2 atm gave an increase in burning velocity.

The effect of temperature on burning velocity is more consistent and is sometimes described by the equation

$$S_u = A + BT^n \qquad [16.2.12]$$

where T is the absolute temperature, A and B are constants and n is an index. A value of 2.0 for the index n has been found for some paraffinic hydrocarbons (Zabetakis, 1965 BM Bull. 627, p. 43). Maximum fundamental burning velocities of selected substances in air and in oxygen are given in Table 16.7.

The actual flame speed in combustion of a flammable mixture is greater, and sometimes very much greater, than the burning velocity. Whereas the burning velocity is a property of the mixture only, the flame speed depends on other factors such as turbulence and pressure waves. If detonation occurs, the flame speed is greater by orders of magnitude than the burning velocity.

16.2.8 Adiabatic flame temperature

The heat radiated by combustion of a flammable mixture depends on the flame temperature, the theoretical maximum value of which is the adiabatic flame temperature. The adiabatic flame temperature is the temperature attained by combustion under adiabatic conditions. It is normally determined for the stoichiometric mixture and values quoted generally refer to this unless otherwise stated.

The adiabatic flame temperature can be calculated, but for an accurate calculation this is not entirely

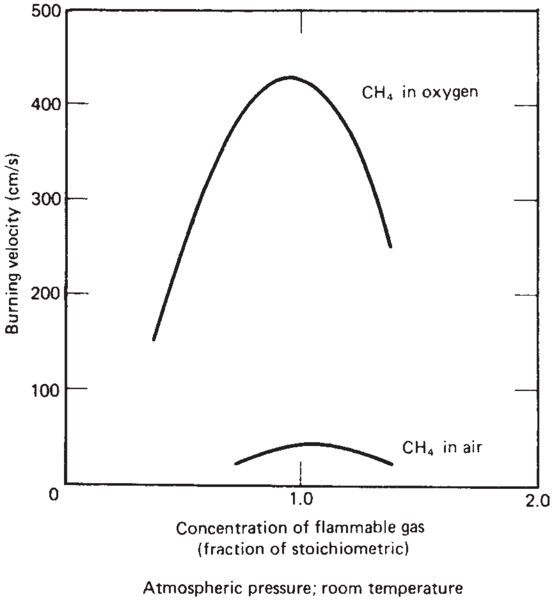

Figure 16.10 *Effect of mixture composition on burning velocity of methane in air and in oxygen (Zabetakis, 1965 BM Bull. 627) (Courtesy of the Bureau of Mines)*

straightforward. Accounts of calculation methods are given by Hoil pen.Watson and Rasyatz (1954–).W.A. Grav. Kilham and Mffller (1976), Barnard and Bradley (1985), Drysdale (1985) and Kuo (1986).

The adiabatic flame temperature may be determined for constant pressure or constant volume conditions. The value normally quoted is for the former. For this case the enthalpy balance is

$$\Delta H_2 + \Delta H_1 + \Delta H_c = 0 \qquad [16.2.13]$$

or

$$\Delta H_2 + \Delta H_1 + (-\Delta H_c) \qquad [16.2.14]$$

with

$$\Delta H_1 = \sum_{i=1}^{r} n_i \int_{T_1}^{T_0} c_{pi}(T)\,\mathrm{d}T \qquad [16.2.15]$$

$$= c_{pmr}(T_0 - T_1) \qquad [16.2.16]$$

$$\Delta H_2 = \sum_{i=1}^{p} n_i \int_{T_0}^{T_2} c_{pi}(T)\,\mathrm{d}T \qquad [16.2.17]$$

$$= c_{pmp}(T_2 - T_0) \qquad [16.2.18]$$

where c_p is the specific heat at constant pressure of component i (kJ/kmol°C), c_{pm} is the mean specific heat over the range of interest (kJ/kmol°C), ΔH_c is the heat of combustion (kJ/mol of fuel), ΔH_1 is the enthalpy change between states 1 and 0 (kJ/kmol of fuel), ΔH_2 is the enthalpy change between states 1 and 2 (kJ/kmol of fuel), n is the number of moles per mole of fuel, p is the number of products, r is the number of reactants and subscripts i, p and r denote component i, products and reactants, and 0, 1 and 2 denote the standard state, initial state and final state, respectively.

The specific heat c_{pi} of a reactant or product is a function of the temperature T. It is commonly represented in the form

$$c_{pi} = a_i + b_i T + c_i T^2 + d_i T^3 \qquad [16.2.19]$$

where a_i (kJ/kmol°C), b_i (kJ/kmol°C K), c_i (kJ/kmol°C K^2) and d_i (kJ/kmol°C K^3) are constants.

Then from Equations 16.2.17–16.2.19 the mean specific heat of product i is

$$c_{pmi} = \frac{\left(a_i T + b_i T^2/2 + c_i T^3/3 + d_i T^4/4\right)_{T_0}^{T_2}}{T_2 - T_0} \qquad [16.2.20]$$

and the mean specific heat of the product mixture is

$$c_{pmp} = \sum_{i=1}^{p} n_i c_{pmi} \qquad [16.2.21]$$

If necessary, equations similar to Equations 16.2.20 and 16.2.21, derived from Equations 16.2.15 and 16.2.19, may be used to obtain c_{pmr}, but generally the initial temperature T_1 is close to the standard temperature T_0 so that a point value of c_{pmr} may be used. If in fact $T_1 = T_0$, then $\Delta H_1 = 0$.

Table 16.8 gives values of the constants in Equation 16.2.19 for the determination of point values of the specific

heats c_p. Table 16.9 gives values of the mean specific heat c_{pm} over the interval 0°C to t°C.

In the foregoing the implicit assumption is that the products of combustion are those given by the simple stoichiometric equation, which for hydrocarbons yields only CO_2 and H_2O. In fact, for flame temperatures above about 1370°C dissociation of the products of combustion occurs. At adiabatic flame temperatures, dissociation and ionization absorb a significant amount of energy and result in an appreciable lowering of the temperature of the flame. This is illustrated in Table 16.10, which shows that for propane the values obtained for the adiabatic flame temperature are 2219 K using a comprehensive set of equilibriums, 2232 K using a simplified set and 2324 K considering only the formation of CO_2 and H_2O.

Calculations of the adiabatic flame temperature allowing for dissociation are complex. A computer program that performs such calculations has been described by Gordon and McBride (1971, 1976). An account of its use is given by Kuo (1986).

Table 16.11 gives some theoretical and experimental values of flame temperature quoted by B. Lewis and von Elbe (1987) and Siegel and Howell (1991). The theoretical values given in the table are adiabatic flame temperatures at constant pressure. Details of the experimental temperatures are given in the footnote to the table. Lewis and von Elbe state that the experimental flame temperatures were probably influenced somewhat by heat loss and other factors, but that the error is small; Siegel and Howell describe the experimental values as 'maximum temperatures'.

16.2.9 Degree of flammability

Comparisons are often made between the flammability either of different substances or of different mixtures of the same substance in air. There is no single parameter that defines flammability, but some that are relevant are (1) the flashpoint, (2) the flammability limits, (3) the AIT, (4) the ignition energy and (5) the burning velocity.

The flashpoint of a substance is often treated as the principal index of flammability, a substance being regarded as highly flammable if it has a low flashpoint. The other flammability characteristics are also important, however. The flammability of the substance is increased by wide flammability limits and by a low minimum AIT, low MIE and a high maximum burning velocity.

The mixtures that have the lowest AITand ignition energy and the highest burning velocity, tend to occur near to, but normally not exactly at, the stoichiometric composition.

16.2.10 Quenching effects

Flame propagation is suppressed if the flammable mixture is held in a narrow space. Thus there is a minimum diameter for apparatus used for determination of flammability limits such that below this diameter the flammable range measured is narrower and inaccurate. Ultimately, if the space is sufficiently narrow, flame propagation is suppressed completely. The largest diameter as which flame propagation is suppressed is known as the quenching diameter. For an aperture of slot-like cross-section there is a critical slot width.

Hydrogen	2490			2318

[a] Given by Siegel and Howell (1991), quoting Barnett and Hibbard (1957) and Gaydon and Wolfhard (1960). Values for combustion in dry air at 298 K.

[b] Given by B. Lewis and von Elbe (1987), quoting Loomis and Perrott (1928), G.W. Jones, Lewis and Seaman (1931) and G.W. Jones *et al.* (1931). See text.

The term 'quenching distance' is used sometimes as a general term covering both quenching diameter and critical slot width and sometimes meaning the latter only. An account of quenching distances is given by Potter (1960). He gives the following empirical relation between quenching diameter D_o and critical slot width $D_{\parallel}$:

$$D_{\parallel} = 0.65 D_o \qquad [16.2.22]$$

He also discusses the effect of pressure and temperature on these variables.

There is a maximum experimental safe gap (MESG) that avoids the transmission of an explosion occurring within a container to a flammable mixture outside the container. The MESG is measured in a standard apparatus. One apparatus consists of a spherical vessel with the gap between a pair of flat equatorial flanges, the breadth of the gap being 1 in. A value of less than 1 in. causes a decrease in the MESG, but a greater value has no effect. An account of maximum safe gaps is given by Lunn and Phillips (1973).

Critical slot widths and MESGs for selected substances in air are given in Table 16.12. It is emphasized that these values relate to a stationary flame. If the gas flow is in the direction of flame propagation, a smaller gap is needed to quench the flame and, conversely, if the gas flow is in the opposite direction, a larger gap will effect quenching. If the gas velocity is high enough, a condition can occur in which a flame propagating against the flow is stabilized at a constriction and causes local overheating.

For some substances, notably acetylene, carbon disulfide and hydrogen, the quenching diameters and distances are very small. These quenching effects are important in the design of flameproof equipment and of flame arresters.

Table 16.12 *Critical slot widths and maximum experimental safe gaps for selected substances in air*

	Critical slot width[a,b] (mm)	*Maximum experimental safe gap*[b,c] (mm)
Acetone	–	1.01
Acetylene	0.52	0.37[d]
Ammonia	–	3.18
Benzene	1.87	0.99
n-Butane	–	1.07[e]

Ethylene oxide	1.18	0.59
Hydrogen	0.50	0.20
Methane	2.16	1.14
n-Pentane	2.07	0.89[e]
Propane	1.75	0.92
Propylene	–	0.91
Vinyl chloride	–	0.96

Sources: Critical slot width: Potter (1960). Maximum experimental safe gap: Lunn and Phillips (1973), except as given in footnotes.

[a] Critical slot widths are for stoichiometric mixtures and are corrected where necessary to atmospheric pressure and 25°C.

[b] Where several values of critical slot width or maximum experimental safe gap are given in original reference, the value quoted here is the smallest.

[c] Maximum experimental safe gaps are corrected where necessary to atmospheric pressure and 20°C.

[d] Data for acetylene and carbon monoxide should be interpreted with care. For acetylene under certain ill-defined circumstances external ignitions have been reported at flange gaps too small to measure. For carbon monoxide data are for moist (not saturated) gas. Addition of moisture greatly increases the burning velocity of carbon monoxide.

[e] Burgoyne (1965a). Maximum experimental safe gap at atmospheric pressure.

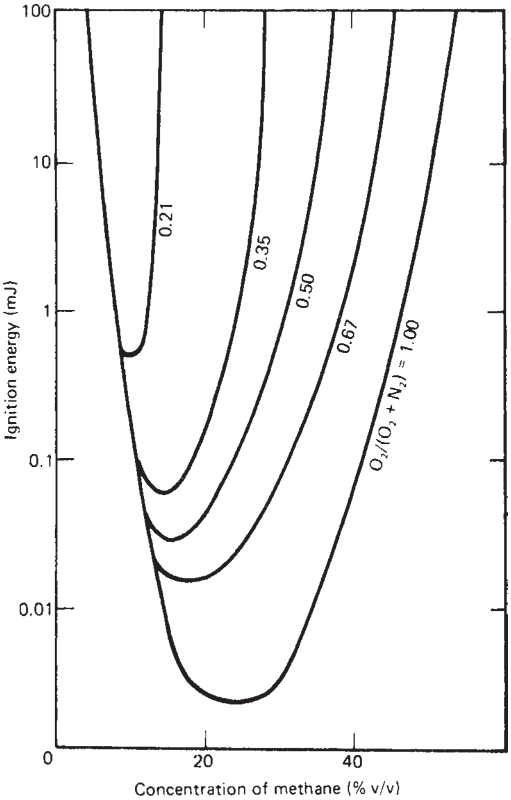

Figure 16.12 *Minimum spark ignition energies in methane–oxygen–nitrogen mextures at 1 atm pressure (B. Lewis and von Elbe, 1961) (Courtesy of Academic Press)*

16.2.11 Flammability in oxygen

The flammability of a substance depends strongly on the partial pressure of oxygen in the atmosphere. The oxygen concentration affects both the flammability limits and the other flammability parameters. In general, increasing oxygen content alters the LFL only slightly, but its effect on the UFL is marked. Figure 16.11 illustrates the effect of oxygen concentration on the flammability limits of methane–oxygen–nitrogen mixtures. Conversely, there is a minimum oxygen content to support combustion. For the system shown in Figure 16.11 this is approximately 12%. Increasing the oxygen content reduces the ignition energy and the quenching distance of methane–oxygen–nitrogen mixtures as shown in Figures 16.12 and 16.13, respectively. Again the effect is a marked one.

The increase in burning velocity of methane when air is replaced by oxygen was illustrated in Figure 16.10.

16.2.12 Uncertainty in data

It has already been emphasized that there is frequently some uncertainty in the data available for design. The point is illustrated by the data on flammability characteristics

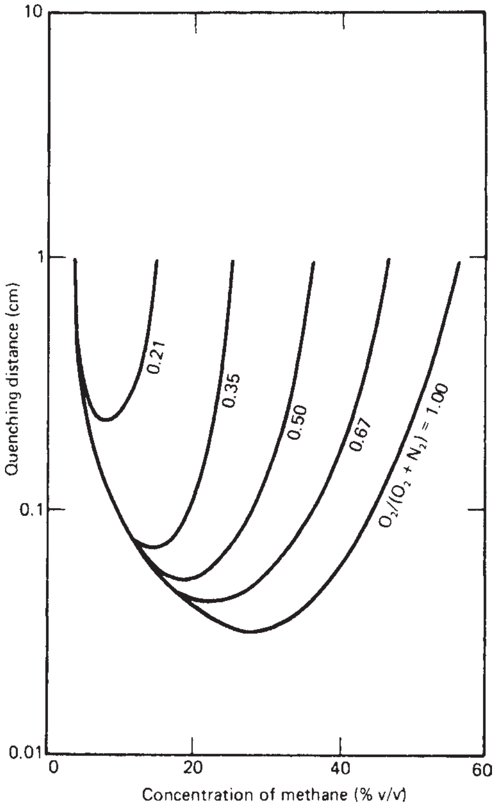

***Figure 16.13** Quenching distances in methand–oxygen–nitrogen mixtures at 1 atm pressure (B. Lewis and von Elbe 1961) (Courtesy of Academic Press)*

given in Table 16.13. The LFL of ethylene–air mixtures at atmospheric pressure and temperature is generally taken as 2.7%, as indicated in the table, and it is not regarded as particularly uncertain. But as the figures show, previous values differ from this by a factor as high as 1.22. On the other hand, the MIE of ammonia–air mixtures at atmospheric pressure and temperature appears still to be subject to some uncertainty. The situation is similar for the AIT of acetone, methanol and methylethyl ketone mixtures with air at atmospheric pressure.

16.3 Combustion Phenomena

The use of the flammability characteristics just described is a simplification of rather complex combustion phenomena, which for engineering purposes it is necessary to make. It is convenient at this point, therefore, to indicate some of this combustion background, both as a commentary on the flammability characteristics just described and as an introduction to the subsequent sections on flames and fires.

Accounts of basic combustion are given in *The Science of Flames and Furnaces* (Thring, 1952), *Flames, Their Structure, Radiation and Temperature* (Gaydon and Wolfhard, 1953–), *Some Fundamentals of Combustion* (Spalding, 1955), *Combustion, Flames and Explosions of Gases* (B. Lewis and von Elbe, 1961, 1987), *Combustion Theory* (F.A. Williams, 1965), *Fundamentals of Combustion* (Strehlow, 1968a), *Flames and Combustion Phenomena* (G.N. Bradley, 1969), *Flame and Combustion* (Barnard and Bradley, 1985), *An Introduction to Fire Dynamics* (Drysdale, 1985), *Principles of Combustion* (Kuo, 1986) and *Combustion of Liquid Fuel Sprays* (A. Williams, 1990).

Selected references on combustion phenomena are given in Table 16.14. Some topics in combustion research relevant to loss prevention are shown in Table 16.15.

In this section the following aspects of combustion are reviewed:

(1) flame propagation;
(2) diffusion and premixed flames;
(3) premixed flame flashback and blowoff;
(4) diffusion flame characteristics;
(5) flame stretch and wrinkling;
(6) reaction kinetics and transport processes;
(7) thermal explosion theory;
(8) flammability limits;
(9) ignition phenomena;
(10) burning velocity;
(11) quenching effects;
(12) cool flames;
(13) combustion in tubes.

Some of the reviews are essentially historical, illustrating the development of the basic concepts.

16.3.1 Flame propagation

A useful starting point for consideration of combustion is the propagation of the flame as an adiabatic planar combustion wave, as shown in Figure 16.14. At the front of the combustion zone the temperature is that of the burnt gas T_b. From this maximum value the temperature then falls off. Within the wave there is a plane at temperature T_1 where transition occurs from a heat source to a heat sink in that the heat supplied by the reaction now falls below the heat lost to the unburnt gas behind. The temperature then falls further until it reaches the temperature T_u of the unburnt gas behind the wave. The first part of the combustion zone, in front of T_1, is the reaction zone and the second part, behind T_1, the preheat zone.

In many practical situations the flame front is not planar. In particular, a small spherical flame has a divergent flame front and undergoes stretch, as described below. However, as the spherical flame becomes larger, the flame front may be approximated by a planar front.

Although it is convenient to start with the model of the adiabatic planar combustion wave, it has often been the case in combustion theory that progress has only been made when this model is abandoned and real, but more complex, situations are considered. Thus, B. Lewis and von Elbe (1961) state:

> The use of the adiabatic plane wave equations for general theoretical deductions of flame behaviour is futile

Table 16.13 *Variability of experimental data on flammability characteristics in air*

Property	*Mixture*	*Value* (% v/v)	*Reference*
Lower flammability limit (upwards propagation of flame)	Ethylene–air[a]	2.75	Jones *et al.* (1935 BM RI 3278)

> because the model is unrealistically restricted by the specification of one-dimensional, adiabatic propagation in an infinite medium for an infinite time. For one thing, the model does not yield limits of inflammability as they are known to the experimenter. (p. 210)

An important feature in combustion work is the flow regime. In particular, there is a distinction between a flame propagating in a stagnant gas and in a flowing gas. Another distinction is that between laminar and turbulent flow. Flammability characteristics such as the ignition energy or burning velocity are affected by the flow regime.

16.3.2 Diffusion and premixed flames

A fundamental distinction is made between (1) premixed flames and (2) diffusion flames. In a premixed flame the air for combustion is mixed with the fuel gas before it issues from the orifice, while in a diffusion flame gas or liquid leaving the orifice is pure fuel and the air for combustion has to diffuse to it from the surrounding atmosphere. Both types of flame may be produced on a bunsen burner, a premixed flame being obtained by opening the primary air inlet and a diffusion flame by closing it.

With a premixed flame the rate of burning is limited by reaction kinetics, while, in principle, with a diffusion flame the rate limiting mechanism is diffusion. At high turbulence in a diffusion flame, however, kinetics and diffusion may be of roughly equal importance.

Another distinction in flames is that between (1) laminar flames and (2) turbulent flames. The criterion for transition from the laminar to the turbulent regime in a flame is the Reynolds number. The relevant Reynolds number, however, is that of the flame, which is actually several times less than that of the cold gas leaving the tube, because the gas viscosity at the flame temperature is that much greater.

16.3.3 Premixed flame flashback and blow-off

The behaviour of a premixed flame burning on a tube or similar burner is a function of the concentration of the fuel and of the gas velocity. Aspects of particular interest are flashback, blow-off, lift and blow-out of the flame. These features have been studied for flames of butane–air mixture by Wohl, Kapp and Gazley (1949) and are shown in Figure 16.15. In region A a stable flame can exist only at the burner port and in region B only lifted off the port. In region C the flame may be stable either on the port or lifted off it. In region D flashback can occur down the burner pipe.

The limits for flashback, blow-off and lift are determined by the velocity gradients at the boundary of the flame. In the flame the gas velocity is opposed by the axial component of the burning velocity. Flashback occurs under conditions where the gas velocity is low relative to the

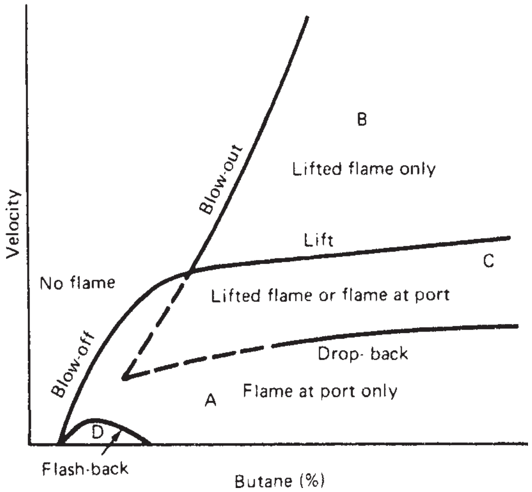

Figure 16.15 *Scheme of characteristic regions of flame stability for a premixed flame (after Wohl, Kapp and Gazley, 1949) (Courtesy of the Combustion Institute)*

burning velocity. Blow-off at lower fuel concentration and lift at high fuel concentrations occur where the gas velocity is high relative to the burning velocity. The lift curve is an extension of the blow-off curve. The limits for blow-out and drop back of a lifted flame are not determined by the boundary velocity gradients and their shapes are specific for each burner diameter.

For laminar flow, from the Poiseuille equation the boundary velocity gradient g is

$$g = 4V/\pi r^3 \quad [16.3.1]$$

where r is the distance from the centre of the tube to the boundary of the stream and V is the volumetric flow of gas. The critical boundary velocity gradient for flashback g_F may be obtained from Equation 16.3.1 using the volumetric flow for flashback V_F. Likewise, the critical boundary velocity gradient for blow-off g_B may be obtained using the volumetric flow for blow-off V_B.

Data on critical velocity gradients for flashback and for blow-off have been given by M.E. Harris *et al.* (1949).

16.3.4 Diffusion flame characteristics

The behaviour of a diffusion flame is a function of the fuel velocity. As aspect of particular interest is the dimensions of the flame. This is illustrated in Figure 16.16, which is based on the work of Hottel and Hawthorne (1949) and a further interpretation by Gugan (1976). In the laminar regime the flame length is approximately proportional to the velocity, while in the turbulent regime it is independent of velocity. Turbulence spreads from the flame tip downwards. As velocity increases there are successively a region where the flame may be on the port or lifted, a region where only a lifted flame occurs and a point beyond which there is blow-off.

There are a number of correlations for the dimensions of a diffusion flame. The simple equation given by Jost (1946) for flame length is

$$L = \frac{d^2 u}{4D} \quad [16.3.2]$$

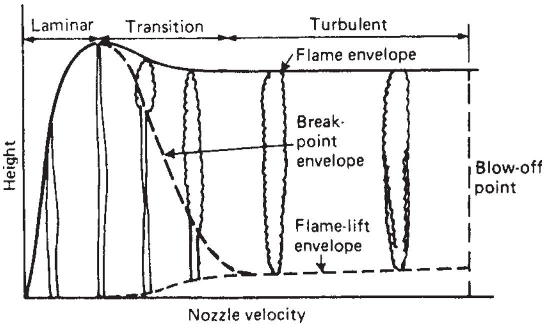

Figure 16.16 *Scheme of characteristic regions of flame stability for a diffusion flame (after Hottel and Hawthome, 1949; Gugan, 1976) (Courtesy of the Combustion Institute and the Institution of Chemical Engineers)*

where d is the diameter of the pipe (m), D is the diffusion coefficient (m^2/s), L is the flame length (m), and u is the fuel velocity (m/s).

For the laminar regime the diffusion coefficient D may be taken as the molecular diffusion coefficient D_m, which is a constant with respect to velocity. The flame length in this regime is thus proportional to velocity. But for the turbulent regime, D may be taken as the eddy diffusion coefficient D_e, which is proportional to the velocity u. The flame length in this regime is thus independent of velocity.

For the turbulent regime an equation commonly used to predict flame length is that of Hawthorne, Weddell and Hottel (1949):

$$L = \frac{5.3D}{C_t}\left\{\frac{T_f}{\alpha_t T_n}\left[C_t + (1 - C_t)\frac{M_s}{M_n}\right]\right\}^{1/2} \qquad [16.3.3]$$

where C_t is the concentration of fuel in the stoichiometric mixture (mole fraction), D is the diameter of the pipe (m), L is the flame length (m), M_n is the molecular weight of the fuel, M_s is the molecular weight of the surrounding fluid (normally air), T_f is the absolute adiabatic flame temperature (K), T_n is the absolute temperature of fuel in the pipe (K), and α_t is the ratio of the number of moles of unreacted and reacted gas in the stoichiometric mixture.

The shape of the flame envisaged in this treatment is an inverted cone with the apex at the orifice such that

$$\frac{L}{D} = 5.3\frac{W}{D} \qquad [16.3.4]$$

where W is the diameter at the top of the flame (m).

Another equation for the diameter of the flame is given by Baron (1954):

$$Z = 0.29x[\ln(L/x)]^{1/2} \qquad [16.3.5a]$$

and

$$Z_{max} = 0.12L \quad \text{at} \quad x = 0.61L \qquad [16.3.5b]$$

where x is the axial distance (m), Z is the flame diameter (m) and the subscript max denotes the maximum.

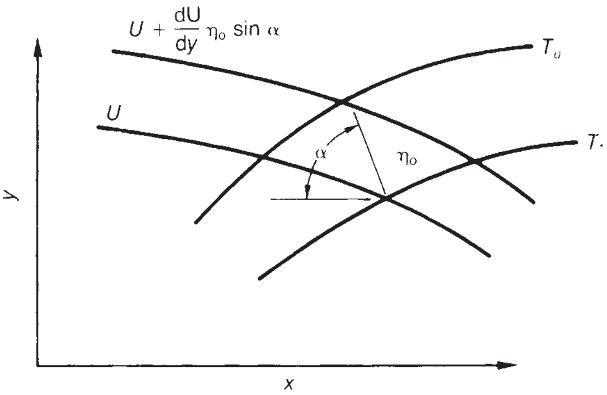

Figure 16.17 *Scheme of stretch of combustion wave in a flow field (after B. Lewis and von Elbe, 1961) (Courtesy of Academic Press)*

16.3.5 Flame stretch and wrinkling

Two properties of the laminar combustion wave which are of particular importance in combustion theory are flame stretch and flame wrinkling. If a combustion wave enters a flow field where there are significant changes of velocity over a distance comparable with the width η_o of the wave, significant stretching of the flame occurs. If a flow line of velocity U intersects the T_1 surface of the wave, as shown in Figure 16.17, the velocity of the flow line at a distance η_o along the line normal to this surface at the point of intersection is $U + (dU/dy)\,\eta_o \sin\alpha$. The ratio of the mass flows normal to this surface over the distance η_o is $1 + (dU/dy)(\eta_o/U)\sin\alpha$ and where the flow velocity is much greater than the burning velocity this reduces to $1 + (dU/dy)(\eta_o/U)$. The fractional increase, or stretch, is thus

$$\frac{dU}{dy}\frac{\eta_o}{U} = K \qquad [16.3.6]$$

where K is the Karlovitz number, which is thus a measure of the flame stretch.

The parameter η_o may be obtained from the heat balance in the combustion wave:

$$c_p \rho_u S_u (T_1 - T_u) = k\left(\frac{dT}{dx}\right)_1 \qquad [16.3.7]$$

The distance η_o is taken as

$$\eta_o = (T_1 - T_u)/(dT/dx)_1 \qquad [16.3.8]$$

Then from Equations 16.3.7 and 16.3.8

$$\eta_o = k/c_p \rho_u S_u \qquad [16.3.9]$$

where c_p is the specific heat, S_u is the fundamental burning velocity, ρ is the density, k is a constant and the subscript u denotes unburnt gas.

If the flame stretch is sufficiently great, the flame is quenched. The Karlovitz number K, as a measure of flame stretch, is therefore also a criterion of quenching.

The Karlovitz number K may also be defined in terms of the critical velocity gradient for blow-off. The definition is

$$K = g_B\eta_o/S_u \quad [16.3.10]$$

The flame stretch concept may also be applied to a spherical combustion wave in stagnant gas. If a sphere diameter d of burnt gas exists with an unburnt outer shell thickness η_o, the ratio of the surface areas after and before combustion of this shell is

$$= \frac{\pi(d + 2\eta_o\rho_u/\rho_b)^2}{\pi d^2} \quad [16.3.11]$$

$$\approx 1 + 4\eta_o\rho_u/d\rho_b \quad [16.3.12]$$

The fractional flame stretch is then

$$K = 4\eta_o\rho_u/d\rho_b \quad [16.3.13]$$

Critical values of K for spark ignition are given by B. Lewis and von Elbe (1961) and lie mainly in the range 0.5–1.5.

If in the combustion wave of a stoichiometrically unbalanced mixture the diffusivity of the deficient component substantially exceeds that of the excess component, the gas mixture entering the wave stratifies so that there are alternate increases and decreases in the burning velocity. The wave becomes wrinkled and exhibits a cellular structure.

16.3.6 Reaction kinetics and transport processes

Chemical reaction and transport processes govern at the most fundamental level the process of combustion. There are available reaction kinetic schemes for the reaction of many of the main compounds of interest. Certain reactions have proved of particular interest to investigators. For example, Semenov (1935) discusses the reactions of oxygen with hydrogen, carbon monoxide and hydrocarbons and of hydrogen with chlorine and bromine. B. Lewis and von Elbe (1961) also discuss the reactions of oxygen with hydrogen, carbon monoxide and hydrocarbons and those in the H_2–CO–O_2 system. The reactions in the hydrogen–bromine systems have been of particular interest, as discussed by Lovachev *et al.* (1973).

16.3.7 Thermal explosion theory

Many problems in combustion involve the self-heating of a reactive mass in a defined volume. The theory that deals with this, thermal explosion theory, or simply thermal theory, is therefore important in combustion and has numerous applications.

The concept of thermal explosion derives from Van't Hoff (1884), who identified the condition for thermal ignition as one in which no equilibrium between the reacting system and its surroundings can exist. This was developed qualitatively by Le Chatelier (1937), who characterized the problem as one in which the variation of heat production is a curve and that of heat loss is a straight line, as illustrated in Figure 16.18. A quantitative treatment of thermal explosion theory was described in *Chemical Kinetics and Chain Reactions* by Semenov (1935), and developed by Semenov, Frank-Kamenetsky and Zeldovich (e.g. Zeldovich and Frank-Kamentsky, 1938; Frank-Kamenetsky, 1939a,b; Semenov, 1940). Accounts of thermal explosion theory are given in *Diffusion and Heat Exchange in Chemical Kinetics* (Frank-Kamenetsky, 1955) and *Selfheating: Evaluating and*

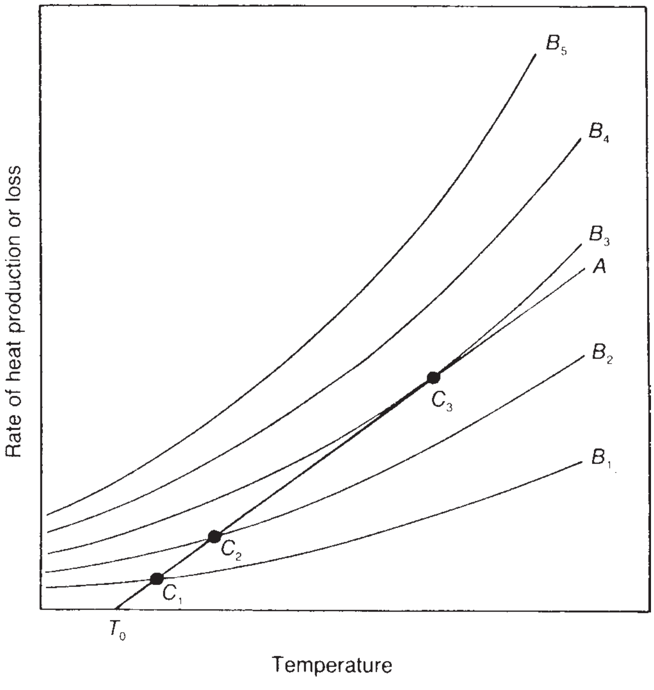

Figure 16.18 *Heat generation by and removal from a chemical reaction (after Semenov, 1935; Knox, 1967a)*

Controlling the Hazards (Bowes, 1984) and by P. Gray and Lee (1967b) and Merzhanov and Averson (1971).

The basic concepts of thermal explosion theory are as follows. For a mass subject to an exothermic reaction the unsteady-state heat balance is

$$c\rho\frac{\partial T}{\partial t} = k\nabla^2 T + Q \qquad [16.3.14a]$$

$$= k\left[\frac{d^2T}{dx^2} + \frac{d^2T}{dy^2} + \frac{d^2T}{dz^2}\right] + Q \qquad [16.3.14b]$$

with

$$Q = Q'\rho A\exp(-E/RT) \qquad [16.3.15]$$

where A is the pre-exponential factor, c is the specific heat of the reacting mass, E is the activation energy, k is the thermal conductivity, Q is the heat released per unit volume, Q' is the heat of reaction per unit mass, t is the time, T is the absolute temperature, x, y and z are the distances from the centre of the hot spot in the x, y and z directions, respectively, ρ is the density and ∇^2 the Laplacian operator with respect to the distance x.

The exponential term in Equation 16.3.15 may be approximated as follows:

$$\exp(-E/RT) \approx \exp\{-(E/RT_o)[1 - (T - T_o)/T_o]\} \qquad [16.3.16]$$

$$= \exp\{-(E/RT_o)\exp\{(E/RT_o^2)(T - T_o)\}\} \qquad [16.3.17]$$

where T_o is the initial temperature.

A dimensionless parameter θ is defined as

$$\theta = \frac{E}{RT_o^2}(T - T_o) \qquad [16.3.18]$$

Substituting from Equation 16.3.18 in Equation 16.3.17 gives

$$\exp(-E/RT) = \exp(-E/RT_o)\exp\theta \qquad [16.3.19]$$

Another dimensionless parameter δ is defined as

$$\delta = \frac{Q'\rho Ar^2}{k}\frac{E}{RT_o^2}\exp(-E/RT_o) \qquad [16.3.20]$$

where r is the semi-thickness or radius of the reacting volume.

Then, defining two further dimensionless parameters

$$\zeta = x/r \qquad [16.3.21]$$

$$\tau = \frac{kt}{c\rho r^2} \qquad [16.3.22]$$

Equation 16.3.14 becomes, in dimensionless form,

$$\frac{d\theta}{d\tau} = \nabla^2\theta + \delta\exp\theta \qquad [16.3.23]$$

where ∇^2 is now the Laplacian operator with respect to ζ.

From Equation 16.3.14 the following equation for the temperature may be obtained for particular geometries:

$$c\rho\frac{dT}{dt} = k\left[\frac{d^2T}{dx^2} + \frac{m}{x}\frac{dT}{dx}\right] + Q \qquad [16.3.24]$$

or, in dimensionless form,

$$\frac{d\theta}{d\tau} = \frac{d^2\theta}{d\zeta^2} + \frac{m}{\zeta}\frac{d\theta}{d\zeta} + \delta\exp\theta \qquad [16.3.25]$$

where $m = 0$, 1 or 2 for a slab, cylinder or sphere, respectively.

There are numerous assumptions that may be made concerning the geometry, the boundary conditions, the physical properties and the reaction kinetics of the thermal explosion problem and there are numerous applications of the theory. This has given rise to a large literature.

The application of the thermal explosion model to combustion problems is considered in this section, while its application to self-heating of solid materials is discussed in Section 16.6.

16.3.8 Flammability limits

It is convenient for design purposes to define flammability limits, but the question of whether such flammability limits are a fundamental physicochemical property has been the subject of some debate. Reviews of the fundamentals of flammability limits have been given by Egerton (1953), B. Lewis and von Elbe (1961), Lovachev *et al.* (1973), Lovachev (1979) and Macek (1979).

The determination of practical flammability limits is usually effected using the BM apparatus as described by Coward and Jones (1952 BM Bull. 503). In this apparatus it is found that the lower limit concentration is lower and the upper limit concentration is higher for upward than for downward propagation. Since for design purposes it is desirable to use the wider limits, Coward and Jones recommend the use of the flammability limits for upward propagation.

In his review, Egerton states three conditions that a satisfactory theory of flammability limits should meet. It should predict (a) the existence of a lower limit, (b) the value of the lower limit concentration and (c) the value of the burning velocity at the lower limit. He discusses the relation between the flammability limit and the flame temperature attained at the limit.

Egerton and Fowling (1948) have drawn attention to the relationship that exists, given complete combustion, between the lower and upper limits if a limit mixture requires a certain concentration of fuel to provide the temperature necessary for flame propagation. Provided allowance is made for the different specific heats of the two mixtures; the upper limit might then be estimated from the lower one. This approach is applicable only if combustion is complete. This is not the case for hydrocarbon–air mixtures.

For the UFL Egerton and Fowling found the principal determining factor to be the heat of combustion per mole of mixture. Egerton states that the direction of propagation is important because of the effect of convection. The upward propagating flame is assisted by convection.

It is desirable to have some more fundamental method of measuring flammability limits than the standard tube method. Such a method is the flat flame method described by Egerton and Thabet (1952). This method appears better suited to the provision of fundamental data than the standard method, although it is not suggested that it should replace the latter for practical determinations. Egerton (1953) presents data on the different limit flame temperatures obtained by the standard tube and flat flame methods, as shown in Table 16.16. The temperature given by the latter is lower and more constant.

Spalding (1957d) has presented a theory of flammability limits. He argues that a theory, which is capable of predicting the existence of a limit of flammability, needs to take account of heat loss. The novel feature of his theory is that it allows for heat loss by radiation. The theory for the laminar one-dimensional flame is thus brought into line with the theoretical treatments of other types of flame, each of which exhibits a zone of stable operation limited on one side by chemical kinetics and on the other by heat loss to the surroundings. The theory is not dependent on any particular assumptions about the dependence of the reaction rate on concentration and temperature, other than that the dependence of the rate should be steeper than that for the heat transfer. Spalding found that at the flammability limit there is a small but finite burning velocity. In addition, he showed that there exist two burning velocities, of which only the upper one is stable in normal circumstances.

Table 16.16 *Flammability limits: lean limit flame temperatures from standard tube and flat flame methods (after Egerton, 1953) (Courtesy of the Combustion Institute)*

Gas	*Lower limit* (%)	*Flame temperature* (°C)	
		Tube method	*Flat flame method*
Methane	5.26	1254	1222
Propane	3.10	1383	1200
n-Butane	1.93	1445	1233
n-Pentane	1.62	1485	1158
n-Heptane	1.26	1569	1228

Other workers who have given theories of flammability limits based on heat radiation include Zeldovich (1941) and Rozlovsky (1970). Later workers have tended to argue that the heat radiation theory is difficult to reconcile with experimental phenomena. The work of Egerton and Fowling (1948), showing that heat radiation loss is small, is often quoted.

The contrasting views on flammability limits are described by Dixon-Lewis and Isles (1959). Although the limits are often treated as fundamental properties, they state that the limits obtained experimentally are essentially convection or quenching limits, depending on the conditions.

In their review of flammability limits, B. Lewis and von Elbe (1961) emphasize that, despite the theoretical problems, the experimentally determined limits have proved to be reliable for practical purposes. They state that there is no solution to the theoretical problem of flammability limits in terms of adiabatic one-dimensional propagation. Spalding's model represents the only feasible approach in terms of one-dimensional propagation, but the attribution of heat loss to radiation is not regarded as satisfactory by experimentalists, who prefer to believe that heat absorption by the unburned gas is the important effect.

Lewis and von Elbe illustrate the effect of the direction of propagation by the data shown in Table 16.17. They refer to the work of Linnett and Simpson (1957), who draw attention to the role of convection. Evidently, convection currents are generated which are capable of quenching the flame. Such convectional quenching implies that heat is transferred to the unburned gas.

Lewis and von Elbe suggest that the mechanism of such quenching may be flame stretching. Stretching leads to extinction if the stretch exceeds a critical value of the Karlovitz number. The latter is inversely proportional to the burning velocity. Thus flames with low burning velocity, such as occur at the flammability limit, are particularly susceptible to stretch and hence extinction. These effects accord with the existence of narrow limits for downward propagation of the flame, since flame stretch is greater for downward propagation.

Table 16.17 *Flammability limits: the effect of the direction of flame propagation (B. Lewis and von Elbe, 1987; after A.G. White, 1922, 1924) (Courtesy of Academic Press)*

Mixture	*Direction of propagation*	*Fuel concentration* (%)		*Stoichiometric fraction ratio*	
		Lower	*Upper*	*Lower*	*Upper*
Methane–air	Upwards	5.35	14.85	0.54	1.7
	Horizontal	5.40	13.95	0.54	1.6
	Downwards	5.95	13.35	0.60	1.5
Ethane–air	Upwards	3.12	14.95	0.54	2.9
	Horizontal	3.15	12.85	0.54	2.5
	Downwards	3.26	10.15	0.56	1.9
Pentane–air	Upwards	1.42	8.0	0.55	3.3
	Horizontal	1.44	7.45	0.56	3.1
	Downwards	1.48	4.64	0.57	1.9
Benzene–air	Upwards	1.45	7.45	0.53	2.9
	Horizontal	1.46	6.65	0.53	2.6
	Downwards	1.48	5.55	0.54	2.1

They also discuss the susceptibility of the flammability limits to diffusional stratification. Experiments by Coward and Brinsley (1914) in hydrogen–air mixtures with 4.1–10% hydrogen show that some hydrogen remains unburned. This effect has been explained by Goldmann and co-workers (Goldmann, 1929) as being due to diffusional stratification. Such stratification leads to local differences in concentrations and to locally increased burning velocities.

Lewis and von Elbe also mention that, according to the work of Markstein, upward flame propagation tends to promote cell formation. Cell formation, and Markstein's theory, is discussed below.

A further discussion of preferential diffusion is given by Furno *et al.* (1971). Coward and Jones (1952 BM Bull. 503) describe work on hydrogen–air mixtures in which burning is propagated upward by the buoyancy of individual flamelets and explain this by preferential diffusion. When the deficient reactant, in this case hydrogen, is the faster diffusing one, a flame zone concave to the burned gas will be enriched in this reactant. In downward propagation flame surfaces of small curvature are opposed by buoyancy, and the lean limit concentration is thus higher.

Furno *et al.* refer to the quantitative treatment of preferential diffusion given by Spalding (1955). He observed that the concentrations most easily ignited by electrostatic spark ignition were 0.9 and 1.8 stoichiometric ratios for methanol–air and heptane–air mixtures, respectively, and that the ratio of these two figures is close to the ratio $(D_o/D_f)^{1/2}$ where D_f and D_o are the diffusivities of the fuel and oxygen, respectively. Spalding suggests that the actual fuel–oxygen ratio in the developing flame kernel is stoichiometric. Furno *et al.* extend this argument and suggest that the ratio of the limits for upward and downward propagation may be given by this group also. They state that the data available to verify this hypothesis are sparse, but quote the results shown in Table 16.18.

Table 16.18 *Stoichiometric ratios*[a] *of most easily ignited mixtures and of limit mixtures in upward and downwards propagation (after Furno et al., 1971) (Courtesy of the Combustion Institute)*

Mixture	$(D_o/D_f)^{1/2}$[b]	*Optimum ratio for ignition*	*Ratio of upwards to downwards propagation limit*
			Upper limit
Methane–air	0.96	0.9	1.02
Ethane–air	1.29	1.2	1.24
Propane–air	1.44	1.3	1.43
Butane–air	1.55	1.5	1.41
Pentane–air	1.63	–	1.72
Hexane–air	1.70	1.7	–
Heptane–air	1.78	1.8	–
Benzene–air	1.52	–	1.46
			Lower limit
Hydrogen–air	0.54	–	0.46
Methane–air	0.96	0.9	0.92

[a] Fuel concentration/stoichiometric fuel concentration.

[b] D_f, diffusivity of fuel; D_o, diffusivity of oxygen.

Furno *et al.* also discuss the limit temperatures. It would be helpful if the rich limit temperature could be taken to be the same as the lean limit temperature. This would be equivalent to saying that in heavy hydrocarbon–air mixtures downward propagation reaches its limit at a stoichiometric ratio of about 1.9.

Several reviews of flammability limits have been given by Lovachev and co-workers (Lovachev, 1971, 1979; Lovachev *et al.*, 1973). Like earlier reviewers, Lovachev (1971) states that a theory based on radiant heat loss does not account for the experimental phenomena and prefers to explain flame extinction as due to heat loss into the unburned gas due to convection flows.

Lovachev *et al.* (1973) emphasize the role of convection. They state that agreement exists that convection is the reason for the difference between upward and downward propagation, but not on the mechanisms involved. They refer to three proposed mechanisms: Drozdov and Zeldovich (1943) have suggested unequal flame speeds and heat transfer; Linnett and Simpson (1957) have suggested differences in the flame surface; and B. Lewis and von Elbe (1961) have suggested flame stretching.

They quote a relation, derived by Lovachev (1971), for the flame velocity at the flammability limit. They discuss the question of whether the upward or downward propagation limit is more appropriately regarded as the true flammability limit. They acknowledge the practical reasons why Coward and Jones adopted the upward propagation limit, but opt for the downward propagation limit as the more fundamental.

They state that for hydrocarbon–air mixtures the lean limit flame temperature is approximately constant. Different experimental methods give different values, those obtained by the flat flame method being the lowest quoted. They draw attention to the results of Gibbs and Calcote (1959), who found that for such mixtures the flame speeds are similar. This suggests that the heat release and the flame temperature should also be similar.

Lovachev (1979) outlines the various factors that influence the measured flammability limits, which he terms the ignition scheme. He states that the flammability limits determined in a large chamber of volume 8 m^3 are wider than those given by the standard tube method. Thus there are some compounds which are classed as flammable by the former method, but which would be classed as non-flammable by tests conducted in the latter one. He describes experiments showing the buoyant deformation of the flame kernel in large confinements. The illustrations given show a transition from a sphere to a vertically oblated sphere with an inflection at its based, somewhat kidney-shaped.

Lovachev also describes the effect of turbulence on flammability limits and quotes several pieces of work that illustrate this. These include work by K.N. Palmer and Tonkin (1961) on propane–air mixtures in horizontal tubes. At flow velocities of 0.5 m/s the limits widened, but with a four-fold increase they narrowed again. He states that the experimental studies carried out on turbulence effects have been done with tubes that are too narrow and ignition sources that are too weak. He points out that flammability limits given in handbooks are for non-turbulent conditions, but that in practice turbulence effects are not negligible.

Macek (1979) discusses the concept that extinction occurs when the burning velocity is so low that it is overcome by the dissipation processes and refers to the accounts of these processes by Burgess (1969) and Burgess and Hertzberg (1975).

The effect of pressure on flammability limits is discussed by Egerton (1953), B. Lewis and von Elbe (1961) and Lovachev *et al.* (1973).

The temperature effect on flammability limits is discussed by Egerton (1953) and Lovachev *et al.* (1973).

Other aspects of flammability limits include the effect of additives and of inhibitors. Additives are discussed by B. Lewis and von Elbe (1961), and inhibitors are considered by Lovachev *et al.* (1973) and Lovachev (1979).

Further aspects of flammability limits are considered in Sections 16.3.10 on burning velocity and 16.3.11 on quenching.

16.3.9 Ignition phenomena

Ignition of a flammable mixture be effected either by raising the temperature of the bulk gas until it ignites spontaneously or by local ignition of a part of the gas. The modes of ignition considered here are principally:

(1) auto-ignition;
(2) local ignition;
  (a) spark ignition,
  (b) hot surface ignition,
  (c) friction and impact ignition,
  (d) hot gas jet ignition,
  (e) hot particle ignition,
  (f) flame torch and jet ignition,
  (g) compression ignition.

Auto-ignition

Auto-ignition, or spontaneous ignition, is of practical interest not only in relation to hazards, but also in combustion systems such as gas engines and turbines. Auto-ignition, though simple in concept, needs careful definition. A definition of such ignition has been given by Sage and Weinberg (1959), who state that if the temperature of an infinite volume of reactants at constant pressure is raised instantaneously and homogeneously above some critical value and maintained there, an explosion will occur homogeneously throughout the volume, thus forestalling flame propagation. As these authors point out, available AIT data are based on experiments far removed from the conditions of this definition. Under the conditions described ignition can occur even if the concentration of the gas mixture is outside the normal flammability limits. These limits constrain flame propagation, but in this case the ignition occurs homogeneously throughout the mixture and propagation is not involved.

Measurement of the AIT is usually carried out by heating the flammable gas mixture in a spherical vessel. With this method there is found to be an effect of the surface/volume ratio, the AIT decreasing as the vessel volume increases. This effect was observed by Setchkin (1954) and has been found by other workers.

A method of measurement that matches more closely their definition of the AIT has been described by Sage and Weinberg (1959). The method is a two-stage one. A series of experiments is conducted in which, in the first stage, the flammable gas mixture is brought to a temperature somewhat below the ignition temperature and, in the second stage, a small quantity of energy is added which ignites the gas. The AIT is found by extrapolation of these results to determine that temperature for which no additional energy is required.

The application of thermal theory to spontaneous ignition has been discussed by several workers, including P. Gray and Harper (1959a,b), Kuchta, Barkowiak and Zabetakis (1965) and Cullis and Foster (1973). For a spherical vessel with ignition at the the relation between the vessel radius r and the absolute ignition temperature T is, to a first approximation,

$$\ln r \propto 1/T \qquad [16.3.26]$$

It has been shown for a large number of fuels that if the AIT is plotted against vessel volume the lines pass through a single point, as shown in Figure 16.19 (Coffee (1982b), based on work by Beerbouwer (1974)).

A comparison of the values of the ignition temperature obtained in work using heated vessels (auto-ignition), hot wires and hot gas jets has been made by Kuchta, Cato and Zabetakis (1964). Their results are shown in Table 16.19. The values of the ignition temperature obtained with the Pyrex Erlenmeyer flask are appreciably lower than the other values.

The variation of ignition temperature with heat source dimensions has been discussed by Kuchta, Bartkowiak and Zabetakis (1965). They state that thermal theory predicts that the ignition temperature varies inversely with the logarithm of the heat source size, as in relation 16.3.26. While this behaviour was observed for one material studied (engine oil) over the whole range of surface areas, the other hydrocarbons tested exhibited in large vessels an ignition temperature appreciably lower than that predicted by this equation.

The variability of values of the AIT given in the literature has already been mentioned. This is illustrated by the values for methane quoted by C. Robinson and Smith (1984), which range from 537°C to 748°C. They state that the convention is to quote the lowest value found in the literature, but in the case of methane they could not determine the origin of the widely quoted value of 537°C and give the value of 601°C determined by themselves as the lowest of those for which experimental details are available. The AIT of mixtures has been studied by Cullis and Foster (1974). They found that for the binary mixture studied (*n*-decane and 2,2,5-trimethylhexane) the ignition tendency is controlled largely by the more ignitable component. It was necessary to go to nearly 50% of the less ignitable component before the ignition temperature started to rise appreciably.

Ignition delay time

In spontaneous ignition there is an induction period, or ignition delay, before ignition occurs. This delay is of interest both theoretically in relation to reaction kinetics and practically in relation to ignition in combustion systems. The ignition delay may be as little as a fraction of a second at higher temperatures, or several minutes close to the AIT.

Ignition delay decreases with increasing temperature. Semenov (1959) has given the following relation:

$$\ln \tau = \frac{k_1 E}{T} + k_2 \qquad [16.3.27]$$

where E is the apparent activation energy, τ is the time delay and k_1 and k_2 are constants.

Ignition delay has been studied by many other workers, including Brokaw and Jackson (1955), Ashmore and Levitt

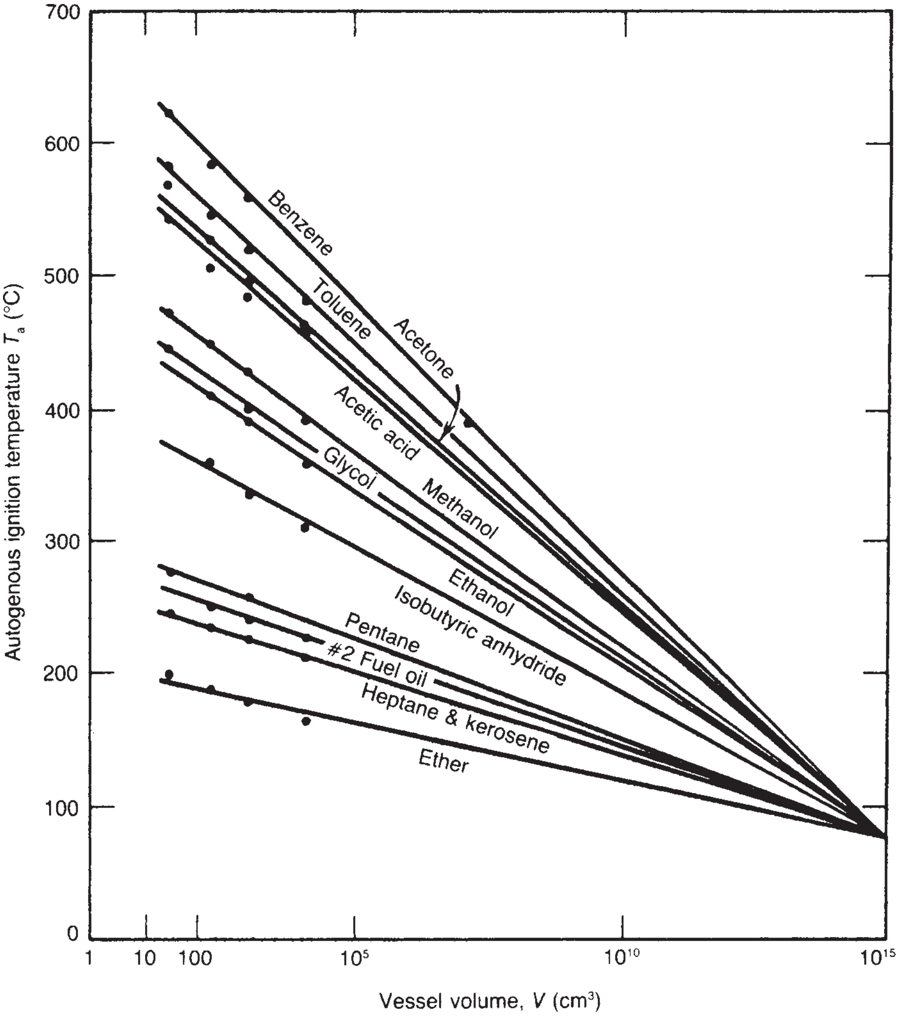

Figure 16.19 *Effect of vessel volume on the auto-ignition temperature (Reproduced with permission from Safety and Accident Prevention in Chemical Operations. 2nd ed., by H.H. Fawcett and W.S. Wood, ©, 1982, John Wiley and Sons Inc.)*

(1959), P. Gray and Harper (1959a,b), Voevodsky (1959) and Bascombe (1967). For propane–air mixtures with flowing gas, Brokaw and Jackson found the following variations of ignition delay with oxygen concentration and pressure p:

$$\frac{1}{\tau} \propto [O_2]^{1/4} \qquad [16.3.28]$$

$$\propto \ln p \qquad [16.3.29]$$

but did not find a constant activation energy relation with temperature.

Spark ignition

Turning to local ignition, it is convenient first to consider spark ignition. Here the ignition energy is determined by using the spark between two electrodes to ignite the flammable gas mixture. Apart from its implications for hazards, spark ignition has long been of practical interest for combustion in car engines and jet engines. A more recent aspect is lean burn engines for cars.

The results obtained for spark ignition energy are critically dependent on the electrode and spark arrangements. In early work this was not fully appreciated. In particular, the electrodes were usually too close together so that quenching occurred and the results obtained were too high.

It was suggested in early work, such as that of B.W. Bradford and Finch (1937), that there was a specifically electrical effect involving excitation of reactant molecules, but this suggestion was rejected by von Elbe (1953) in favour of a thermal effect.

A model of spark ignition has been developed by von Elbe and Lewis (1949) and von Elbe (1953) and is described

Table 16.19 *Ignition temperatures of flammable gas mixtures with different heated surface areas (Kuchta, Cato and Zabetakis, 1964) (Courtesy of Combustion and Flame)*

Substance	*Ignition temperature* (°C)			
	Pyrex Erlenmeyer flask[a] (2.2 cm radius, 13 cm long)	*Cylindrical Pyrex vessel* (0.5 cm radius, 15 cm long)	*Inconel wire* (0.5 cm radius, 5 cm long)	*Air jet*[b] (0.5 cm radius, >10 cm long)
Methane	537	745	–	1040[c]
Ethane	515	580	–	840[c]
n-Butane	405	630	–	910[c]
n-Hexane	234	605	670	765
n-Octane	220	585	660	755
n-Decane	208	585	650	750
Benzene	562	685	–	1020[d]
Hydrogen	554	635	–	640[c]

[a] Minimum AIT values obtained in a 200 cm^3 Erlenmeyer flask equivalent cylinder radius 2.2 cm.
[b] Hot air jet injected into fuel–air mixture, except as noted by footnotes (c) and (d).
[c] Hot air jet injected into fuel only.
[d] Hot nitrogen jet injected into fuel–air mixture.

by B. Lewis and von Elbe (1961). In simple terms, the argument is that the volume heated needs to exceed a certain critical size, otherwise the temperature gradient is too great and heat is lost too fast for combustion to be sustained. There is a MIE needed to overcome quenching by the unburnt gas.

More formally, the theory envisages a preheat zone and a reaction zone. A heat balance is taken between a plane x in the combustion wave and the plane b where combustion is complete and, assuming that the heat transferred by mass diffusion is less than that transferred by heat conduction, the enthalpy per unit mass within the wave is larger than that at the boundary b of the burnt gas or that at the boundary u of the unburnt gas, the two latter being equal. Thus there is a wave of thermal energy, or excess enthalpy, travelling with the combustion wave. It is this excess enthalpy which ensures that the temperature gradient is such that heat flow into the preheat zone balances the heat liberated in the reaction zone. When a flame grows spherically, the combustion wave requires from some external source a continuous supply of excess enthalpy in proportion to the growth of its surface, until the wave has effectively become a planar one. On this theory, the MIE is equal to the excess enthalpy requirement of the minimum flame.

Von Elbe defines the MIE H in terms of the excess enthalpy per unit area h and the critical diameter d at which the flame can propagate unaided:

$$H = \pi d^2 h \qquad [16.3.30]$$

There are a number of models of spark ignition, including those of Fenn (1951), Khitrin and Goldenburg (1957), Mayer (1957), Swett (1957), Penner and Muffins (1959), Rose and Priede (1959a,b), Ballal and Lefebvre (1975a), Adelman (1981), Maly (1981) and Sher and Refael (1982). Adelman gives a review of spark ignition models.

Fenn (1951) derives the critical diameter of the spark kernel by equating the heat released in the volume of the kernel to that transferred across its surface. The MIE H is then

$$H = \frac{K\pi d^3 c_p \rho}{6}(T_f - T_o) \qquad [16.3.31]$$

where T_f is the absolute adiabatic flame temperature and K is a constant. He states that the value of K is probably less than unity.

The model of Khitrin and Goldenberg (1957) is based on the thermal theory. Swett (1957) used long duration discharges and his treatment assumes that only part of this energy contributes to the ignition.

Ballal and Lefebvre (1975a) consider a spark kernel of the shape shown in Figure 16.20. It is assumed in this model that the heat release occurs only within the flame front, rather than throughout the whole kernel volume. The criterion for ignition is that the width d_c of the kernel is just equal to twice the width δ_L (laminar) or δ_T (turbulent regime) of the flame zone:

$$d_c = 2\delta_L \quad \text{Laminar regime} \qquad [16.3.32a]$$

$$= 2\delta_T \quad \text{Turbulent regime} \qquad [16.3.32b]$$

The authors give correlations for d_c for stagnant gas conditions and for laminar and turbulent flow regimes. For the stagnant gas condition

$$d_c = \frac{2k}{c_p \rho S_L} \qquad [16.3.33]$$

where S_L is the laminar burning velocity.

The model given by Adelman (1981) takes account not only of the heat balance on the spark kernel but also of the rate of growth of the kernel. Adelman states that spark kernels with the same spark energy input show identical growth in inert and combustible mixtures up to the critical point and that it is the spark discharge itself rather than combustion, which is responsible for kernel growth up to this point.

In his review Adelman relates the critical diameter of the spark kernel to the flame thickness δ_L and gives

$$\delta_L \approx \frac{k}{c\rho S_L} \qquad [16.3.34a]$$

$$= \frac{\alpha}{S_L} \qquad [16.3.34b]$$

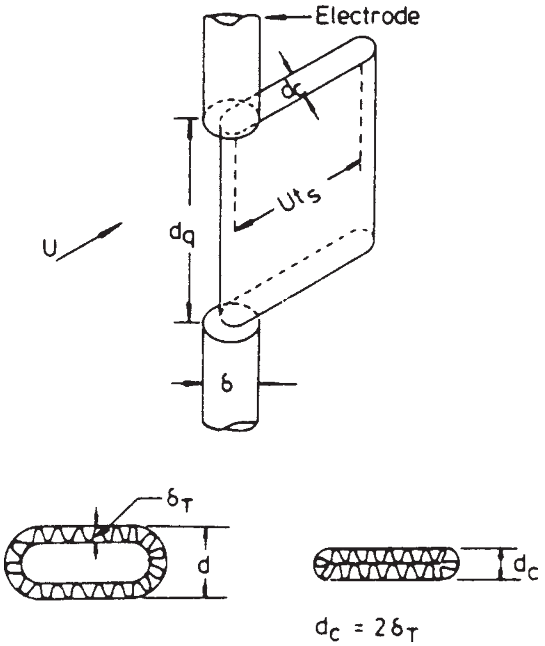

Figure 16.20 *Idealized model for the formation of a spark kernel (Ballal and Lefebvre, 1975a). d_q quenching distance; t_s spark duration; U, flow velocity (Courtesy of the Combustion Institute)*

where $\alpha(=k/c_p\rho)$ is the thermal diffusivity. He defines a characteristic flame dimension l_L as the value of the group α/S_L at ambient conditions and states that the flame thickness is about $10\,l_L$. Critical radii tend to be of the order $5\,l_L$–$8\,l_L$ and thus about 0.5–0.8 of the flame thickness.

Maly (1981) distinguishes three modes of spark discharge – breakdown, arc and glow – and gives an ignition model. He emphasizes the importance of the breakdown mode. He states that ignition depends not so much on the total energy supplied but rather on high energy density deposition over a short time.

Minimum ignition energy

Work on measurement of ignition energy for spark ignition includes that of Blanc *et al.* (1947, 1949) and Moorhouse, Williams and Maddison (1974). The former determined ignition energies of hydrocarbon–oxygen–nitrogen mixtures over a range of concentrations, while the latter determined MIEs energies.

The problems in making such measurements have been discussed by a number of investigators. Rose and Priede (1959a) state that MIEs obtained by Lewis and von Elbe are some 1/100 of those obtained in early work in which the electrodes were too close together so that quenching could occur. Moorhouse, Williams and Maddison (1974) state that to obtain reproducible results they found it necessary to recondition the electrodes after about 15 trials.

Moorhouse, Williams and Maddison discuss the effect on the MIE of molecular structure.

The effect of turbulence on the MIE has been investigated by de Soete (1971). He states that turbulence causes an increase in the MIE, due mainly to an increase in flame front thickness, but also to a decrease in the fraction of energy that is effective.

Another study of the effect of turbulence is that of Ballal and Lefebvre (1975a). They state that the overriding effect of turbulence is heat loss by diffusion. They found that the MIE increases with increase in velocity and in turbulence intensity.

The effect of pressure and temperature on the MIE E is correlated by Moorhouse, Williams and Maddison (1974) as follows:

$$E = AP^{\alpha}T^{\beta} \qquad [16.3.35]$$

where P is the absolute pressure, T is the absolute temperature, A is a constant and α and β are indices. The values of the indices α and β were approximately 2 and -2, respectively.

Measurements of hot wire ignition energies have been made by number of workers, including Stout and Jones (1949). Different combinations of excitation current and time were used and the ignition energy was found to increase as the current was decreased and the time increased. A linear relation between the MIE and excitation time t was found:

$$E = A + Bt \qquad [16.3.36]$$

Hot surface ignition

Another mode of local ignition is contact with a hot surface. The AIT sets a lower limit to the temperature at which a hot surface may cause ignition, but it has long been known that in most situations of practical interest the hot surface temperature required to cause ignition is considerably higher than the AIT.

Interest has therefore centered on the difference between the hot surface ignition temperature and the AIT, or temperature excess. Research has shown that this temperature excess is a function of the material, area and geometry of the hot surface, of the gas and gas concentration, and the fluid flow and heat transfer conditions.

Some gases that have been widely used in work on hot surface ignition include methane, propane, butane and pentane. The AITs of these gases are 595, 470, 360 and 285°C, respectively.

Guest (1930 BM Tech. Pap. 475) investigated the ignition temperature of methane–air mixtures using various hot surface materials and areas up to 108 mm, and obtained values of 897–1420°C.

The effect of the area of the hot surface has been studied by Rae, Singh and Danson (1964), who exposed a methane–air mixture to hot surfaces of different size. Some typical results are shown in Figure 16.21. The work on hot particles by Silver (1937) and Paterson (1939–), described below, shows a similar decrease of the temperature excess as the hot surface area increases.

The effect of gas velocity has been studied by Mullen, Fenn and Irby (1949), who were concerned with the ignition of gas flowing past heated rods at high velocity as in a jet engine. Working with pentane–air mixtures, they found that the temperature excess increased with gas velocity.

Gas velocity has also been investigated by Goodall and Ingle (1967), who studied the ignition of kerosene in a wind

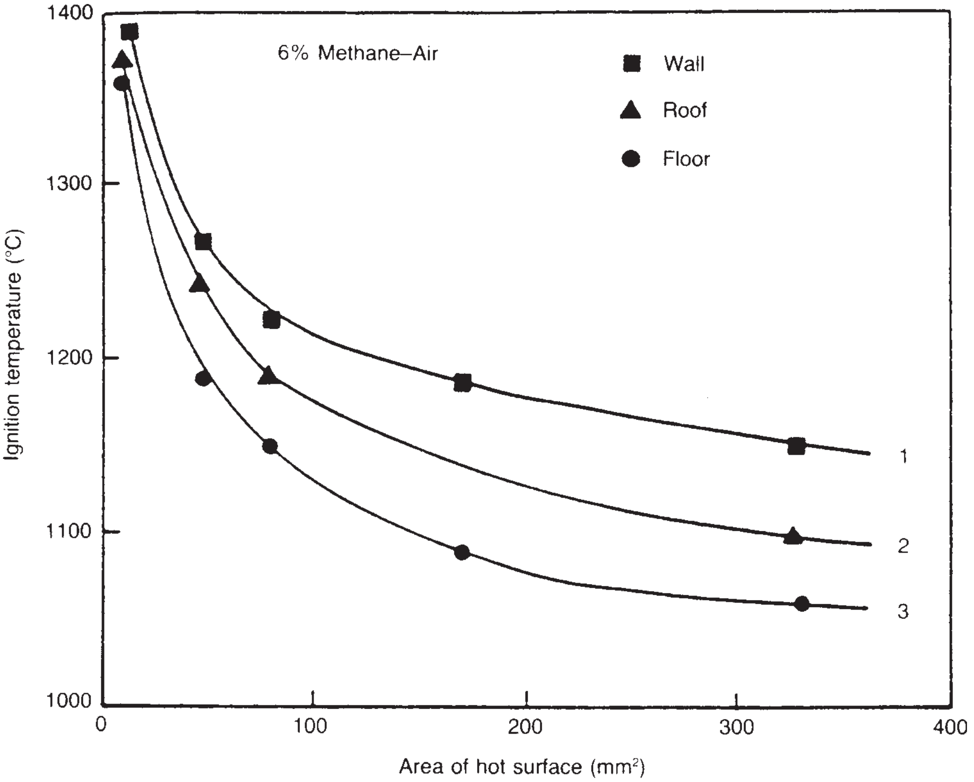

***Figure 16.21** Hot surface ignition temperature: effect of hot surface area on ignition temperature (Laurendeau, 1982; after Rae, Singh and Danson, 1964) (Courtesy of Combustion and Flame)*

tunnel. The hot surface temperature required to cause ignition in the experiments was as follows:

Gas velocity (m/s)	*Surface temperature for ignition* (°C)
0.3	405
1.5	660
3.0	775

The AIT of kerosene is given as 208–257°C, depending on the method of measurement

A number of workers have studied ignition of a flammable gas–air mixture on a vertical plate. A criterion widely used in this work has been the van't Hoff criterion that ignition occurs when the temperature gradient normal to the hot surface at some point becomes zero. Investigations have been done under forced convection by Toong (1957) and under natural convection by Ono *et al.* (1976).

L.D. Chen and Faeth (1981a) found that the zero temperature gradient condition is not always the appropriate one, that the lume above the hot surface influences ignition and needs to be taken into account, and that near limiting conditions there needs to be a substantial distance above the surface for the deflagration wave to develop so that quenching surfaces may suppress the deflagration.

Sharma and Sirignano (1969, 1970) have studied other geometries. Bull and co-workers have conducted an extensive investigation of the parameters influencing hot surface ignition.

Hot surface ignition is essentially a two-stage process, with initiation of a cool flame in the first stage followed by 'hof ignition'. A distinction is made between ignition and propagation. Propagation is confined between the flammability limits, but auto-ignition is not so bounded. In constant volume tests substantial, rapid pressure rises have been obtained with very rich mixtures.

Bull has conducted experiments using a parallel plate reactor (D.C. Bull and Quinn, 1975; D.C. Bull, 1977). In this apparatus the hot surface is placed above a cold surface so as to limit heat transfer to the conduction mode. Studies were conducted on propane, butane and hexane, and ignition diagrams for these gases obtained. The absolute results depended on the design of the apparatus, but certain trends emerged. A typical ignition diagram is shown in Figure 16.22. The figure shows the effect of the surface temperature. Another result of this work is to demonstrate that if there is even a modest temperature gradient normal

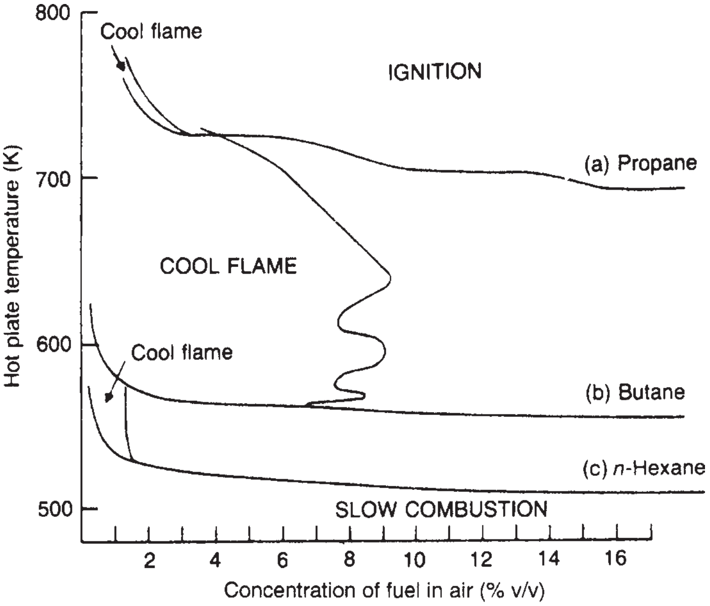

Figure 16.22 *Hot surface ignition temperature: ignition temperature boundaries for selected fuel-air mixtures in a parallel plate reactor (D.C. Bull, 1977). Plate separation 50 mm 'hot' and 'cold' plates at the same temperature – see text (Courtesy of DECHEMA)*

to the hot surface, a much higher temperature excess is required for ignition.

D.C. Bull, Cairnie *et al.* (1980) have also described research directed at understanding of the influence of fluid flow on hot surface ignition. Experiments were done on ignition by a hot vertical plate under laminar flow conditions. These conditions are favourable for experimentation and modelling and also approximate to the practical cases of a hot vertical surface or a hot large diameter pipe. The work showed that as the gas flows over the vertical surface it undergoes self-heating. Figure 16.23 gives the results obtained for a non-reacting gas and for a reacting gas.

The authors found that their initial model with reaction kinetics based on the Arrhenius equation was deficient. It predicted thermal runaway when the van't Hoff criterion of zero temperature gradient is satisfied, but this did not fit the experimental results. A second, more complex model, based on the acetaldehyde kinetics model, described below, was more successful. Figure 16.24 shows some predictions given by this latter model. Bull and Grant (D.C. Bull and Grant, 1975; D.C. Bull, 1977) have investigated ignition by a hot horizontal pipe, using two concentric pipes. They found that there was a region of high temperature gradient at the hot inner pipe, then a region of nearly constant temperature, then a cool region at the cold outer pipe. Ignition occurred in the region of nearly constant temperature. They derived a model, correlating their results in terms of the ratio of the pipe diameters, the Rayleigh number and the temperature across the annular gap.

Work was also done to investigate ignition by a hot exhaust pipe in the open air. The model showed that for ignition to occur there would need to be a very high temperature excess with high convective flows and ignition in the wake of the pipe. Under these conditions the residence time in the hot region may be less than the induction time.

Work on the development of a model for hot surface ignition has been described by Harrison and Cairnie and co-workers (A.J. Harrison and Cairnie, 1988; A.J. Harrison *et al.*, 1988). These authors have developed a chemical reaction model for the hot surface ignition of acetaldehyde–air mixtures. The full model is a 20-reaction model, but has been simplified successively to 8-, 5- and 2-species models. Some success has been achieved in describing the initiation of cool flame behaviour for hot vertical plate and continuous stirred tank reactor configurations. Below about 500°C, the ignition process depends critically on a build up of intermediate compounds. This indicates that the one-step ignition model often used is inappropriate.

Bartknecht (1988) has described work on ignition by steel pins heated by rubbing against a steel wheel. The pins were 6 and 8 mm in diameter with heated surfaces of area 2.9 and 4.0 cm^2, respectively. The lowest temperatures that he reports for ignition are 1248°C for methane and propane, and 1169°C for butane.

Work on ignition by heated rods has been described by Adomeit (1965), who investigated, in particular, ignition delay.

Friction and impact ignition

If one body strikes another, ignition may occur by impact or friction. In either case the ignition occurs as a result of a rise in surface temperature. If one body strikes another normal to its surface, there is impact but little friction. Impact causes a surface temperature rise in two ways (Bowden and Tabor, 1954). Kinetic energy is converted to heat. This causes a surface temperature rise, which may

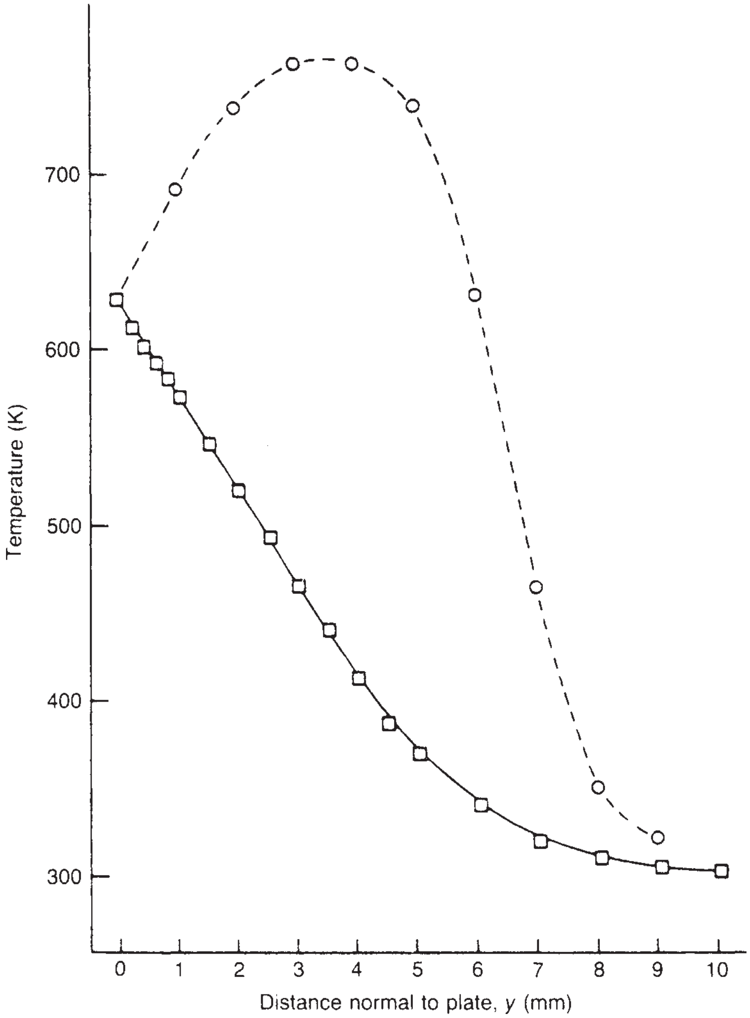

Figure 16.23 *Hot surface ignition temperature: boundary layer temperature profiles (D.C. Bull et al., 1980). (□) experimental values for air (non-reacting flow); (○) experimental values for 7.1% diethyl ether–mixture (reacting flow); and (--) theoretical values for air. Plate temperature 623 K; distance up plate 0.1 m. (Reproduced with permission)*

lead to exothermic oxidation of the surface resulting in a further temperature rise. The second of these effects tends to predominate.

The surface temperature rise depends on the oxidation characteristics and the thermal conductivity and does not simply correlate with the energy of impact. The heat generated by oxidation is highest for easily oxidizable metals such as iron and aluminium. The heat of oxidation of iron is several times that of copper and its thermal conductivity is less; the surface temperature rise of iron exceeds that of copper.

If one body is pressed against the surface of another and made to move, there is friction and this causes a surface temperature rise. If the first body strikes the second at an angle, there is a combination of impact and friction, which is described as frictional impact.

It has long been known that striking rusty steel covered with aluminium paint may produce incendive sparks. The effect is due to a chemical reaction, known as the thermite reaction. In this reaction the temperature can reach 3000°C. Following a study in 1941 by the Safety in Mines Research Board, which showed that no sparks were obtained unless the steel surface was rusty and that the effect varied with the type of paint, work was done by Kingman, Coleman and Rogowski (1952) to define more closely the conditions under which this effect occurs. Using both ferrous and nonferrous strikers, they confirmed that sparks occurred only if rust was present. They found that no oil bound paint gave sparks unless the specimen had been preheated to at least 150°C. Cellulose nitrate paints, however, gave sparks after preheating to 100°C. In an appended note, HM Senior Chemical Inspector of Factories stated that the earlier report had given rise to exaggerated fears and that aluminium

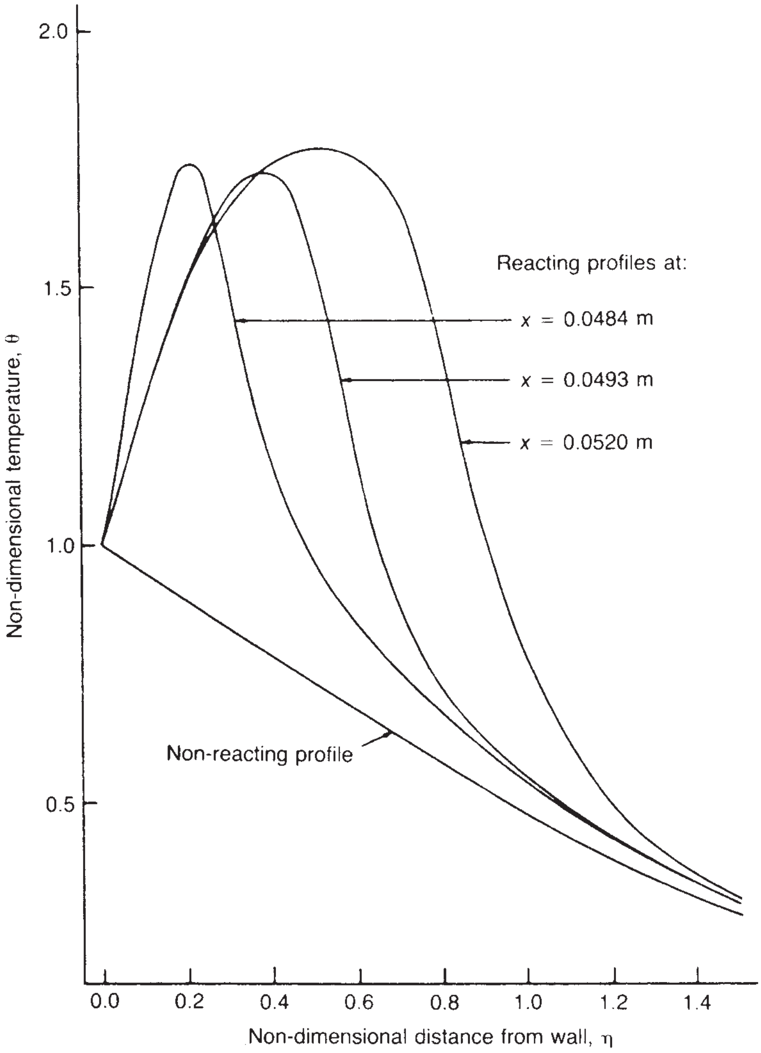

Figure 16.24 *Hot surface ignition temperature: theoretical boundary layer temperature profiles in a parallel plate reactor.* $\theta = (T - T_\infty)/\Delta T$; $\eta = [(g\Delta T^2\rho_\infty)/(4T_\infty\mu_\infty^2)]^{1/4} \frac{1}{x} \int^y \frac{\rho}{\rho_\infty}\, dy$ *(D.C. Bull et al., 1980). Reproduced with permission*

paint could be used in hazardous areas provided cellulose nitrate based paints were avoided and that no aluminium paint, whatever its base, should be used if it was likely to be heated to 150°C. A review of ignition by friction and impact has been given by F. Powell (1969), with particular reference to ignition of firedamp in coal mines. He states that frictional heating, usually by coal cutting machines, is the largest single cause of ignition in British mines. With regard to surface temperature rise he states that impact normal to the surface tends to give a relatively small surface temperature rise, that sliding friction gives surface temperatures sometimes approaching the melting points of the two materials and that frictional impact sometimes gives surface temperatures equal to the melting points. He reviews impact or rubbing between rocks, impact or sliding of metals on rocks, impact or rubbing between metals, and grinding and drilling operations.

In a study of impact of metals on metals, Titman and Wynn (1954) ignited methane–air mixtures with steel balls shot at steel and aluminium targets. Burgess and Wheeler (1929) were able to ignite methane–air mixtures with a steel locomotive wheel rubbing on steel rails, but only by using a shield to concentrate the sparks.

Powell describes extensive work in which ignition of mainly methane–air mixtures has been obtained by the impact of light alloys such as aluminium. In most cases ignition was by the thermite reaction. It is characteristic of light alloys that they tend to give a smear on rusty steel. Even if ignition does not occur at the time, a glancing blow from a hard object at some later time may produce the thermite reaction and cause ignition. For this reason the use of light alloys in British mines is severely restricted. However, ignitions have been obtained with light alloys where neither rust nor steel were involved. W.G. Thomas (1962) ignited methane–air mixtures by shooting aluminium pellets at clean steel targets. In an investigation of an explosion in a ship's tank, Rae (1965) obtained ignitions of methane–air mixtures by dropping brass onto partly consumed magnesium anodes.

Ignition by the frictional impact of steel on rock has been studied by Blickensderfer (1975) in connection with ignition by coal-cutting machines. In severe impact a smear of molten metal is deposited on the rock. Most of the impact energy is converted to heat at the interface. This hot smear has the potential to ignite methane–air mixtures. In experimental work in which a metal object representing a cutting tool was secured to a flywheel and made to impact on rock, it was found that the impact energy had little effect on the probability of ignition, but that the impact speed had a strong effect. Hot streak temperatures of 1400°C were obtained. The effect of an increase in the impact speed was to increase the area rather than the temperature of the hot surface. This work includes a model of hot smear ignition.

Ignition of methane–air mixtures has been obtained by both ferrous and non-ferrous metals striking against quartzite materials, such as sandstone or concrete containing sand. This work is relevant to the use of 'non-sparking' tools.

Hot gas jet ignition

Ignition of flammable gas–air mixtures by jets of hot gas has been studied by Wolfhard and Vanpee (1959) to determine the degree of hazard of ignition of methane in coal mines from hot spent gases from the detonation of an explosive charge.

Ignition temperatures for a hot jet of air entering a cold, pure fuel are shown in Table 16.20 and those for a hot jet of nitrogen entering an ethylene–air mixture at an optimum concentration (close to stoichiometric) for ignition are shown in Table 16.21.

Table 16.20 *Hot gas jet ignition: ignition temperatures of a hot air jet entering a cold, pure fuel (Wolfhard and Vanpee, 1959) (Courtesy of the Combustion Institute)*

Fuel	*Ignition temperature* (°C)
Methane	1190
Ethane	945
Propane	1010
n-Butane	1025
Ethylene	875
Propylene	1060
iso-Butylene	1070
Acetylene	755
Carbon monoxide (commercial)	765
Hydrogen	670

Table 16.21 *Hot gas jet ignition: ignition temperatures for a hot jet of nitrogen entering an ethylene–air mixture of optimum concentration (close to stoichiometric) for ignition (Wolfhard and Vanpee, 1959) (Courtesy of the Combustion Institute)*

Jet flow (cm^3/s)	*Maximum temperature within jet* (°C)
25	1020
35	1035
50	1040
70	1050
100	1100
130	1140

Hot particle ignition

Investigations of the ignition of flammable gas–air mixtures by hot particles have been conducted by Silver (1937) and Paterson (1939–). Hot particles are another potential source of ignition in the use of blasting explosives in coal mines.

Silver carried out experiments in which hot particles were injected into flammable gas–air mixtures. The gases were coal gas, pentane and hydrogen and the particles quartz and platinum. The particle velocities were in the range 2–5 m/s. The particle temperature necessary to give ignition decreased as the particle diameter increased. Figure 16.25 shows some results obtained for the effect of particle diameter on the particle temperature required for ignition.

Paterson extended this work, using a wider range of gases and materials and particle velocities up to 65 m/s. Some results showing the effect of particle velocity and diameter on the particle temperature required for ignition are shown in Figure 16.26. Paterson's work shows that for small particles and for high particle velocities the surface temperatures required for ignition are very high.

A model for ignition by a hot inert particle has been described by Su, Homan and Sirignano (1979). Sharma and Sirignano (1970) have given a model for ignition by a hot projectile.

Flame torch and jet ignition

Flame torch ignition of a flowing flammable gas mixture is important in combustion systems. The work of Mullen, Fenn and Irby (1949) has already been mentioned. Work on this topic has also been done by Wang *et al.* (1981). Ignition of a vapour cloud by a flame jet has been studied by Mackay *et al.* (1988) in the context of vapour cloud explosions. These are described in Chapter 17.

Compression ignition

If a mixture of flammable gas and air is compressed, the resultant temperature rise may take the mixture into the temperature range in which auto-ignition occurs. This effect is exhibited in the diesel engine and is sometimes known as the diesel effect.

There is a considerable body of work on compression ignition, coming from several sources. Compression ignition is another of the modes of ignition studied in relation to ignition of firedamp in coal mines. Ignition by the pressure wave from a blasting explosive has been investigated by W.C.F. Shepherd (1949).

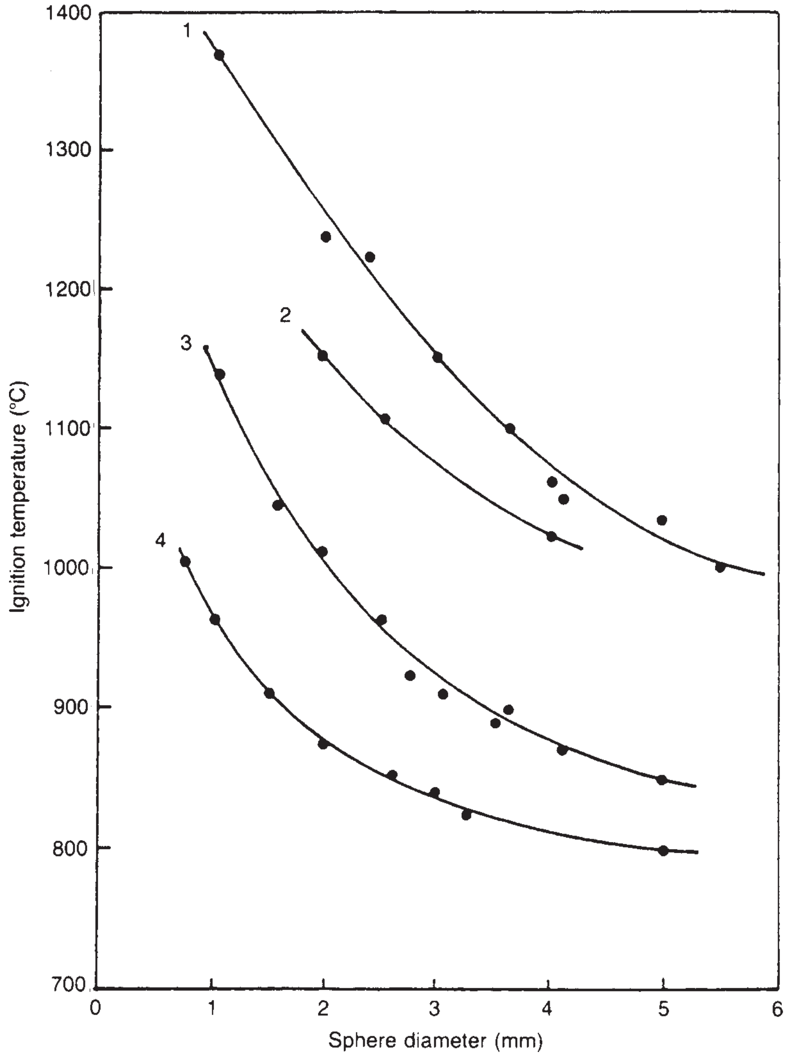

Figure 16.25 *Hot surface ignition temperature: effect of particle diameter on the particle temperature required for ignition of fuel–air mixtures by a hot particle travelling through the mixture (Laurendeau, 1982; after Silver, 1937; and Paterson, 1939–) 1, 3% pentane at ≈4 m/s; 2, 3% pentane at ≈1, 2 m/s; 3, 10% coal gas at ≈1.2 m/s (Courtesy of Combustion and Flame)*

Another motivation for research on compression ignition is the study of fast chemical reactions. Compression is a convenient method of effecting the very rapid translation of a reaction mixture into the temperature range of interest. The technique has been described by Jost (1949). According to Jost, for hydrocarbon–air mixtures over the temperature range of interest the value of the ratio of specific heats 7 is about 1.3. He also states that the variation with hydrocarbon concentration is not negligible.

A major aspect of research on combustion is the behaviour of shock waves, and ignition by shock waves is one aspect of this. Such work has been described by J.W. Meyer and Oppenheim (1971b), Vermeer, Meyer and Oppenheim (1972) and Eubank *et al.* (1981). Regimes of weak and strong ignition and ignition time delay are features that have been particularly investigated.

Research into internal combustion engines and diesel engines is another source of work on compression ignition. Work on compression ignition, and 'knock', in internal combustion engines is illustrated by the work of Halstead *et al.* (1975). There are also some studies of compression ignition of particularly sensitive chemicals such as those by Beeley, Griffiths and Gray (1980) on isopropyl nitrate and J.F. Griffiths and Perche (1981) on ethylene oxide (EO).

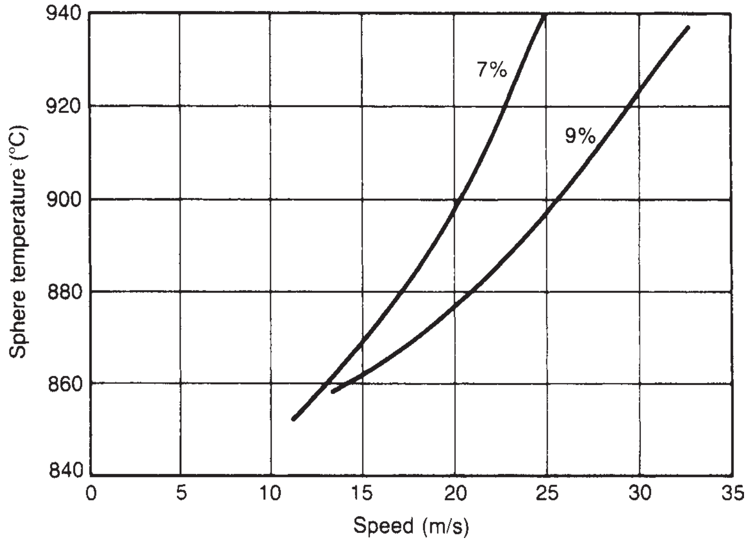

Figure 16.26 *Hot surface ignition temperature: the effect of particle velocity on particle temperature for the ignition of fuel-air mixtures by a hot particle travelling through the mixture (after Paterson, 1939–). Parameter of curves is concentration of coal gas in air (% v/v) (Courtesy of the Philosophical Magazine)*

Ignition in compression is a form of auto-ignition. The comment made earlier is therefore applicable, that, given a homogeneous mixture, ignition may occur outside the normal flammability limits, since these apply essentially to propagation of the flame.

16.3.10 Burning velocity

It is usual to distinguish between flame speed, which is the actual speed of the flame front in a given situation, and burning velocity, which is a property, or at any rate a quasi-property, of the flammable gas mixture. Definition of the burning velocity is not, however, straightforward, Linnett (1953) states that it seems impossible to define a burning velocity which is equally applicable to both planar and spherical flames and will have the same value for both cases, but suggests that the best approach is to use a value obtained by dividing a suitable flame area into a volumetric flow rate. It has been shown by Spalding and Yumlu (1959) that there are in fact two burning velocities, the higher value normally being the stable one.

There are a number of methods available for the measurement of burning velocity. These are reviewed by Linnett (1953) and by Andrews and Bradley (1972b). They include:

(1) propagating flame methods
  (a) soap bubble,
  (b) bomb,
  (c) tube,
  (d) flame kernel;
(2) cylindrical burner
  (a) cone angle,
  (b) total area;
(3) nozzle burner
  (a) cone angle,
  (b) total area.

With the cylindrical burner and nozzle burner methods measurement may be based on luminous flame, shadow or schlieren techniques.

A model for a spherical flame is given in Chapter 17. Other early models, including those by Semenov (1940), Tanford and Pease (1947) and Manson (1949), are reviewed by Dugger and Simon (1953). Further rather more complex models have been given by Yang (1961) and by Spalding, Stephenson and Taylor (1971).

Near the limits of flammability there is a minimum burning velocity to sustain combustion. This minimum burning velocity is influenced by natural convection. It has been suggested by Simmons and Wright (1972) that the following equation, derived by R.M. Davies and Taylor (1950) for the rise of an air bubble up a tube through a denser fluid, may be applied to the rise of a bubble of hot gas through a flammable gas mixture: $\frac{1}{2}$

$$v_o = 0.464(gr)^{1/2} \qquad [16.3.37]$$

where g is the acceleration due to gravity (cm/s^2), r is the radius of the tube (cm) and v_o is the velocity of the bubble (cm/s).

The effects of pressure and temperature on burning velocity have been the subject of several studies including those by Andrews and Bradley (1972a, 1973a), Halstead, Pye and Quinn (1974), Gulder (1982) and Lijima and Takeno (1986).

For methane, Andrews and Bradley (1972a, 1973) found that the burning velocity decreases with increasing pressure according to the relation

$$S_u \propto p^{-m} \qquad [16.3.38]$$

where $m = 0.5$. A similar relation was obtained by Gülder (1982) for methanol, ethanol and iso-octane with values of m of the order of 0.2. On the other hand, for hydrogen, Lijima and Takeno (1986) report an increase in burning velocity with pressure.

Burning velocity is generally reported to increase with temperature. Gülder (1982) found the relation

$$S_u \propto T^n \qquad [16.3.39]$$

where $n = 1.75$ for methanol and ethanol and $n = 1.56$ for *iso*-octane. Andrews and Bradley (1972a) obtained for methane the relation

$$S_u = 10 + 0.000371 T_u^2 \qquad [16.3.40]$$

where S_u is the burning velocity (cm/s) and T is the absolute temperature of the unburned gas. Lijima and Takeno (1986) obtained similarly strongly positive correlations of burning velocity with temperature for both methane and hydrogen.

The effect of physical and chemical properties on burning velocity has been studied by Golovina and Fyodorov (1957). The effect on burning velocity of the recirculation of the products of combustion has been investigated by Putnam (1974).

The variability in the values of burning velocity given in the literature is discussed by Andrews and Bradley (1972b). For methane they quote values ranging from 31 to 50 cm/s and the variation is as great for most of the other gases considered.

Relations for the burning velocity of mixtures have been given by Payman and Wheeler (1922) and Spalding (1956). The Payman and Wheeler rule is

$$S_{u,m} = \sum S_{u,i} y_i \qquad [16.3.41]$$

where y is the mole fraction in the fuel–oxidant mixture and subscripts i and m denote component i and the mixture, respectively.

Spalding's treatment is based on the concept that the sole effect of mixing two fuel–air mixtures is to alter the flame temperature to a common value. In the simplified form given by Yumlu (1967a), the Spalding rule is

$$S_{u,m}^2 = \sum S_{u,i}^2 \alpha_i \qquad [16.3.42]$$

where α is the ratio of the mass of fuel i and the corresponding amount of oxidant to the total mass of fuel and oxidant.

The burning velocity so far considered is the laminar burning velocity S_L. The burning velocity is increased by turbulence and it is necessary to consider also the turbulent burning velocity S_T.

The definition of burning velocity becomes more difficult if the conditions are turbulent. The definition is usually given in terms of the flame surface, but this surface is difficult to specify. A rigorous definition of turbulent burning velocity has been given by J.M. Richardson (1956). Its application has been discussed by Palm-Leis and Strehlow (1969).

Measurement of the turbulent burning velocity has usually been carried out utilizing a modification of the burner method used for laminar burning velocity. The method of flame propagation in a vessel has also been used.

There are a number of correlations and models of turbulent burning velocity. Most of these involve parameters for the turbulence due to the gas flow such as the axial component of turbulence u' and the radial component v'. Turbulence generated by the flame is also taken into account in some treatments.

Treatments of turbulent burning velocity have been reviewed by B. Lewis and von Elbe (1961). The first model was that by Damköhler (1940), who suggested that the flame front is strongly distorted by turbulence and that under these conditions for a stable flame the burning velocity must exceed not only the average velocity U but also the velocity $U + u'$. This leads to the relation

$$S_T \propto u' \qquad [16.3.43]$$

In this model S_T is independent of S_L. Shchelkin (1943) modified the Damköhler model by assuming that the distortions of the flame front are cone shaped. Then from geometrical considerations he obtains

$$\frac{S_T}{S_L} = [1 + (2u'/S_L)^2]^{1/2} \qquad [16.3.44]$$

The model is a crude one, and in recognition of this the 2 in Equation 16.3.44 may be replaced by an undetermined number B of the order of unity. Equation 16.3.44 reduces to relation 16.3.43 for large values of $(u'/S_L)^2$

Thus, according to these theories, under conditions of high turbulence the turbulent burning velocity S_T should be independent of the fuel gas. Work by D.T. Williams and Bellinger (1949) has shown, however, that this is not so.

Karlovitz, Denniston and Wells (1951) have developed a model that addresses this problem. The model is based on the concept of an undulated flame front and yields the relations

$$\frac{S_T}{S_L} = 1 + \frac{S_t}{S_L} \qquad [16.3.45]$$

with

$$S_t = \left(2S_L u' \left\{1 - \frac{S_L}{u'}[1 - \exp(-u'/S_L)]\right\}\right)^{1/2} \qquad [16.3.46]$$

where S_t is the average velocity of displacement of the turbulent wave. At low turbulence, Equation 16.3.46 reduces to

$$\frac{S_T}{S_L} = 1 + \frac{u'}{S_L} \quad 1 < \frac{u'}{S_L} \qquad [16.3.47]$$

and at high turbulence it reduces to

$$\frac{S_T}{S_L} = 1 + \left(\frac{2u'}{S_L}\right)^{1/2} \quad \frac{u'}{S_L} > 1 \qquad [16.3.48]$$

In this model, therefore, the turbulent burning velocity remains dependent on the laminar burning velocity, even at high turbulence.

In their work, D.T. Williams and Bellinger (1949) obtained the correlation

$$u_t = 0.1761\, u_n d^{0.2564} \mathrm{Re}^{0.238} \quad 3000 < \mathrm{Re} < 35{,}000 \qquad [16.3.49]$$

where d is the burner diameter (cm), u_n is the laminar burning velocity (cm/s) and u_t is the turbulent burning velocity (cm/s).

Fine (1958) describes two models for the effect of turbulence on burning velocity. One treatment is based on the effect of turbulence in inducing flame wrinkling and gives

$$\frac{S_T}{S_L} = f(u'/S_L) \qquad [16.3.50]$$

The other model involves the effect of turbulence on thickening of the reaction zone. Fine applied these models in an attempt to determine by studying the effect of pressure whether the Reynolds number is the proper correlator, but the results were inconclusive. Correlations of the turbulent burning velocity have been given by a number of workers. Thus Kozachenko (1962) gives a relation of the form

$$S_T = S_L + \phi_1 \qquad [16.3.51]$$

and Gökalp (1980) one of the form

$$S_T = S_L + \phi_2 \qquad [16.3.52]$$

where ϕ_1 and ϕ_2 are functions of turbulence.

An extensive program of work on the turbulent burning velocity has been undertaken by Bradley and co-workers. Andrews, Bradley and Lwakabamba (1975a) obtained a graphical correlation of turbulent burning velocity in terms of the unburnt gas Reynolds number defined as

$$R_\lambda = u'\lambda/v \qquad [16.3.53]$$

where u' is the root mean square (rms) turbulent velocity, λ is the Taylor microscale and v is the kinematic viscosity. On the assumption that $u'/U = 0.05$ this Reynolds number is given approximately by the relation

$$R_\lambda = (\mathrm{Re} - 2500)^{1/2} \qquad [16.3.54]$$

Abdel-Gayed and Bradley (1977) present a further graphical correlation. For high turbulence they give the relation

$$\frac{u_t}{u_1} = 3.788 R_\lambda^{0.238} \quad R_\lambda > 100;\ u_1/u' \to 0 \qquad [16.3.55]$$

where u_1 and u_t are the laminar and turbulent burning velocities, respectively. Further work is reported by Abdel-Gayed and Bradley (1987), who also give details of the correlations found by previous workers.

Continuing this investigation, Bradley, Lau and Lawes (1992) give the correlation shown in Figure 16.27. They use an integral length scale of turbulence L such that

$$\frac{\lambda^2}{L} = \frac{Av}{u'} \qquad [16.3.56]$$

with a turbulent Reynolds number Re_L defined by

$$\mathrm{Re}_L = \frac{u'L}{v} \qquad [16.3.57]$$

where A is a constant. Then for the parameter group $K\mathrm{Le}$ in Figure 16.27 they give for the Karlovitz flame stretch factor K the relation

$$K = 0.157\left(\frac{u'}{u_1}\right)^2 \mathrm{Re}_L^{-1/2} \qquad [16.3.58]$$

in which the value of A has been taken as 40.4, while the Lewis number Le is defined as

$$\mathrm{Le} = \frac{k}{c_p \rho D} \qquad [16.3.59]$$

where c_p is the specific heat of the gas, D is the diffusion coefficient of the deficient reactant, k is the thermal conductivity of the gas and ρ is the density of the gas. They also give the following limited-range relation:

$$\frac{u_t}{u'_k} = 0.88(K\mathrm{Le})^{-0.3} \quad 0.01 < K\mathrm{Le} < 0.63 \qquad [16.3.60]$$

The correlation given makes use of the rms turbulent velocity $u'$and the effective rms turbulent velocity acting on the flame u'_k. Although in this work use was made of measured values, where necessary Abdel-Gayed and Bradley (1977) also used the relation

$$\frac{u'}{U} = 0.1676\ \mathrm{Re}^{-0.119} \qquad [16.3.61]$$

With regard to u'_k this velocity is given mainly in terms of the ratio u'_k The treatment, described in detail by Abdel-Gayed and Bradley (1987), is complex, but at high turbulence the value of the ratio tends to unity.

The effect of pressure on turbulent burning velocity has been studied by Fine (1958), as already mentioned. He obtained for propane and hydrogen the relation

$$\frac{S_T}{S_L} \propto P^n \qquad [16.3.62]$$

where n is approximately 0.3.

Selected values of the turbulent burning velocity of various fuels are given by Abdel-Gayed and Bradley (1977).

Burning velocity is closely related to quenching distance, as described in the next section.

16.3.11 Quenching effects

Flame propagation may be extinguished by quenching. Such quenching may be due to heat loss to unburnt gas or to a solid surface. Quenching is closely related to several of the other properties already discussed. Explanations for the existence of flammability limits invoke quenching. There is a close inverse relation between burning velocity and quenching.

Quenching is of practical interest in a number of ways. The stabilization of flames on burners is related to quenching. The quenching effect is utilized in equipment designed to stop the passage of flame, such as flameproof motors and flame arresters. The occurrence of unreacted fuel in car exhaust may be attributable to quenching.

For quenching in a gap between surfaces use is often made of the quenching distance d_q. This is sometimes used as a general term covering both the quenching diameter d_o and the critical slot width $d_{||}$and sometimes means only the latter.

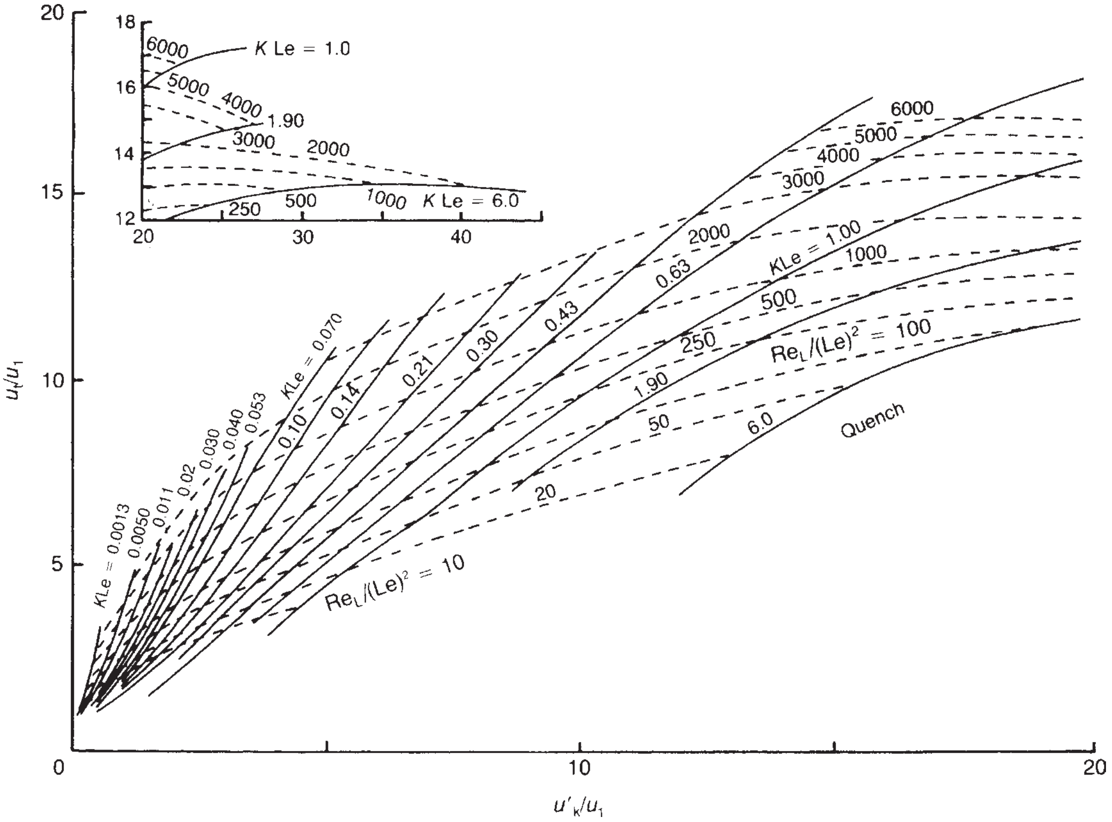

Figure 16.27 Correlation for turbulent burning velocity (D. Bradley, Lau and Lawes, 1992) (Courtesy of The Royal Society)

Potter (1960) gives the relation between the quenching diameter d_o and the critical slot width $d_{||}$ as

$$d_{||} = 0.65d_o \qquad [16.3.63]$$

A third quenching parameter is the depth of penetration of quenching d_p. This is defined as the ratio of the burning velocity to the critical boundary velocity gradient for flashback:

$$d_p = S_u/g_F \qquad [16.3.64]$$

The variation of these three quantities for flammable mixtures of natural gas and air is shown in Figure 16.28. The quenching diameter is the greatest dimension and the depth of penetration of quenching is the smallest.

Measurement of the quenching distance may be made by a number of methods. Reviews of these methods have been given by R. Friedman (1949) and Anagnostou and Potter (1959). Methods include those based on measurement of

(1) flame blow-off and stability;
(2) the critical distance between parallel plates;
(3) the critical tube diameter.

Extensive measurements of quenching distance have been made by Blanc, *et al.* (1949). There are a number of models and correlations for quenching distance. Drawing on earlier work by Mallard and Le Chatelier (1883), R. Friedman (1949) derived a quenching equation. Equating the heat generated to the heat lost to the walls, he obtained for the critical value of the quenching distance x

$$x = \frac{k}{S_u c_{pu}}\left[\frac{1}{f}\,\frac{(T_f - T_i)}{(T_i - T_o)}\right]^{1/2} \qquad [16.3.65]$$

where c_{pu} is the specific heat of the unburnt gas, f is a geometrical factor of the order of unity, k is the thermal conductivity of the gas, T_f is the absolute flame temperature, T_i is the absolute ignition temperature and T_o is the absolute temperature of the unburned gas.

Some theories of quenching involve the Peclet number Pe defined as

$$\mathrm{Pe} = S_u d_q/\alpha_u \qquad [16.3.66]$$

with

$$\alpha_u = k_u/\rho_u c_u \qquad [16.3.67]$$

where α is the thermal diffusivity and subscript u denotes the unburned gas.

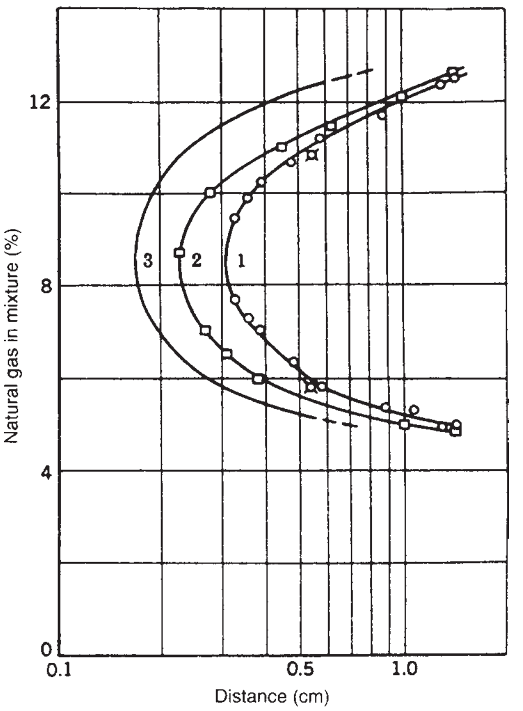

Figure 16.28 Quenching parameters of burner wall for natural gas–air mixtures (B. Lewis and von Elbe, 1961) 1, quenching diameter d_0; 2, quenching distance $d_{\|}$; 3 depth of penetration, d_p (Courtesy of Academic Press)

Equations 16.3.66 and 16.3.67 imply a constant value of the burning velocity-quenching product, which is also used by Potter and Berlad (1957).

$$\frac{d_{\mathrm{q}}}{S_{\mathrm{u}}} = \mathrm{Constant} \qquad [16.3.68]$$

Ballal and Lefbvre (1977) have attempted to correlate the quenching distance for turbulent flow conditions using

$$d_{\mathrm{q}} = \frac{\mathrm{Pe}\alpha}{S_{\mathrm{u}}} = A \qquad [16.3.69]$$

where A is a constant, but found that it was necessary to modify this relation and proposed instead

$$d_{\mathrm{q}} = A + 13\mathrm{Pr}^{-0.05}(u'/S_{\mathrm{L}})^{0.5} \qquad [16.3.70]$$

Kydd and Foss (1964) emphasize the influence on quenching of three-dimensional effects.

Several investigators have studied the effect on quenching distance of gap length. R. Friedman (1949) states that the quenching distance appears to depend not on gap length but on gap width only. On the other hand, Maekawa (1975) obtained for quenching in rectangular channels the relation

$$d_{\mathrm{q}} = k_1 L \exp(-k_2 L) + k_3 L \qquad [16.3.71]$$

where L is the gap length and k_1 to k_3 are constants.

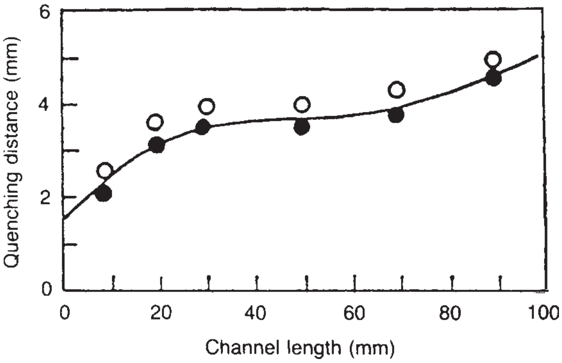

Figure 16.29 Quenching distance in a rectangular duct (Maekawa, 1975) (Courtesy of Combustion Science and Technology)

Some results from this work are shown in Figure 16.29.

Mention should also be made of experiments by Wolfhard and Bruszak (1960) in which they investigated the propagation of flame down narrow tubes between two chambers. In experiments with methane the flame did not propagate through tubes of diameter less than 3 mm. But ignition could still occur in the outer chamber due to the jet of hot gases. Whether ignition did in fact occur depended on the properties of the jet. Very short channels were more effective in preventing ignition than were 10 mm long ones.

The effect of pressure on quenching distance has been studied by several workers including Brokaw and Gerstein (1957), Potter (1960) and Ballal and Lefebvre (1975a). The quenching distance increases with decreasing pressure.

Potter (1960) states that the quenching distance is approximately inversely proportional to pressure:

$$d_{\mathrm{q}} \propto P^{-1} \qquad [16.3.72]$$

This relation is in fact implied in the use of the Peclet number.

Practical quenching criteria such as the MESG were discussed in Section 16.2.

16.3.12 Cool flames

Certain compounds are capable of slow oxidation at mixture concentrations outside the normal flammability limits and at temperatures lower than those pertaining in normal combustion. Cool flames are of practical interest for several reasons. Much of the work done has been concerned with knock in internal combustion engines and also in jet engines. They are also of interest in relation to hydrocarbon oxidation in chemical reactors.

Cool flames were discovered by Sir Humphrey Davy and were studied by Perkin (1882), who found that they could be obtained with a wide variety of compounds, including hydrocarbons, alcohols and aldehydes. They were most easily demonstrated with diethyl ether and acetaldehyde. They were effectively rediscovered by Prettre, Dumanois and Lafitte (1930) and Townend and Mandlekar (1933).

Townend and co-workers carried out a series of studies on cool flames. The characteristics of such flames are illustrated by the work of Hsieh and Townend (1939a–c). The concentration region within which cool flames occur is illustrated by the results for hexane–air mixtures obtained by Hsieh and Townend (1939b), as shown in Figure 16.30(a). They state:

> Reference to the results at 1500°C shows that at pressures up to 4.1 atm there was only one range of inflammable mixtures, viz. that for normal flames. This was at first unaffected by increase in initial pressure, the lower limit being lower by about 0.3% and the higher limit raised by about 1% of hexane at pressure up to 4 atm. At a pressure of 4.1 atm a cool flame range was located with mixtures of composition between 11 and 22% of hexane, the normal range at the same pressure extending over mixtures of hexane content between 1.2 and 7.0%. The 'normal' and 'cool' flame ranges were thus separated by a range of non-flammable mixtures containing between 7 and 11% of hexane. At pressures higher than 4.8 atm the two ranges of inflammability became superposed so that at, 6.5 atm, mixtures containing between 1 and 14.5% of hexane were capable of propagating 'normal' flames and those between 14.5 and 32% 'cool' flames.

Hsieh and Townend (1939a) also investigated the ignition of cool flames both by spontaneous ignition and by hot wire ignition, in order to establish that the cool flame process is the same in both modes. Their results for ether–air mixtures are shown in Figure 16.30(b).

The results of cool flame experiments may also be presented as an ignition diagram in which the regions of the different modes of combustion are shown on a plot of temperature vs. pressure for a given mixture composition. An ignition diagram for a propane-oxygen mixture given by Newitt and Thornes (1937) is shown in Figure 16.31. Ignition diagrams for a number of compounds have been given by Townend (1937). A characteristic feature of an ignition diagram is the peninsular region. Apart from its practical significance, the diagram provides a test of theories for cool flames.

Cool flames are associated with a negative temperature coefficient for the overall combustion over a limited range of temperature, as illustrated by the data shown in Figure 16.32 for the reaction rate of propane and oxygen obtained by Seakins and Hinshelwood (1963). The negative temperature coefficient is discussed by Knox, who interprets it as evidence of a fundamental change from one reaction mechanism to another.

Interpretations of cool flames in terms of the reaction kinetics have been undertaken by a large number of workers. Reviews are given by von Elbe and Lewis (1937a), Ashmore (1967) and Knox (1967a).

Von Elbe and Lewis (1937b) review the theories of Norrish and Foord (1936), Ubbelohde (1935, 1936), Jost, von Muffling and Rohrmann (1936), Pease (1935), Semenov (1935) and von Elbe and Lewis (1937a). They discuss the role of unbranched and branched chain reactions and of the intermediate aldehydes and peroxides formed.

Thermal and isothermal theories of cool flames have been proposed by Semenov (1935) and are discussed by Ashmore (1967). In the thermal theory, which applies both to unbranched and branched chain reactions, a rapid increase in reaction rate occurs as a result of self-heating, while in the isothermal theory, which applies to branched chain reactions only, the reaction rate increases as a result of exponential growth in the chain centres at the end of an isotherm induction period.

A series of investigations of pre-flame and ignition behaviour and of cool flames has been carried out by Barnard and co-workers (e.g. Barnard and Ibberson, 1965 Barnard and Kirschner, 1967; Barnard and Sankey, 1968; Barnard and Watts, 1972; Barnard and Harwood, 1973a) and by Salooja (1966, 1967, 1968a,b).

A feature of cool flames is the occurrence of multiple flames, one after the other. Coffee (1982b) quotes observation of up to 11 cool flame zones.

The periodicity of cool flames is another feature that is of theoretical interest. Attempts have been made to apply to cool flames the theory developed by Lotka (1920) for essentially biological phenomena, which for certain conditions predicts oscillations in the concentration of intermediate species. This aspect is discussed by B.F. Gray and Yang (1969). Cool flames exhibit an ignition delay, or induction period. Studies of ignition delay in cool flames include those of J.E. Johnson, Crellin and Carhart (1954), Fish (1968) and Barnard and Watts (1972). Fish obtained for the variation of ignition delay with pressure the relation

$$\tau = kP^{-n} + c \qquad [16.3.73]$$

where P is the absolute pressure, τ is the ignition delay, c and k are constants and n is an index.

Cool flames result in rises in pressure and temperature, but these are more modest than with normal combustion. Correlations for pressure and temperature effects are given by Fish (1968) and by Luckett and Pollard (1973). For the pressure rise Fish found

$$\Delta P_{\mathrm{cf}} = kP_{\mathrm{o}}^{m} \qquad [16.3.74]$$

where P_{o} is the absolute initial pressure, ΔP_{cf} is the pressure rise for a cool flame, k is a constant and m is an index. The value of the index m was $1 < m < 2$.

The temperature rise was found by Fish to be a function of the oxygen concentration of the mixture. For low oxygen concentrations the rise in temperature corresponded closely to the rise in pressure, assuming the ideal gas law.

Cool flames in mixtures have been studied by Salooja (1968b). He found that for binary mixtures two different types of behaviour could be distinguished: those cases for which the ignition tendency is (1) intermediate between those of the two compounds and (2) even greater than that of the more ignitable component.

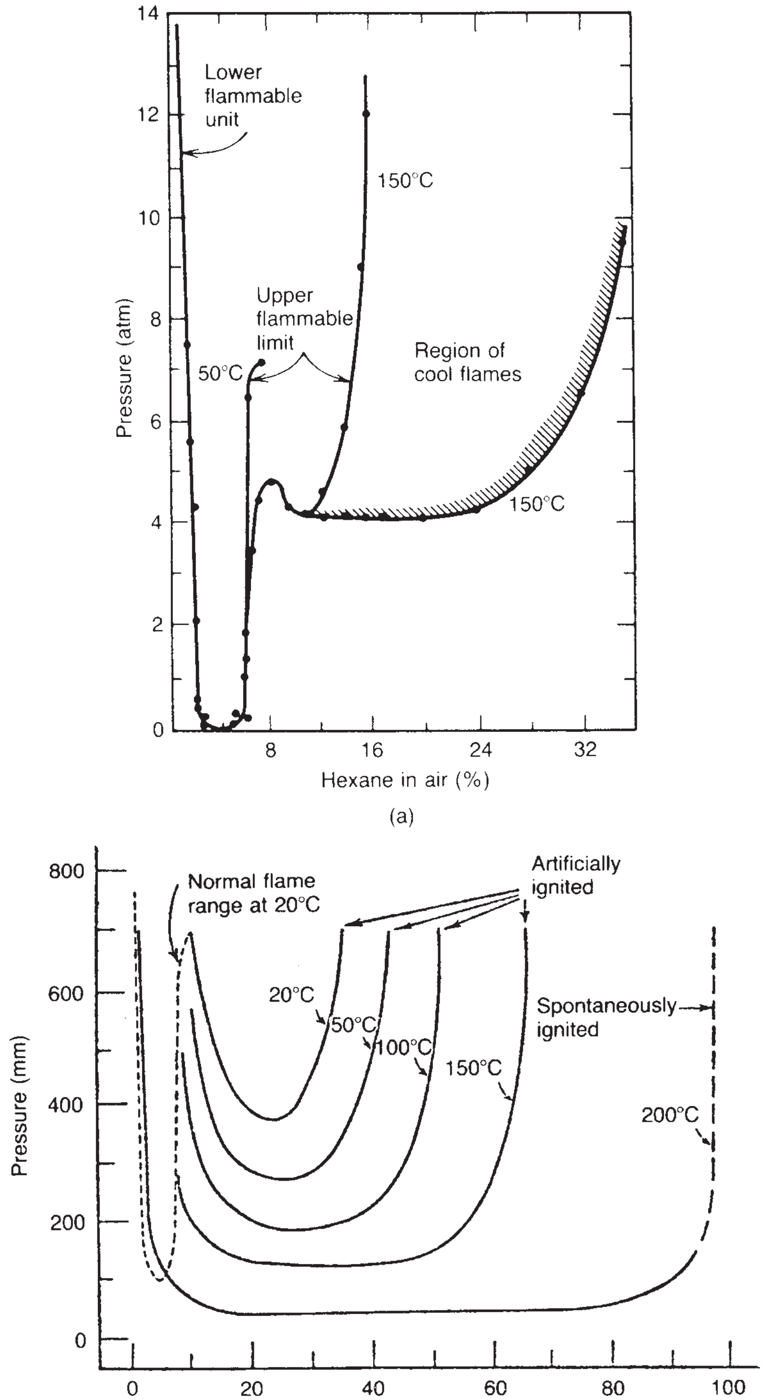
The features of cool flames have been compared with those of normal flames by Coffee (1982b) as follows:

	Normal flames	*Cool flames*
ΔT_{cf}	800–2000°C	1–200°C
$P_{\mathrm{if}}/P_{\mathrm{o}}$	6–10 (confined spaces)	Low (<2)
Products	CO_2, H_2O	CO, CH_2O

P_{cf}, absolute final pressure of cool flame; P_{o}, absolute initial pressure; ΔT_{cf}, temperature rise for cool flame.

16.3.13 Combustion in tubes

The behaviour of flames in tubes has been extensively studied. Early work was carried out by Mallard and Le Chatelier (1883) and by Wheeler and co-workers, the latter including the work by Mason and Wheeler (1917, 1920a–c), Chapman and Wheeler (1926, 1927), Ellis (1928), Ellis and



(a)

(b)

Wheeler (1925, 1928a,b), Kirby and Wheeler (1931a,b) and H. Robinson and Wheeler (1933).

Much work on combustion in tubes has dealt with detonation, and with the transition from deflagration to detonation; this is considered in Chapter 17. There is also, however, a body of work which is concerned with the more general aspects of combustion in tubes, including tubes containing obstacles, in respect of features such as vibratory oscillations, flame acceleration, pressure rise and so on.

Such work includes *Non-Steady Flame Propagation* by Markstein (1964) and that by M.W. Evans *et al.* (1949), Schmidt, Steinicke and Neubert (1953), Guenoche (1964), Leyer and Manson (1971), Andrews, Herath and Phylaktou (1990) and Phylaktou, Andrews and Herath (1990).

The latter authors have reviewed some of the findings of this work. They consider four cases: Case 1, a tube open at one end with ignition at the open end; Case 2, a tube open at one end with ignition at the closed end; Case 3, a tube open at both ends; and Case 4, a tube closed at both ends.

Case 1 appears to provide the simplest propagation conditions and has been the most widely investigated. After a short initial phase, the flame propagates for some distance at a fairly constant velocity. This phase is sufficiently prolonged to permit measurement of the burning velocity. As the flame progresses, there begin vibrations of the combustion surface that can turn into violent oscillations. Towards the end of the tube the flame velocity falls rapidly to a roughly constant value.

In Case 2 the flame accelerates rapidly and develops violent vibrations. In the work of Mason and Wheeler (1920a,b), using a long tube, this resulted in extinction of the flame.

In Case 3 the behaviour of the flame is somewhat similar to that in Case 1, with a short initial phase followed by propagation at a higher velocity, since the unburned gas can be pushed out of the open end. In this phase there is a slight acceleration. Vibration begins and the velocity increases, either with smooth acceleration or with oscillations.

In Case 4 with ignition at one end it was found by Kirby and Wheeler (1931b) that initially the flame accelerated rapidly, then decelerated and travelled at a comparatively low speed until it approached the far end, when it accelerated somewhat. The time of attainment of maximum pressure coincided with that of the arrival of the flame at this end.

Phylaktou, Andrews and Herath (1990) describe experiments on the Case 4 configuration using a pipe with a length/diameter (L/D) ratio of 21.6 with a wide range of gas concentrations and a variety of gases. All gases exhibited two distinct regimes: vibratory near the stoichiometric concentration and non-vibratory near the limits of flammability. In the near-limit mixtures the flame speeds were higher than those in the stoichiometric mixtures, and the initial rates of pressure rise were high. For the near stoichiometric mixtures vibration was found to enhance the rate of pressure rise.

Further accounts of combustion in pipes, and also in vessels, as well as treatment of detonation are given in Chapter 17.

16.4 Flammability of Aerosols

It is also relevant to consider the combustion of aerosols such as fogs, mists and sprays. Such aerosols may be produced by condensation of a saturated vapour or by atomization of liquid by mechanical forces. The former may be referred to as a condensed fog or mist and the latter as a mechanical spray. Normally in a condensed mist the diameter of most of the drops is less than 10 μm, while in a mechanical spray it is greater than 100 μm.

Accounts of the combustion of aerosols, particularly liquid sprays, include *Combustion of Liquid Fuel Sprays* (A. Williams, 1990) and those by F.A. Williams (1959), Faeth (1977, 1979, 1983) and Kuo (1986).

A large proportion of work in this field is directed towards the combustion of atomized fuels at burners in furnaces and boilers. Some of the work deals with the combustion of single droplets of fuel, and some deals with the combustion of an aerosol cloud.

16.4.1 Combustion of aerosols

A suspension of finely divided droplets of flammable liquid in air can give a flammable mixture which has many of the characteristics of a flammable gas–air mixture and which can burn or explode. The combustion of aerosols has been the subject of a series of studies by Burgoyne and co-workers (Burgoyne and Richardson, 1949b; Burgoyne and Cohen, 1954; Burgoyne, Newitt and Thomas, 1954; Burgoyne, 1957, 1963).

In classic experiments using aerosols of tetrahydronaphthalene, or tetralin, with droplets of closely controlled diameter in the range 7–55 μm, Burgoyne and Cohen (1954) found that below a droplet diameter of 10 μm, the aerosol behaved like a vapour in respect of the LFL and the burning velocity. With a droplet diameter above 40 μm, the behaviour of the aerosol was different. The droplets were observed to burn individually in their own air envelopes, one burning droplet igniting the next.

If the droplet size, and hence the distance between droplets, exceeds a critical value, the flame does not propagate. The critical distance is of the same order of magnitude as the radius of the sphere of air required for the combustion of a droplet.

Coarser aerosols are capable of sustaining a flame at substantially lower fuel–air ratios than fine aerosols and vapours. The difference lies in the ability of the droplets to move in relation to the ambient air. Coarse particles are responsive to acceleration and move randomly, and thus communicate flame more readily.

Burgoyne's work has also shown that the burning velocity and the quantity of inert gas required for the suppression of flammability in aerosols with small droplet diameters are those of the equivalent vapour–air mixture.

In addition to this work on the conditions for combustion to occur in an aerosol, there have been other studies that have investigated the behaviour and shape of the flame in a droplet cloud. The studies include those by J.A. Browning and Krall (1955), J.A. Browning, Tyler and Krall (1957), Reichenbach, Squires and Penner (1962), Rosser (1967), Mizutani and Nishimoto (1972), Mizutani and Nakajima (1973), Polymeropolous (1974, 1984), Hayashi and Kumagai (1975), Polymeropoulos and Das (1975) and Ballal and Lefebvre (1978, 1979, 1981a).

Another aspect of the combustion of aerosols, which has been actively investigated, is ignition and extinction. Work on this topic has been described by Polymeropoulos and Peskin (1969), Kapila, Ludford and Buckmaster (1975), Law (1975) and Pindera and Brzustowski (1984).

The explosion of aerosols of flammable liquids is considered in Chapter 17.

16.4.2 Burning of single droplets

The combustion of the individual liquid droplets of an aerosol has been the subject of a good deal of work, particularly in relation to spray combustion in gas turbines and rockets.

Work on this topic includes that by Godsave (1953), Hottel, Williams and Simpson (1955), Kobayasi (1955), Agoston, Wise and Rosser (1957), Bolt and Saad (1957), Wise and Agoston (1958), Aldred and Williams (1966), Eisenklam and Arulachanam (1966), Faeth (1967), Sioui and Roblee (1969) and Yule, Ereaut and Ungut (1983). Reviews are given by A. Williams (1973, 1990).

Research in this area includes work on: the formation of droplets by atomization and other mechanisms, and the size distribution and velocities of the droplets produced;

the evaporation of and the drag on the droplets; and the mass burning rate of the droplets.

The mass burning rate $\dot{m}_F$ of a liquid droplet is

$$\dot{m}_f = -\frac{d}{dt}\left(\frac{\pi}{6} d_L^3 \rho_L\right) \qquad [16.4.1]$$

where d_L is the diameter of the droplet and $\rho_L$is the density of the liquid. This equation can be rearranged to give

$$-\frac{d}{dt}(d_L)^2 = \frac{4\dot{m}_F}{\pi d_L \rho_L} \qquad [16.4.2]$$

It is found experimentally that

$$-\frac{d}{dt}(d_L)^2 = K \qquad [16.4.3]$$

where the constant K is known as the burning constant. This constant is therefore

$$K = \frac{4\dot{m}_F}{\pi d_L \rho_L} \qquad [16.4.4]$$

There are a number of correlations of the burning constant, predominantly for conditions of forced convection, as in spray combustion. One of the most widely used is that of Wise and Agoston (1958).

16.4.3 Flammability limits

Burgoyne and co-workers, as described above have studied the flammability limits of the aerosols of flammable liquids. Burgyone (1963) quotes early work by Haber and Wolff (1923), who obtained for the LFL the results shown in Table 16.22.

As already described, Burgoyne and Cohen (1954) found in their studies on tetralin a difference in behaviour between aerosols with a droplet diameter d_L less than 10 μm and those with a droplet diameter more than 40 μm. The LFLs were found to be 46 mg fuel/l of aerosol for $d_L < 10$ μm and 18 mg fuel/l of aerosol for $d_L > 40$ μm; for intermediate diameters the LFLs change linearly between these two concentrations.

For aerosols in which the droplet diameter is less than 10 μm the LFL of the liquid and vapour suspension is virtually the same as that of the substance wholly in vapour form at the somewhat higher temperature necessary for vaporization. Above a droplet diameter of 10 μm the lower limit of flammability decreases as the drop diameter increases.

Above a droplet diameter of 20 μm another phenomenon was identified as significant, namely the rate of sedimentation of the droplet. For this effect Burgoyne (1963) gives the following treatment. He defines a flame front concentration C_f that is related to the volumetric concentration C_v as follows:

$$\frac{C_f}{C_v} = \frac{V_f + V_a + V_s}{V_f + V_a} \qquad [16.4.5]$$

where C_f is the volumetric flame front concentration, C_v is the volumetric concentration, V_a is the downward velocity of the air, V_f is the upward velocity of the flame through the suspension and V_s is the sedimentation velocity of the drops relative to the air.

The LFL concentrations obtained by experiment were close to the flame front concentrations as defined by Equation 16.4.5. In some experiments with larger drop diameters the LFL measured was less than one-tenth of that for the equivalent vapour–air mixture. The burning velocity and the quantity of inert gas required for the suppression of flammability are also affected by large drop sizes.

In general, for flammable aerosols in air, it is found that for small droplet diameters the LFLs, measured as mass of fuel per unit volume of aerosol, are similar to those for vapour–air mixtures. Some values of the LFLs of vapours are quoted by Burgoyne (1963). For most of the substances which he lists the LFLs of the vapour lies in the range 0.04–0.10 g/l (or oz/ft^3). Further details are given in Section 16.2.

16.4.4 Minimum ignition energy

A method of obtaining the MIE of a dust cloud, which is also applicable to a vapour and an aerosol has been given by Ballal (1983b). Ballal has correlated MIEs for a number of mixtures of gases, vapours, liquid droplets and dusts with air at atmospheric pressure, the size of the liquid and solid particles being of the order of 50 μm. The correlation is in terms of the Spalding mass transfer number B:

$$B = \frac{q_{st}H + c_{pa}(T_g - T_b)}{L + c_p(T_b - T_s)} \qquad [16.4.6]$$

where c_p is the specific heat of the fuel, c_{pa} is the specific heat of air, H is the heat of combustion, L is the latent heat of vaporization, q is the mass ratio of fuel to air, and subscripts b, g, s and st denote the boiling point of the fuel, gas, the surface of the fuel and stoichiometric, respectively.

Figure 16.33 (a) gives an approximate relation between the MIE E_{min} and B for homogeneous and two-phase mixtures of the type described. For a more accurate estimate Ballal gives the MIE E_{min} as a function of the quenching diameter d_q:

$$E_{min} = \pi C_p \rho_a \Delta T d_q^3 \qquad [16.4.7]$$

Table 16.22 *Lower flammability limits of some vapours and mists in air (after Haber and Wolff, 1923)*

	Temperature (°F)	*Mist concentration* (oz/ft^3)	*Temperature* (°F)	*Vapour concentration* (oz/ft^3)
Petroleum 356–428°F	75	0.044	140	0.043
Tetralin	84	0.0409	212	0.0416
Quinoline	97	0.0662	230	0.064

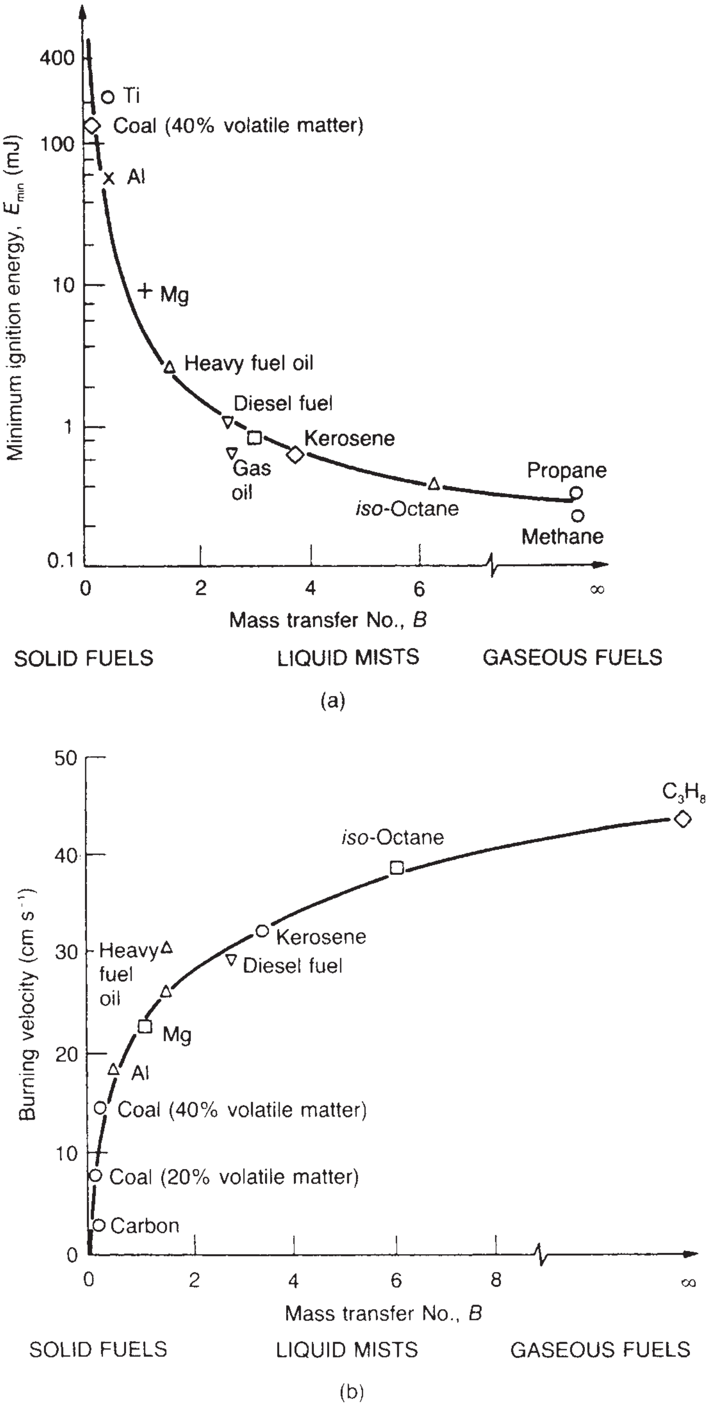

Figure 16.33 *Some properties of mixtures of air with flammable vapours, aerosols or dusts: (a) minimum ignition energy (after Ballal, 1983b) (Courtesy of Combustion and Flame); and (b) fundamental burning velocity (after Ballal, 1983a) (Courtesy of the Combustion Institute)*

with

$$d_{\mathrm{q}} = (8\alpha)^{\frac{1}{2}} \left\{ \left[\frac{C_3^3 \rho_{\mathrm{p}} D_{32}^2}{8C_1 f^2 (k/c_{\mathrm{p}}) \phi \ln(1+B)} + \frac{12.5\alpha}{S_{\mathrm{u}}^2} \right]^{-1} - \frac{9qC_1^2 \epsilon \sigma T_{\mathrm{p}}^4}{c_{\mathrm{p}} \rho_{\mathrm{p}} C_3^3 f D_{32} \Delta T_{\mathrm{st}}} \right\} \quad [16.4.8]$$

where c_{pg} is the specific heat of the gas, C_1 is the ratio of the surface mean area to the Sauter mean diameter, C_3 is the ratio of the volume mean diameter to the Sauter mean diameter, D_{32} is the Sauter mean diameter, f is the swelling factor of the fuel, k is the thermal conductivity of the fuel, S_{u} is the laminar burning velocity, α is the thermal diffusivity of the particle, ϵ is the emissivity of the particle, ρ is the density, ΔT is the temperature difference, σ is the Stefan–Boltzman constant, ϕ is the equivalence ratio and subscript p denotes fuel.

16.4.5 Burning velocity

Ballal (1983a) has also given a method of obtaining the laminar burning velocity of a dust cloud, which is also applicable to a vapour and an aerosol. Figure 16.33(b) gives an approximate relation between laminar burning velocity S_{u} and B for homogeneous and two-phase mixtures. For a more accurate estimate Ballal gives the laminar burning velocity as a function of the thickness δ_{r} of the reaction zone:

$$S_{\mathrm{u}} = \frac{\alpha \Delta T_{\mathrm{r}}}{\delta_{\mathrm{r}} \Delta T_{\mathrm{pr}}} \quad [16.4.9]$$

with

$$\delta_{\mathrm{r}} = \alpha_{\mathrm{g}}^{0.5} \left\{ \left[\frac{C_3^3 \rho_{\mathrm{f}} D_{32}^2}{8f^2 C_1 (c_{\mathrm{p}}/k)_{\mathrm{g}} \phi \ln(1+B)} + \frac{\alpha \Delta T_{\mathrm{r}}}{S_{\mathrm{g}}^2 \Delta T_{\mathrm{pr}}} \right]^{-1} - \frac{9qC_1^2 \epsilon \sigma T_{\mathrm{p}}^4}{c_{\mathrm{pg}} \rho_{\mathrm{f}} C_3^3 f D_{32} \Delta T_{\mathrm{r}}} \right\}^{-0.5} \quad [16.4.10]$$

where c_{pg} is the specific heat of the gas, S_{g} is the laminar burning velocity of the gases liberated from the particles, α_{g} is the thermal diffusivity of the gas, and subscripts f, g, pr and r denote the fuel, gas, pre-reaction zone and reaction zone, respectively.

These correlations of Ballal are subject to a number of qualifications, as discussed by the author and by Nettleton (1987), who nevertheless concludes that the approach is applicable to many practical situations. Nettleton quotes some typical ranges of the laminar burning velocity S_{u} in air. These are: $0.05 < S_{\mathrm{u}} < 0.2$ m/s for particulate suspensions; $0.2 < S_{\mathrm{u}} < 0.35$ m/s for fogs; $0.3 < S_{\mathrm{u}} < 0.4$ m/s for hybrid fog and vapour; and $S_{\mathrm{u}} < 0.5$ m/s for mixtures with gas or vapour. For stoichiometric mixtures of acetylene or hydrogen in air, $S_{\mathrm{u}} > 1.0$ m/s. For the estimation of turbulent burning velocity, Nettleton quotes Equation 16.3.45 as one in common use.

16.4.6 Chemical decomposition

If a condensed mist is formed from the saturated vapour of a liquid hydrocarbon of high boiling point, prolonged contact with a source of heat can result in the formation of cracking products such as hydrogen or acetylene, which reduce the LFL and increase the burning velocity and the quantity of inert gas required for the suppression of flammability.

16.5 Ignition sources

Selected references on ignition sources are given in Table 16.23.

Ignition models
English and Waite (1989); A.W. Cox, Lees and Ang (1990)

Some potential ignition sources on process plants include the following:

(1) flames;
(2) hot work;
(3) hot surfaces;
(4) hot particles;
(5) friction and impact;
(6) chemical energy;
(7) hot materials and gases;
(8) reactive, unstable and pyrophoric materials;
(9) engines;
(10) vehicles;
(11) lightning;
(12) radio frequency (RF) emissions;
(13) smoking;

(14) arson and sabotage;
(15) self-heating;
(16) static electricity;
(17) electrical equipment.

Each of the above sources can cause ignition of a flammable gas–air mixture outside the plant.

Insofar as they can occur inside the plant, these sources can also cause ignition of a flammable gas–air mixture inside it. In addition, ignition of a flammable gas–air mixture inside the plant may occur due to:

(18) autoignition
(19) compression effects.

Table 16.24 gives a more detailed breakdown of these ignition sources.

These ignition sources are discussed in this section, with the exception of self-heating, static electricity and electrical equipment, which are considered in Sections 16.6, 16.7 and 16.8, respectively. Information on the most frequent sources of ignition was given in Table 2.11.

The modelling of ignition sources for the purpose of hazard assessment is considered in Section 16.10.

Many potential sources of ignition are associated with activities. These need to be controlled by a permit-to-work system. This aspect is discussed in Chapter 21.

The area of flammable hazards should be fenced off and strict security enforced on persons entering the area. In particular, matches and cigarette lighters should be given up on entry. Equipment brought into the area should be suitable for use within it.

16.5.1 Flames

The flames of burners in fired heaters and furnaces, including boiler houses, may be sources of ignition on process plants. The source of ignition for the explosion at Flixborough may well have been burner flames on the hydrogen plant. The flame at a flare stack may be another source of ignition. Such flames cannot be eliminated. It is necessary, therefore, to take suitable measures such as care in location and use of trip systems.

Burning operations such as solid waste disposal and rubbish bonfires may act as sources of ignition. The risk from these activities should be reduced by suitable location and operational control.

Smoldering material may act as a source of ignition. In welding operations it is necessary to ensure that no smoldering materials such as oil-soaked rags have been left behind.

Small process fires of various kinds may constitute a source of ignition for a larger fire. The small fires include pump fires and flange fires; these are dealt with in Section 16.11.

Dead grass may catch fire by the rays of the sun and should be eliminated from areas where ignition sources are not permitted. Sodium chlorate is not suitable for such weed killing, since it is a powerful oxidant and is thus itself a hazard.

16.5.2 Hot work

Hot work, such as welding, cutting and grinding activities, is a potential source of ignition. In welding, for example, this applies not only to the welding flame or arc, but also to material ignited by the welding.

Table 16.24 Some ignition sources on process plants

A General	
Flames	Flare: elevated or ground level flare; full flare or pilot condition; incinerator Furnace: natural or forced draught furnace Fired heater Boiler Laboratory heater: bunsen burner; furnace Personnel heater: solid fuel or electrical fire Burning operations: burning rubbish; burning during demolition Firing: explosion for demolition; other explosives Warning flare: hazard warning flare; fog warning detonator Accidental fire Hot material: brand; hot particles
Hot work	Welding: arc welding; oxyacetylene welding Cutting: oxyacetylene cutting Grinding Hot tapping
Hot surface	General: vessel and pipework Machinery: engines; turbines; exhausts Laboratory equipment: hot plate; oven Hot particles: soot
Friction and impact	Impact: hand tool; power tool; boot stud; loosening of caked material; moving vehicle Rubbing: belt, conveyor, roller; brake, clutch on machinery; skidding of road or rail tanker
Hot material or gas	Discharged material: hot ash from boiler; used catalyst; hot process material Hot gas
Pyrophoric, reactive and unstable materials Engines	Ingestion of flammable: petrol, diesel or gas engine mixture Chemical effects Friction and impact: thermite reaction (see above) Instrument: catalytic element
Smoking	Means of lighting: matches; lighter Item smoked: cigarette; cigar; pipe
Vehicles	General vehicles: petrol, diesel or electrically driven Crane Forklift truck Helicopter Aircraft
Atmospherics	Lightning
Radio frequency transmission	See Subsection 16.5.12

Arson, sabotage	Fire Explosion
Compression	Ingestion of flammable mixture: compressor; high speed blower
Mechanical rupture	Spark associated with rupture giving rise to release
Self-heating	Dust layer Oil soaked lagging See also Section 16.6
Static electricity	See Section 16.7
Electrical	Machinery: motors, alternators, dynamos, converters Fixed equipment: contact devices such as switches, relays, contactors Fixed equipment—failures: failure of protective equipment; failure causing arcing Insulator: arcing across spark gaps at high voltage insulators Wiring: loose connection; poor joint; damaged wiring Cable: broken cable; damaged cable; water ingress Batteries: connecting up damaged battery Instrument Heating tape Lighting Fault current conductor: poor joint Portable equipment: meter; radio; TV; camera; hearing aid Ground movement: sparking due to ground movement such as earthquake or subsidence
B Internal	
Auto-ignition[a]	
Compression	Pump: compression by pumping against closed valve Hammer blow: compression by hammer blow in pipeline Liquid slug: compression by liquid slug Air bubbles: compression of air bubbles in liquid
Reactive, unstable material	Pyrophoric material Incompatible material: material which reacts with material of construction
Catalytic material	
Hot material	Hot catalyst; hot dust; hot gas
Hot surface	External hot work Rotating machinery: ingestion of tramp metal Distressed machinery: hot bearings; hot particles Lamp: damaged wander lamp
Electrical	Heater – failure: failure causing overheating
Self-heating	See Section 16.6
Static electricity	See Section 16.7

---

[a] A flammable mixture can undergo a combustion reaction outside the normal flammability limits. These limits apply essentially to propagation rather than ignition as such.

Hot work accounts for an appreciable proportion of ignition incidents. In the vast majority of cases the material ignited is in the equipment being worked on. It is relatively rare for hot work to be the source of ignition of a vapour cloud.

It is necessary to exercise close control of hot work by training, supervision and use of a permit system.

16.5.3 Hot surfaces

Surfaces of plant equipment are frequently hot and some may be potential ignition sources. Hot surfaces include:

(1) hot process equipment;
(2) distressed machinery.

Much process equipment operates at high temperature. Although the equipment is usually lagged, there may be some surfaces, which could be a source of ignition.

Machinery in distress, such as a pump with a faulty bearing, may run hot and this hot spot is a potential source of ignition.

Traditionally, the AIT was taken as the limiting temperature above which a hot surface might ignite a gas mixture. Codes for HAC have tended to quote AITs as hot surface temperature limits.

It has long been appreciated, however, that there is a difference between the hot surface temperature that will ignite a flammable gas–air mixture and the AIT. This temperature excess depends on the conditions. Relevant factors include the fuel and fuel concentration, the material, area and geometry of the surface, and the fluid flow and heat transfer conditions.

Hot surface ignition has been the subject of a good deal of work and details are given in Section 16.3. This work consistently shows that an appreciable temperature excess is necessary for ignition to occur. It also demonstrates that the temperature excess required increases as the hot surface area decreases. The necessary temperature excess also increases as the gas velocity increases. One effect of increasing the gas velocity is to reduce the residence time of the gas and this may then fall below the ignition induction period.

Industrially oriented work by Husa and Runes (1963) indicated that for hot surfaces in the open air a temperature excess of several hundred degrees was required to give ignition. The systems investigated were, however, not well defined by the standards of more recent work.

Practical guidance is given in API Publ. 2216: 1991 *Ignition Risk of Hydrocarbon Vapors by Hot Surfaces in Open Air*. This draws attention to the work of Hilado and Clark (1972b) and Goodall and Ingle (1967) on the effects on ignition of the induction time and of gas velocity, respectively, and the work of Husa and Runes. It states that as a rule of thumb, and based on open air tests, ignition by a hot surface should not be assumed unless the surface temperature is at least 200°C above the normally accepted minimum ignition temperature.

A hot surface is a potential ignition source inside as well as outside the plant. The rule of thumb just quoted is not intended to apply in this case, although induction time and gas velocity are again relevant factors.

16.5.4 Hot particles

Another form of hot surface is a hot particle. A hot particle that is common on plant is soot from burners or from a flare. Hot soot from chimneys may be a source of ignition. It is a particularly important potential source of ignition on ships.

16.5.5 Friction and impact

Impact, friction and frictional impact can be a source of ignition for a flammable gas–air mixture. A review has been given by F. Powell (1969). An account of some of the fundamental phenomena is given in Section 16.3.

Essentially, incendive sparks caused by impact and friction are due to the generation of a surface hot spot. A falling object can give an incendive spark. The temperature rise may correlate only weakly with the kinetic energy but can be sufficient to cause ignition. It is normal to adopt procedures to prevent damage to the plant by falling objects. However, dropping of objects can occur which may not be controlled by these measures such as drums, hand tools, etc.

Ignition by a falling object is likely to be most serious in a space that already contains a flammable atmosphere. Objects such as tank washing machines or cathodic protection anodes in ships' cargo tanks illustrate this. Cigarette lighter flints can also cause a mechanical spark if the lighter is dropped.

One situation that is liable to cause ignition in frictional impact is where rusty steel with an aluminium smear is hit by a hard object. Under these conditions the thermite reaction occurs. This reaction, which can reach a temperature of 3000°C, is an effective ignition source. The source of the aluminium may be aluminium paint or the impacting object itself.

Work by Kingman, Coleman and Rogowski (1952) has shown that oil bound paints do not give sparks unless preheated to 150°C. Subject to avoidance of such heating, therefore, such paints may be used on steel in hazardous areas.

The striking of quartzite materials, including concrete containing sand, by a metal tool is another situation liable to give incendive sparks. A report by the Department of Scientific and Industrial Research (DSIR) (1963) gives details of fires attributed to frictional sparks, most of which involved various metals and concrete or stone.

An aspect that has received a good deal of attention over the years is the use of 'non-sparking tools'. Materials used in such tools characteristically do not readily oxidize and have high thermal conductivity.

Reviews of the use of non-sparking tools have been given by F. Powell (1969) and Cross and Fairer (1982). Essentially, some investigators have concluded that regular steel tools are no more hazardous than non-sparking tools, while others believe there is a benefit to safety in the use of non-sparking tools. Anfenger and Johnson (1941) performed experiments on the incendivity of sparks produced by steel on a grinding wheel, which ignited carbon disulfide but not petrol vapour.

On the basis of this work and practical experience the American Petroleum Institute (API) in *Sparks from Hand Tools* (1956) concluded that there is no significant increase in safety from the use of non-sparking tools. API Publ. 2214: 1989 *Spark Ignition Properties of Hand Tools* states that nothing essentially new has been learned since the 1956 publication and that the fire records of more and more companies which have never used, or have ceased to use, non-sparking tools amply confirm the position then taken. Non-sparking hand tools are discussed further in Chapter 21.

Other workers such as those at the DSIR (1963) and Riddlestone and Bartels (1965) draw attention to ignitions caused by the striking of metals on concrete or stone and point out that it is in this situation that the ignition risk is significant, and that metals used in non-sparking tools are also liable to give ignition in this case. For this rather different reason they conclude that non-sparking tools offer little benefit.

Another point that detracts from the potential benefit of non-sparking tools is that they tend to be soft, so that hard particles can become embedded in the tool.

Other workers have seen a benefit in the use of non-sparking tools. On the basis of impact and grinding experiments Fischer (1965) recommends the use of steel tools for work where there may be Class I gases, but not where there may be Class II gases.

Certain gases such as hydrogen, acetylene and carbon disulfide are particularly sensitive to ignition by impact and friction. If such a gas is present, there is a potential ignition risk in the use of any tool. Non-sparking tools are considered further in Chapter 21.

A study of ignitions by impact, friction and frictional impact has been made by Billinge (1981). He classifies these ignitions as due to impact, rubbing or cutting and grinding, and as high, medium or low energy. The individual incidents are shown in Table 16.25 and the analysis of these incidents is given in Table 16.26.

16.5.6 Chemical energy

There are several forms of chemical energy that may give ignition. They include (1) the thermite reaction, (2) reactive, unstable and pyrophoric materials and (3) catalytic instruments. The thermite reaction is obtained from aluminium smears on rusty steel, as described above. Reactive, unstable and pyrophoric materials are considered below.

Some instruments contain catalytic elements, which measure the temperature rise resulting from combustion of a flammable gas. Generally, these instruments (such as flammable gas detectors) are intended to operate in hazardous areas and are therefore designed so that they should not act as an ignition source.

16.5.7 Hot materials and gases

Hot materials such as hot ash, hot used catalyst or hot process material, and hot gases may, in principle, act as ignition sources. Generally, however, operations involving such hot materials are excluded from hazardous areas and they do not figure as a significant ignition source.

Table 16.25 *Some incidents involving friction and impact ignition relevant to the process industries in the period 1958–78 (after Billinge, 1981): details of incidents (Courtesy of Fire Prevention Science and Technology)*

A Gases and vapours

Fuel	*Cause*	*Classification*
Group IIA		
Petrol	Spark from hammer; hammer on steel clasp; shoe nail on concrete floor; boot nail on concrete floor; dropped tool or steel tipped boot on concrete floor; dropped tool on floor; screwdriver punched through drum lid	Low energy impact
	Falling drum; dropped can of petrol on floor; impact between drums; impact between car and petrol pump; impact between cars	Medium energy
	Sparking from brakes of rail tank wagon	Medium energy Rubbing
	Collision between ships	High energy impact
	Skidding overturned road tanker (×3); barge ripped open by bridge fender	High energy rubbing
Jet fuel	Tanker scraped lock wall	
Crude oil vapour	Magnesium anode impact; pipeline coupling falling onto ship's deck	Medium energy impact
	Collision between ships	High energy impact
Oil vapour	Defective pump	Medium energy rubbing
	Ferrous metal in aluminium polishing and grinding machine	Medium energy cutting and grinding
LPG	Steel cylinders with aluminium smears	Low energy impact
	Crashing rail wagons	High energy impact
Liquefied butane	Crashing road tanker	High energy impact
Propane	Valve knocked off gas tank	Medium energy impact
	Impact of aluminium wrench on pipe joint	Low energy impact
Pentane	Metal object in chopping machine	Medium energy impact
Benzene	Collapsing metalwork	Medium energy impact
Natural gas	Tool dropped down oil well	Medium energy impact
	Mechanical shovel fractured gas main	High energy impact
Methanol	Impact between nozzle and wall	Medium energy impact
	Tramp metal in grinding process	Medium energy cutting and grinding
	Belt rubbing on copper tube	Medium energy rubbing
Ethanol	Friction in centrifuge	Medium energy rubbing
	Impact between digger and center cone of centrifuge	Medium energy impact
	Grindstone sparks	Medium energy cutting and grinding
Hexane/ethanol	Friction in centrifuge	Medium energy rubbing
Isopropanol	Impact of drum on ground	Medium energy impact
Acetone	Impact of drum on ground	Medium energy impact
Acrylic paint solvent	Defective extractor motor fan	Medium energy rubbing
Mixed solvent vapours	Truck ran over drum of solvent	Medium energy rubbing
	Impact between drum or lighter and floor	Medium energy impact
Ethyl chloride	Impact between metal ditch covers	Medium energy impact
Vinyl acetate	Impact between filling nozzle and loading aperture	Medium energy impact
Group IIB		Low energy impact
Ethylene	Unscrewing valve from pipe	Medium energy
	Sparks from bursting tire	
		cutting and grinding
Coke oven gas	Collapsing shelf holding gas meter	Medium energy impact
Group IIC		
Hydrogen	Hammer hitting bolts on steam line; spark between cylinder cap and tool	Low energy impact
	Drilling pipe; abrasive cutting and grinding of pipe	Medium energy cutting and grinding
Acetylene	Moving or opening drum of carbide; cylinder fell from lorry; feed cone dropped into hopper of carbide	Medium energy impact

Table 16.25 *(continued)*

	Sparks from grinding process	Medium energy cutting and grinding
Carbon disulfide	Impact between brass rod and caked material	Low energy impact
Various vapours and solvents	Gear wheels not properly meshed; friction in centrifuge; falling metalwork; dismantling metalwork; agitator fell into mixing tank	Medium energy impact
	Cellulose film rubbing on roller	Medium energy rubbing
	Cutting pipe with (mechanical) hacksaw	Medium energy cutting and grinding
B Powders and dusts		
Foodstuffs		
Grain dust	Nut, bolt or stone in suction pipe; metal object in hopper machine	Low energy impact
	Impact of pulley with wall; foreign body in mill	Medium energy impact
Sugar dust	Wood screw fell into mill	Medium energy impact
	Elevator buckets rubbing on guides	Medium energy rubbing
Peppercorn dust	Foreign body in mill	Medium energy impact
Flour dust	Overheated bearing (×3); overheated motor	Medium energy rubbing
Flour and grain dust	Overheated pulley and belt drive	Medium energy rubbing
Corn dust	Friction between belt drive and pulley guard	Medium energy rubbing
Organic chemicals		
Organic powder	Foreign body in mill	Medium energy impact
Niacin dust	Bolt in mill	Medium energy impact
Phenolic molding powder	Spark from unknown agent	Medium energy impact
	Spark from grinding machine	Medium energy cutting and grinding
Cellulose nitrate dust	Chipping concrete with air hammer	Medium energy impact
Dinitrosopentamethylene tetramine	Impact of fork lift truck with fibre container	Medium energy impact
Diazonium salt	Hammering wedges	Low energy impact
Sodium picramate	Impact of drum on floor	Medium energy impact
Inorganic chemicals		
Giant gel 40% dope/sulfur	Aluminium tamp punch on steel grating bars	Low energy impact
Ammonium perchlorate	Scraping with spatula	Low energy impact
	Spatula left in mixer	Medium energy rubbing
	Friction from beryllium cutting knives	Medium energy cutting and grinding
Thermite	Cleaning edge runner mill	Low energy impact
Aluminium powder	Steel tool on rusty lid of container	Low energy impact
Sulfur	Mechanical shovel striking metal deck; mechanical impact of crane grab with bulkhead; metal grabs striking ships structure; frictional spark from crane grab; mechanical shovel hitting side of ship's hold; steel tub falling into ship's hold	Medium energy impact Medium energy impact
Windproof matches	Carton of matches fell 2 m	
Rocket propellant	Metal–metal contact in mixer	Medium energy rubbing
Pyrotechnic mixture	Metal–metal contact in mixer	Medium energy rubbing
Zirconium dust	Sparks from grinding steel	Medium energy cutting and grinding
Powder	Hopper fell and impacted tram car	Medium energy impact
Oil mist	Overheated pump	Medium energy rubbing

16.5.8 Reactive, unstable and pyrophoric materials

Reactive, unstable or pyrophoric materials may act as an ignition source by undergoing an exothermic reaction so that they become hot. In some cases the material requires air for this reaction to take place, in others it does not.

The most commonly mentioned pyrophoric material is pyrophoric iron sulfide. This is formed from reaction of hydrogen sulfide in crude oil in steel equipment. If conditions are dry and warm, the scale may glow red and act as a source of ignition. Pyrophoric iron sulfide should be damped down and removed from the equipment. No attempt should be made to scrape it away before it has been dampened.

A reactive, unstable or pyrophoric material is a potential ignition source inside as well as outside the plant.

16.5.9 Engines

Engines on process plants are another ignition source and tend to figure significantly.

One type of engine in use for a variety of purposes is the diesel engine. Guidance on the use of diesel engines in relation to hazardous areas is given in a number of codes. One is *Guidelines on Protection of Diesel Engines for Hazardous Zone 2 Areas* (Lloyd's Register, n.d.). Another is *Recommendation for the Protection of Diesel Engines Operation in Hazardous Areas* (Oil Companies Materials Association, 1977).

A discussion of diesel engines in this context has been given by Sokolov (1989), who considers the various potential ignition sources on the engine and the steps that can be taken to prevent ignition by these sources.

One potential ignition source on a diesel engine is the hot gas. Exhaust gas temperatures can be as high as 500°C. Ignition by hot exhaust gas involves turbulent stream ignition, which can occur at a temperature less than the average temperature of the gas mixture. A safety factor is therefore required. Codes typically recommend that the temperature of the exhaust gas should not exceed 0.6–0.8 of the AIT of any flammable gas that may be present. Sokolov quotes the following:

Gas	*Ignition temperature* (°C)	*Safe exhaust gas temperature* (°C)
Methane	595	396
Propane	470	313
Natural gas	482–650	320
Condensate	275	183

Another important part of the engine is the induction and exhaust systems. These systems are designed to avoid detonation but to handle deflagration. There are minimum design pressures which tend to lie in the range 8–10 bar, that for the United Kingdom being 10 bar and that for the United States 8.6 bar. Induction and exhaust systems are provided with flame arresters; exhausts are provided with spark arresters.

Crank cases are another feature of a diesel engine that requires protection.

The preferred start-up arrangements for the engine in a hazardous area are pneumatic, hydraulic or manual rather than electrical.

Diesel engines are generally equipped with shut-down devices and alarms activated by overspeed and by failures of the various subsystems. Depending on the application, the device may act to cut off the fuel or to shut off the air intake and effect gradual gas path deflection.

16.5.10 Vehicles

A chemical plant may contain at any given time considerable numbers of vehicles. These vehicles are potential sources of ignition. Instances have occurred in which vehicles have had their fuel supply switched off, but have continued to run by drawing in, as fuel, flammable gas from an enveloping gas cloud. The ignition source of the flammable vapour cloud in the Feyzin disaster in 1966 was identified as a car passing on a nearby road (Case History A38). It is necessary, therefore, to exclude ordinary vehicles from hazardous areas and to ensure that those that are allowed in cannot constitute an ignition source.

Vehicles that are required for use on process plant include cranes and forklift trucks. Various methods have been devised to render vehicles safe for use in hazardous areas and these are covered in the relevant codes.

16.5.11 Lightning

Lightning is another potential ignition source on process plants. Information on lightning and on lightning protection is given in *Installation of Lightning Protection Systems* (NFPA 780) and *Lightning* (Golde, 1977a).

Lightning has traditionally been a significant ignition source for storage tank fires. A major incident of this kind occurred at Beaumont, Texas, in 1970 (Case History A46).

Guidance on lightning protection is given in BS 6651: 1985 *Code of Practice for Protection of Structures against Lightning*.

16.5.12 Radio frequency transmissions

The possibility exists that RF transmissions from strong sources such as large military transmitters may act as an ignition source on process plants. This has been recognized for some time as instanced by the existence of a British

Standard BS 4992: 1974 *Guide to Protection Against Ignition and Detonation Initiated by Radio Frequency.*

A situation where concern was expressed about such possible interaction arose in Britain in the late 1970s in respect of the transmitter at Crimond operated by the Royal Navy and located about 4 miles from the natural gas terminal at St Fergus. The naval transmitter responded by reducing its power output.

Studies of this hazard were undertaken by a number of workers (A. Hall and Burstow, 1980; A. Hall and Loveland, 1980; Burstow *et al.*, 1981; Howson, Excell and Butcher, 1981; Rosenfeld *et al.*, 1981) and the Health and Safety Executive (HSE) published two reports: *Assessment of the Hazard from Radio Frequency Ignition at the Shell and Esso Sites at Braefoot Bay and Moss Morran, Fife* (HSE, 1978a) and *Report of the Steering Committee on Radio Frequency Ignition Hazards at St Fergus, Scotland* (HSE, 19790).

The British Standard guidance was revised and issued as BS 6656: 1986 *Prevention of Inadvertent Ignition of Flammable Atmospheres by Radio-frequency Ignition*, and revised again in 1991.

The conditions for RF ignition of a flammable mixture to occur are (1) electromagnetic radiation of sufficient intensity, (2) a structure capable of acting as a receiving aerial and (3) a mechanism for creating an incendive spark.

The transmitter may be fixed or mobile. Mobile transmitters include vehicles, ships and aircraft. The standard give details of typical transmitter frequency ranges and power outputs. Transmission may be continuous wave (CW) or modulated. The latter includes pulsed radar.

The degree of hazard depends on the frequency of the transmission. The hazardous range of interest is 15 kHz to 35 GHz. There is little hazard at frequencies below 15 kHz. For frequencies below 30 MHz the most efficient receiver is the loop configuration. At higher frequencies all structures are large compared with the wavelength. A part of a structure may behave as an efficient aerial and is then treated as a long dipole. An aerial can concentrate the power in a particular direction and is said to have gain in that direction.

The structures primarily considered in BS 6656: 1991 are loop-type structures and vertical structures. Some typical loop-type structures are illustrated in Figure 16.34. A loop structure has maximum efficiency and is self-resonant when its internal perimeter is about half one wavelength, but structures with a smaller perimeter can be brought to resonance if there is a discontinuity with stray capacitance across it. Cranes are particularly efficient receivers in this context and require particular attention.

For any potential discontinuity in the structure it is possible to determine the maximum extractable power given (1) the structure perimeter, (2) the transmission frequency and (3) the incident field strength.

Vertical structures include vents, flares and columns. Free-standing structures of this kind are not classed as among the more efficient receivers, since even a concrete base has a low impedance path to ground. They can generally be disregarded, except where the vertical structure is part of a loop.

An RF discharge occurs most readily when two surfaces are drawn apart, thus giving a break-spark. Discharges across a fixed gap are not considered to be a significant problem. It is activities such as maintenance and handling and phenomena such as flexing and vibration of pipe work or thermal expansion of structures, which are liable to give rise to an incendive discharge.

The factor determining RF ignition is the thermal initiation time. For times less than this ignition is governed by the discharge energy, and for times greater than this it is governed by its power. The thermal initiation times are approximately 100 μs for methane and ethylene and 20 μs for hydrogen, which are representative of the Class IIA, IIB and IIC gases, respectively. The standard gives ignition criteria for continuous transmissions and for pulsed radar transmissions.

The potential RF ignition hazard exists only in a few locations. There are few reported incidents of such ignition. BS 6656: 1991 adopts a graded approach to assessment of the hazard. An initial assessment is used for screening and a full assessment is undertaken only if a potential hazard is found to exist.

The initial assessment is based on the search areas given in Table 16.27 and proceeds as follows. The search area around the plant is determined from the table. If there is no transmitter within the search area, there is no hazard. If there is a transmitter with the search area, a check is made as to whether the plant is within the vulnerable zone of the transmitter. The standard gives information on the vulnerable zones for various types of transmitter. If the plant is within the vulnerable zone of a transmitter, a full assessment should be undertaken.

BS 6656: 1991 gives the procedures for a full assessment, including: a flow chart for a theoretical assessment and one for an assessment based on plant measurements; methods of taking measurements; methods of performing the calculations; and worked examples.

If a hazard exists, the principal countermeasures are (1) bonding, (2) insulating, (3) reducing the RF efficiency of structures and (4) de-tuning of structures. Typical applications where bonding might be used are where thermal expansion may result in intermittent contacts and across a pair of flanges prior to their parting in maintenance work. Bonding to ground is not suitable. Insulation may sometimes be used where bonding is impractical; it is a possible solution for intermittent contact by thermal expansion. The RF efficiency of a structure may be reduced at the design stage by altering the internal perimeter. Other measures for reducing efficiency include breaking the loop into smaller sections by the use of conductors and covering the entire area of the loop with a sheet of metallic mesh bonded to the structure at points around the perimeter. If there is one major transmission frequency causing the problem and other measures are not practical, it may be possible to detune the structure by connecting to it reactive components.

Special cases considered in the standard include cranes, mobile and portable transmitters, ships and offshore platforms. The Orford Ness transmitter is accorded special treatment.

16.5.13 Smoking

Smoking and smoking materials are potential sources of ignition. Ignition may be caused by a cigarette, cigar or pipe or by the matches or lighter used to light it. A cigarette itself may not be hot enough to ignite a flammable gas–air mixture, but a match is a more effective ignition source.

It is normal to prohibit smoking in a hazardous area and to require that matches or lighters be given up on entry to that area. The 'no smoking' rule may well be disregarded, however, if no alternative arrangements for smoking are

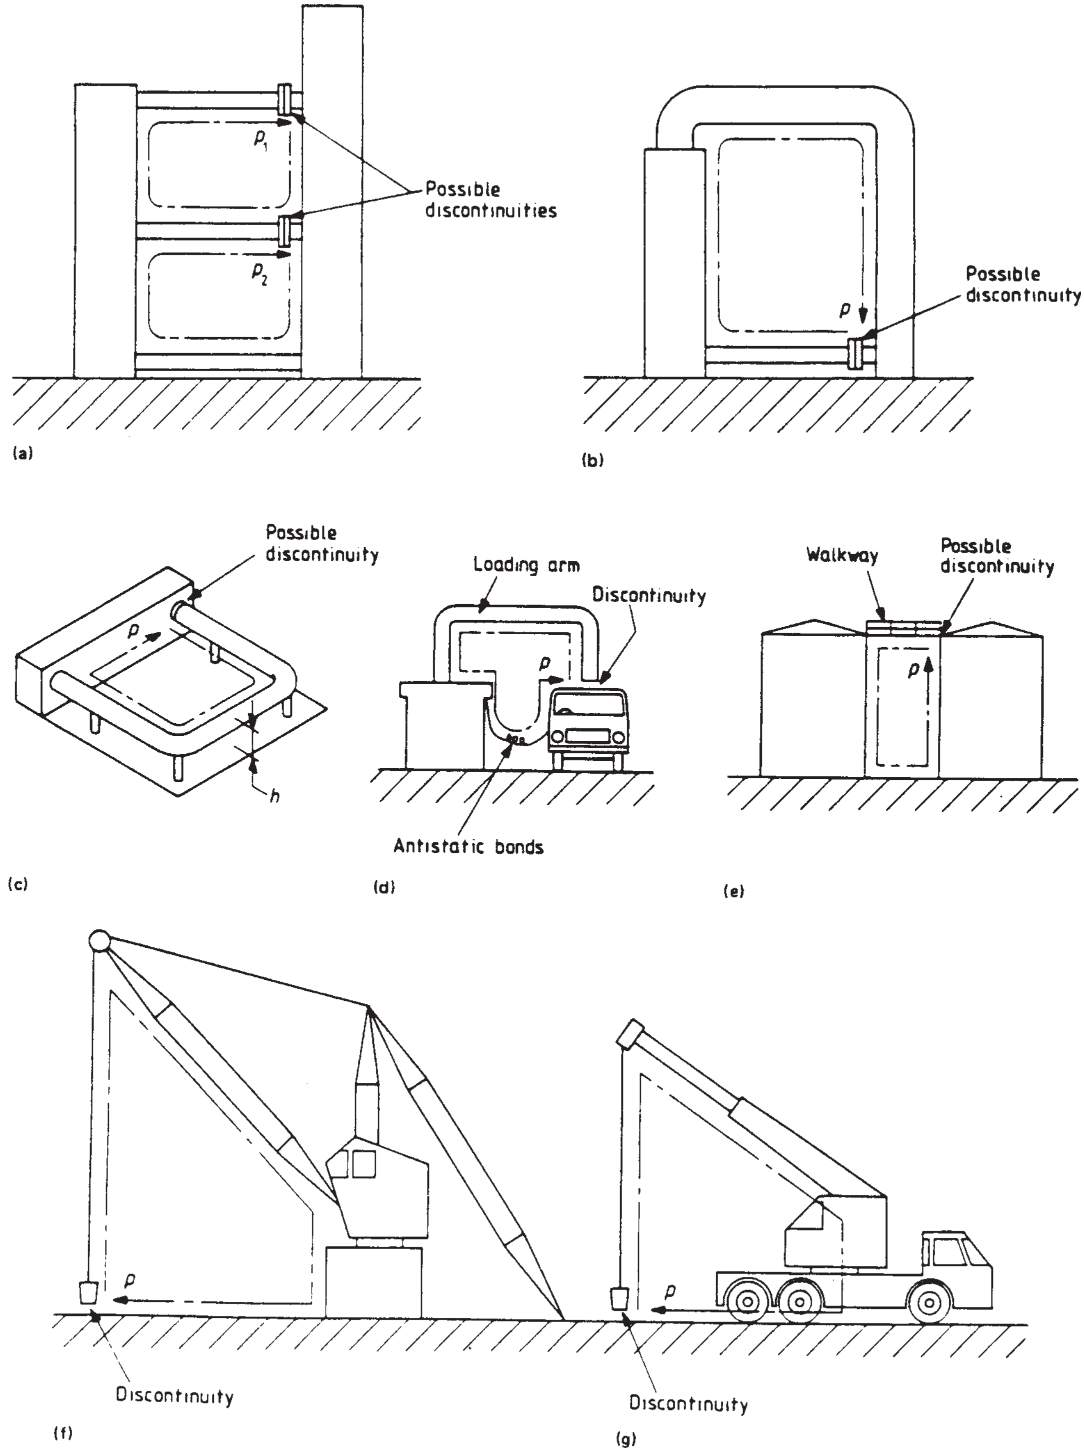

Figure 16.34 *Some typical loop-type structures for RF ignition (BS 6656: 1991): (a) loop formed by columns and pipes; (b) loop formed by columns and pipes; (c) horizontal loop; (d) tanker loading facility; (e) storage tanks; (f) fixed crane; and (g) mobile crane, h, Height of loops; p, internal perimeter of loop (Courtesy of the British Standards Institution)*

Gas group	*Maximum radius* (m)	
	All loop structures of inside perimeter ≤ 40 *m and horizontal loops of height* ≤ 5 *m*	*All other loop structures*
I or IIA	4,100	11,500
IIB	5,200	14,200
IIC	6,500	17,500

[a] Table does not apply to locations to the seaward side of Orford Ness, Suffolk.

provided. It is regarded as desirable, therefore, to provide a room where it is safe to smoke, though whether this is done is likely to depend increasingly on general company policy with regard to smoking.

16.5.14 Arson and sabotage

A source of ignition, which cannot be ruled out, is arson. Information on the frequency of arson as a source of ignition was given in Table 2.11. While arson is probably a less important cause of fires in the process industry than of fires generally, it should nevertheless be considered. Security in relation to arson is discussed in Chapter 20.

16.5.15 Autoignition

Strictly, ignition of a bulk flammable gas–air mixture by heating the mixture to its AIT is the alternative to ignition by a local ignition source. It is convenient, however, to deal with it at this point.

Heating of the bulk gas–air mixture outside the plant will occur by contact with a hot surface, as described above. Autoignition as such may therefore be regarded as a form of ignition, which occurs inside the plant.

The autoignition may occur inside the plant at essentially atmospheric pressure or at some higher pressure. If, however, the heating occurs due to compression, the phenomenon is one of compression ignition, which is described below.

16.5.16 Compression effects

A mixture of flammable gas and air may be heated to its AIT by compression. This effect is often referred to as the diesel effect. There are a number of conditions in process plant that can give rise to such compression.

Compression ignition is described in Section 16.3. The point was made there that, given a homogeneous mixture, such autoignition is not restricted to the normal flammability range.

Compression of a mixture of flammable gas and air may be caused by pumping against a closed valve, by water hammer in a pipeline or by a liquid slug travelling down a line.

A case history involving compression ignition in which a mixture of flammable gas and air was compressed by a pump pumping against a closed valve is described by Anon. (LPB 19 1978, p. 24). The pump had a nominal head of 30 m. Subsequent tests showed that pressure oscillations occurred in the trapped gas, which were up to eight times higher than the equilibrium head of the pump.

Another form of compression ignition can occur due to compression of air bubbles in a flammable liquid. The temperature rise inside such bubbles can be high.

16.6 Self-heating

Self-heating, or spontaneous combustion, of a solid material is generally a process of slow oxidation. Material undergoing self-heating may act as a source of ignition or it may give rise to a fire or explosion. The topic of thermal explosion and self-heating has many ramifications beyond the self-heating of solid materials. These other aspects are considered in Section 16.3.

Early work on self-heating was done by Frank-Kamenetsky (1955) and by Semenov (1935). P.M. Thomas and Bowes, both separately and together, have published a series of treatments (e.g. P.M. Thomas, 1958; P.M. Thomas and Bowes, 1961a, 1967; Bowes, 1976). The subject has been reviewed in *Self-heating* (Bowes, 1984) and by P. Gray and Lee (1967b). Application of the theory to process plant problems has been discussed by Bowes (1976).

Selected references on self-heating are given in Table 16.28.

16.6.1 Self-heating in industrial processes

Materials in process, storage or transport may undergo self-heating. The self-heating is due to the exothermic reaction of slow oxidation of the material. If conditions are critical, this self-heating results in ignition. Examples are materials handled in process equipment such as driers, materials stored in piles in warehouses or in the open, or materials transported in large containers as in ships. A well-known example is the spontaneous combustion of coal stored in piles on the ground.

In some cases the hazard is intensified by the fact that the material enters the storage relatively hot. This can occur, for example, with material that has just been passed through a drier.

Unstable materials may also undergo an exothermic reaction so that self-heating occurs.

Self-heating is liable to occur in oil-soaked lagging. In this case it is the oil, which undergoes oxidation. Self-heating may also occur in dust layers. In both cases the smoldering material may then act as an ignition source.

Self-heating can also occur in oil rags left on steam pipes, in dirty cotton waste put in a boiler suit pocket, or in damp clothing stowed away in a locker.

The substance that undergoes reaction must be reactive and may be bulk solid such as coal or a reactive substance on a substrate such as oil-soaked lagging.

16.6.2 Self-heating incidents

Most incidents due to self-heating arise in the kind of situations just described. Usually they do not have dramatic consequences. This is not always so, however.

In 1987, a severe explosion and fireball occurred at the BP Chemicals EO plant at Antwerp (Case History A115). The cause of the explosion was identified as the decomposition of EO in the purification column. It was concluded that the most probable cause of the explosion was a leak of EO into the insulation of the column, leading to self-heating which ignited the escaping EO.

In 1989, the BASF EO plant at Antwerp suffered two severe explosions, each accompanied by a fireball (Case History A122). The first explosion occurred in a column

separating EO and acetaldehyde. The investigation found that a small leak of EO had probably led to an accumulation of auto-oxidizable polyethylene glycols in the insulation of the column. Self-heating occurred in the insulation. Although the heat released would not have been enough to cause decomposition of the EO flowing past on the inside of the column, it was concluded that decomposition occurred at a section of pipe work where the gas was stagnant.

16.6.3 Self-heating process

If self-heating occurs, the occurrence of a thermal explosion depends on the heat balance in the solid. The heat balance is illustrated in Figure 16.35 (after Semenov). The rate of heat release is a function of the temperature as shown in curve A. Over the lower temperature range the reaction is rate limited and the reaction rate, and hence the heat released, rises rapidly. The rise is often governed by an exponential relation, and in particular by the Arrhenius equation. Over the higher temperature range the rate becomes diffusion limited and increases only weakly with temperature, so that the reaction rate and the heat released then increase relatively slowly.

The heat removed is approximately proportional to the temperature difference between the solid mass, or pile, and the surrounding medium. A series of lines can be drawn corresponding to different effective heat transfer coefficients. Line Bl is tangential to curve A at point 1. For the

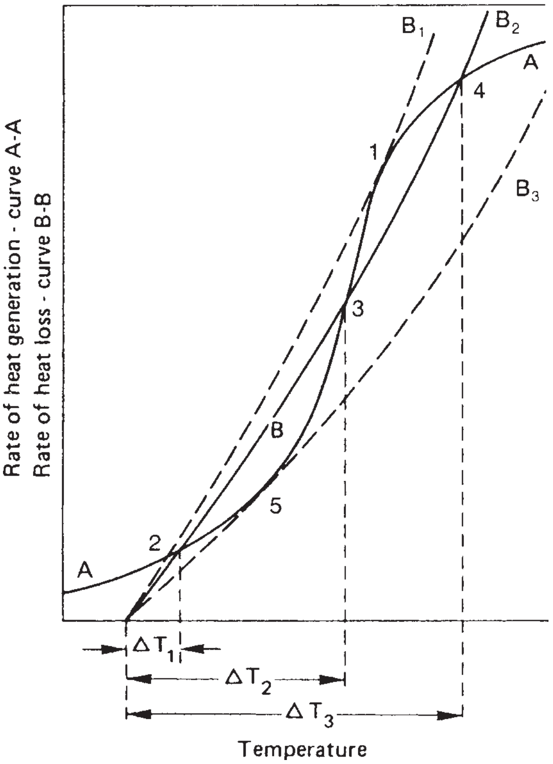

***Figure 16.35** Heat balance in a body undergoing self-heating (Bowes, 1984) (Courtesy of HM Stationery Office. © All rights reserved).*

condition where the heat transfer is greater than this, the heat removed will always be greater than heat released and no thermal explosion will occur. Line B3 is tangential to curve A at point 5. For any condition where heat transfer is less than this, the heat removed will always be less than the heat released and thermal explosion will occur. Line B2 represents the intermediate case. It crosses curve A at the three points 2, 3 and 4, which each constitute a steady state. Points 2 and 4 are stable steady states in that if there is a small increase in the temperature difference AT, the heat removed is greater than that released and the system returns to the steady state point. Point 3, however, is an unstable steady state in that if there is a small increase in AT the heat removed is less than that released so that the system will tend move up curve A to the stable steady state at point 4. Conversely, if there is a small decrease in AT the system will tend to move down curve A to point 2.

It is also instructive to consider the effect of the size of the solid mass and the temperature difference AT between the center of the mass and the surroundings as shown in Figure 16.36. There are two critical dimensions (r_1 and r_2) and four regions (A–D). There are two curves 1 and 2, which typically correspond to moderate heating and smoldering combustion. If the dimension of the solid mass is less than r_1 and the initial temperature difference is in region A, the temperature difference will move to the value on curve 1 corresponding to the value of r. If the dimension is greater than r_1 and the initial temperature difference is in region B, the temperature difference will move to curve 2. If the dimension lies between r_1 and r_2 and the initial temperature difference is in region B or C, there are two possibilities. If the temperature difference tends towards a value within region C, it will move to curve 1. If it tends towards region B, it will move to curve 2. If the dimension lies between r_1 and r_2 and the initial temperature difference is in region A, the temperature difference will move to curve 1, unless an additional heat source shifts it to curve 2. If the dimension is greater than r_2 and the initial temperature difference is in region D, the temperature difference will move to curve 2.

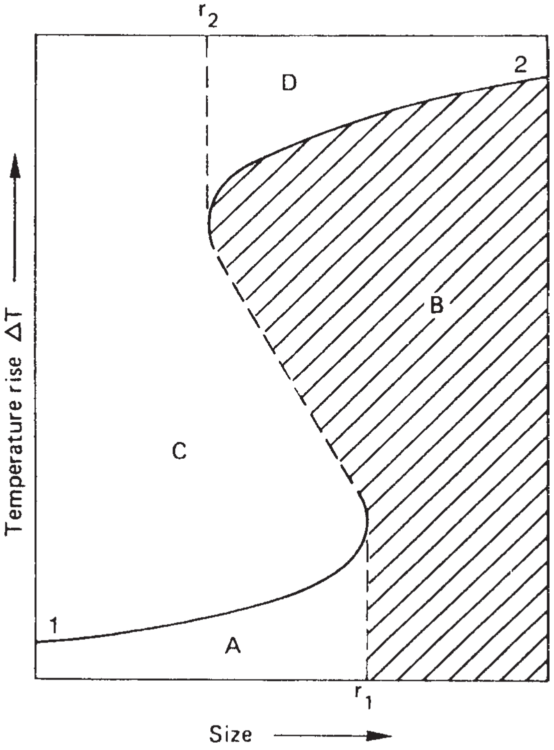

Figure 16.36 Steady states in a body undergoing self-heating (Bowes, 1984) (Courtesy of HM Stationery Office, ©, All rights reserved)

These considerations bring out the importance of the size of the pile. If the size of the pile is small, the system will tend to move towards curve 1, and if the pile is large the system will tend to move toward curve 2.

16.6.4 Elementary relations of self-heating

The basic equation for self-heating is

$$\rho c \frac{\partial T}{\partial t} = k\nabla^2 T + Q \qquad [16.6.1]$$

with

$$Q = Q' \rho A \exp(-E/RT) \qquad [16.6.2]$$

where A is the pre-exponential factor, c is the specific heat, E is the activation energy, k is the thermal conductivity, Q is the heat released by the reaction per unit volume, Q' is the heat of reaction per unit mass, R is the universal gas constant, T is the temperature and ρ is the density.

For the three principal centrisymmetric shapes of interest – the slab, cylinder and sphere – Equation 16.6.1 becomes, in rectangular co-ordinates in one dimension,

$$\rho c \frac{\partial T}{\partial t} = k\left(\frac{\partial^2 T}{\partial x^2} + \frac{j}{x}\frac{\partial T}{\partial x}\right) + Q'\rho A \exp(-E/RT) \qquad [16.6.3]$$

with

$j = 0$ Plane slab
$j = 1$ Cylinder
$j = 2$ Sphere

where x is the distance from the centre of the body.

The heat transfer at the surface is characterized by an overall heat transfer coefficient h such that

$$-k\frac{\partial T}{\partial t} = h(T_s - T_a) \qquad [16.6.4]$$

with

$$h = h_c + h_r \qquad [16.6.5]$$

where h is the heat transfer coefficient at the surface, h_c is the heat transfer coefficient for convection and h_r is the heat transfer coefficient for radiation.

The following dimensionless quantities are defined. The dimensionless distance z is

$$z = x/r \qquad [16.6.6]$$

where r is the half-width or radius, or characteristic length, and z is the dimensionless distance.
The dimensionless time τ is

$$\tau = \frac{kt}{\rho c r^2} \qquad [16.6.7]$$

The dimensionless parameter ϵ is

$$\epsilon = RT_{\mathrm{a}}/E \qquad [16.6.8]$$

where T_{a} is the air absolute temperature.

The dimensionless temperature difference θ is

$$\theta = \frac{E}{RT_{\mathrm{a}}^2}(T - T_{\mathrm{a}}) \qquad [16.6.9]$$

The dimensionless ignition parameter δ is

$$\delta = \frac{E}{RT_{\mathrm{a}}^2}\frac{r^2}{k}Q'\rho A \exp(-\mathrm{E}/RT_{\mathrm{a}}) \qquad [16.6.10]$$

Frank-Kamenetsky introduced the approximation

$$-\frac{E}{RT} \approx -\frac{E}{RT_{\mathrm{a}}} + \frac{\theta}{1+\epsilon\theta} \quad \mathrm{E}/RT_{\mathrm{a}} \leq 1 \qquad [16.6.11a]$$

$$\approx -\frac{E}{RT_{\mathrm{a}}} + \theta \quad \epsilon \leq 1 \qquad [16.6.11b]$$

Then, utilizing Equations 16.6.6–16.6.11, Equation 16.6.3 becomes, in dimensionless form,

$$\frac{\partial\theta}{\partial\tau} = \frac{\partial^2\theta}{\partial z^2} + \frac{j}{z}\frac{\partial\theta}{\partial z} + \delta\ \exp[\theta/(1+\epsilon\theta)] \qquad [16.6.12a]$$

$$\frac{\partial\theta}{\partial\tau} = \frac{\partial^2\theta}{\partial z^2} + \frac{j}{z}\frac{\partial\theta}{\partial z} + \delta\ \exp\ \theta \quad \epsilon \ll 1 \qquad [16.6.12b]$$

and Equation 16.6.4 becomes

$$\frac{\partial\theta}{\partial z} = -\alpha\theta_{\mathrm{s}} \qquad [16.6.13]$$

with

$$\alpha = hr/k \qquad [16.6.14]$$

where α is the Biot number.

Equation 16.6.12 is the basic dimensionless equation of self-heating, as formulated by Frank-Kamenetsky. The parameter <5 is the Frank-Kamenetsky parameter.

Use is also made of the following further dimension-less temperature differences:

$$\theta_{\mathrm{s}} = \frac{E}{RT_{\mathrm{a}}^2}(T_{\mathrm{s}} - T_{\mathrm{a}}) \qquad [16.6.15]$$

$$\theta_{\mathrm{o}} = \frac{E}{RT_{\mathrm{a}}^2}(T_{\mathrm{o}} - T_{\mathrm{a}}) \qquad [16.6.16]$$

where subscripts o and s denote the centre of the body and the surface, respectively. At steady state Equation 16.6.12 becomes

$$\frac{\partial^2\theta}{\partial z^2} + \frac{j}{z}\frac{\partial}{\partial z} = -\delta\exp\theta \qquad [16.6.17]$$

Equation 16.6.17 is the Poisson–Boltzmann equation.

The principal sets of boundary conditions that are used with Equations 16.6.12 and 16.6.17 are:

(1) surface exposed to air – surface heat transfer coefficient finite;
(2) surface exposed to air – surface heat transfer coefficient zero;
(3) surface exposed to air – surface heat transfer coefficient infinite;
(4) one surface against a hot body – constant temperatureat hot face;
(5) one surface against a hot body – constant heat flux at hot face.

The second boundary condition is referred to as the Semenov condition and the third as the Frank-Kamenetsky condition.

16.6.5 Model for a symmetrical slab

One principal configuration is the symmetrical slab. For the steady-state condition the temperature profile for self-heating is as shown in Figure 16.37(a). From Equation 16.6.17, setting $j = 0$

$$\frac{\mathrm{d}^2\theta}{\mathrm{d}z^2} = -\delta\exp\theta \qquad [16.6.18]$$

Assuming a finite surface heat transfer coefficient, the boundary conditions are

$$z = 0; \frac{\mathrm{d}\theta}{\mathrm{d}z} = 0 \qquad [16.6.19a]$$

$$z = \pm 1; \frac{\mathrm{d}\theta}{\mathrm{d}z} = -\alpha\theta_{\mathrm{s}} \qquad [16.6.19b]$$

The general solution of Equation 16.6.18 is

$$\theta = \ln\ C_2 - 2\ln\cosh\left[z(\delta C_2/2)^{1/2} + C_1\right] \qquad [16.6.20]$$

Differentiating Equation 16.6.20 and utilizing boundary condition 16.6.19a,

$$C_1 = 0 \qquad [16.6.21a]$$

and

$$C_2 = \exp\theta_0 \qquad [16.6.21b]$$

Utilizing boundary condition 16.6.19b

$$2D\tanh D = \alpha\theta_{\mathrm{s}} \qquad [16.6.22]$$

with

$$D = \left(\frac{\delta\exp\theta_{\mathrm{o}}}{2}\right)^{1/2} \qquad [16.6.23]$$

Eliminating θ_{s} from Equations 16.6.20 and 16.6.22

$$\ln\delta = \ln\frac{2D^2}{\cosh^2 D} - 2D\frac{\tanh D}{\alpha} \qquad [16.6.24]$$

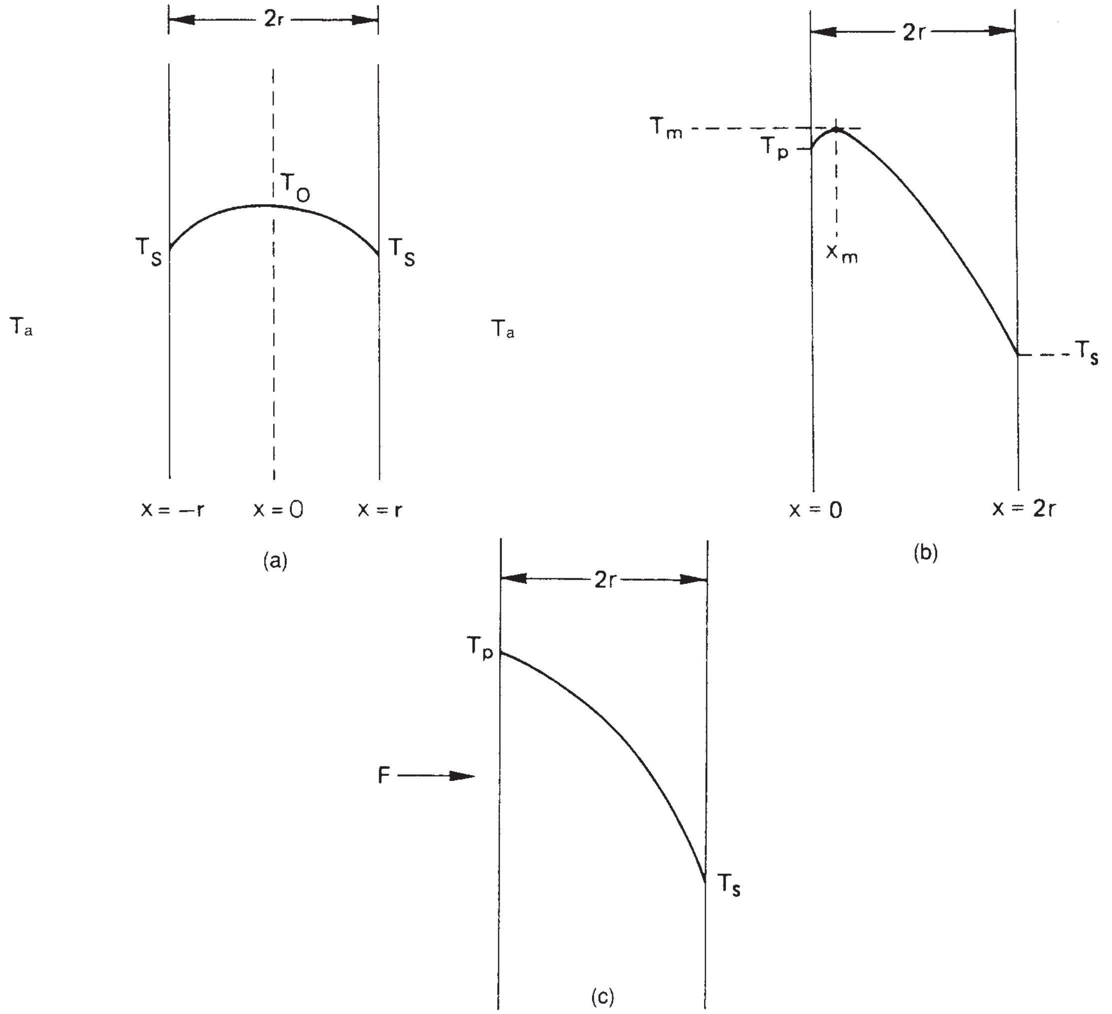

Figure 16.37 *Steady-state temperature profiles in a slab undergoing self-heating: (a) symmetrical slab; (b) asymmetrical slab with constant temperature at a hot face; and (c) asymmetrical slab with constant heat flux at hot face*

16.6.6 Characteristics of symmetrical slab model

It is instructive to consider the characteristics of the slab model. For low values of heat transfer at the surface, and hence of α, Equations 16.6.20–16.6.24 imply that

$$\theta_o \to \theta_s \quad \text{and} \quad \delta \to 0 \qquad \alpha \to 0$$

From Equations 16.6.22 and 16.6.24

$$\frac{(2\delta)^{1/2}\sinh\left[(\delta\exp(\theta_o)/2)^{1/2}\right]}{\alpha} = \theta_s\exp(-\theta_s/2) \qquad [16.6.25]$$

In the region $0<\alpha<1$, $0<\delta<1$, $\theta_o \approx \delta_s$, Equation 16.6.25 reduces to

$$\delta/\alpha = \theta_s\exp(-\theta_s) \qquad [16.6.26]$$

Equation 16.6.26 implies that for a given value of α the parameter δ passes through a maximum with θ_s and has this maximum at $\theta_s = 1$. This value of δ is the critical value δ_c:

$$\delta_c = \alpha/e \qquad [16.6.27]$$

For values of δ less than δ_c there exist steady-state temperature distributions that satisfy Equation 16.6.26, but for values that exceed δ_c there are no such steady states and thermal explosion occurs.

At the other extreme, as α becomes very high Equation 16.6.24 reduces to

$$\ln\delta = \ln\frac{2D^2}{\cosh^2 D} \qquad [16.6.28]$$

Equation 16.6.28 also implies that δ passes through a maximum with D. This maximum occurs at

$$D = \coth D = 1.2 \qquad [16.6.29]$$

which gives a value for δ_c of 0.88.

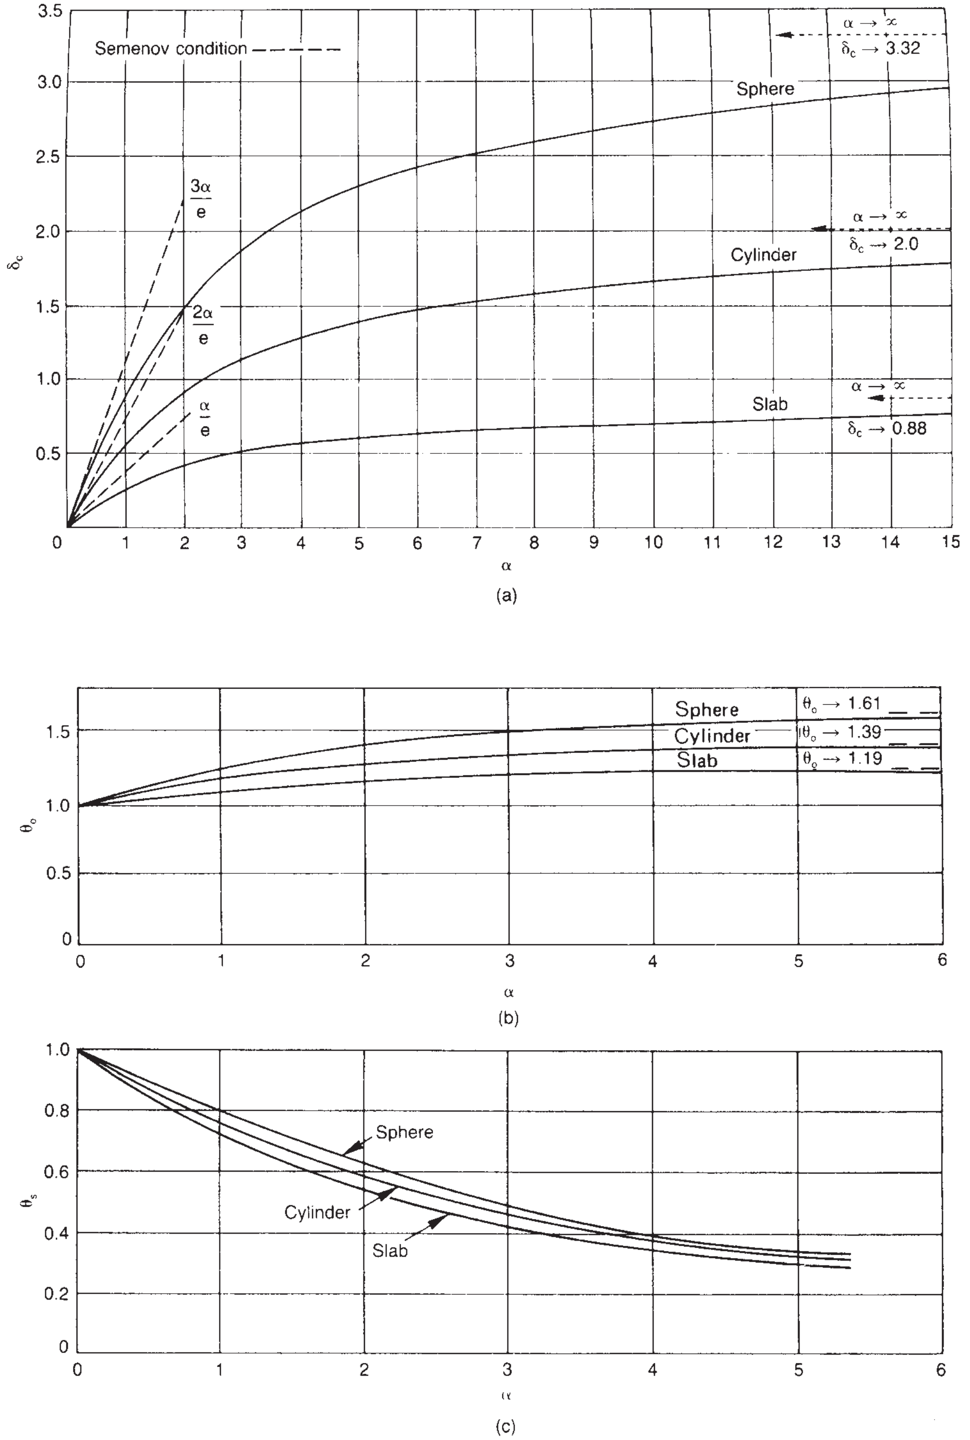

Figure 16.38 *Parameters governing self-heating without reactant consumption for three principal centrisymmetric shapes (P. H. Thomas, 1958): (a) critical values* δ_c *of the self-heating parameter (b) critical values of the dimensionless temperature* θ_o *at the centre and (c) critical values of the dimensionless surface temperature* θ_s *(Courtesy of the Faraday Society)*

Values of δ_c, θ and θ_s for a slab over the whole range of α have been obtained by P.M. Thomas (1958) and are shown in Figure 16.38. The figure also gives the corresponding values for a cylinder and a sphere. The limiting values are:

	$\alpha \to 0$		$\alpha \to \infty$	
	δ_c	θ_o	δ_c	θ_o
Plane slab	α/e	1	0.88	1.19
Cylinder	$2(\alpha/e)$	1	2.00	1.39
Sphere	$3(\alpha/e)$	1	3.32	1.61

16.6.7 Model for a cylinder

Another principal configuration is the infinite cylinder. From Equation 16.6.17, setting $j = 1$

$$\frac{d^2\theta}{\delta z^2} + \frac{1}{z}\frac{d\theta}{dz} = -\delta \exp\theta \qquad [16.6.30]$$

Assuming a finite heat transfer coefficient, the boundary conditions are those given in Equation 16.6.19.
The general solution is

$$\theta = \ln\left[\frac{8B}{\delta(1 + Bz^2)^2}\right] \qquad [16.6.31]$$

where B is a constant of integration. Then from boundary condition 16.6.19b

$$\ln\delta = \ln\left[\frac{8B}{(B+1)^2}\right] - \frac{4B}{\alpha(B+1)} \qquad [16.6.32]$$

The maximum value of δ occurs at

$$\alpha = \frac{4B_c}{1 - B_c^2} \qquad [16.6.33]$$

where the subscript c denotes critical.

Then, utilizing this value of α, the parameters δ_c and θ_s may be obtained from Equations 16.6.31 and 16.6.32.

16.6.8 General model for slab, cylinder and sphere

A general steady-state model for the symmetrical slab, cylinder and sphere may be obtained from Equation 16.6.17. The further approximation is introduced:

$$(j + 1)\beta\theta \approx \delta \exp\theta \qquad [16.6.34]$$

where β is an effective heat transfer coefficient. There is no simple relation for β, but

$$\beta \approx \alpha \quad \alpha \ll 1 \qquad [16.6.35]$$

Then, utilizing Equation 16.6.34 in Equation 16.6.17

$$\frac{d^2\theta}{\delta z^2} + \frac{j}{z}\frac{d\theta}{dz} = -(1 + j)\beta\theta \qquad [16.6.36]$$

It can be shown that

$$\beta = c_1^2 \quad \text{Plane slab} \qquad [16.6.37a]$$

$$= \frac{c_2^2}{2} \quad \text{Cylinder} \qquad [16.6.37b]$$

$$= \frac{c_3^2}{3} \quad \text{Sphere} \qquad [16.6.37c]$$

where c_1 is the first root of

$$c_n \tan c_n = \alpha \qquad [16.6.38a]$$

c_2 is the first root of

$$c_n J_1(c_n) = \alpha J_0(c_n) \qquad [16.6.38b]$$

and c_3 is a solution of

$$c_n \coth c_n + \alpha - 1 = 0 \qquad [16.6.38c]$$

where J_0 and J_1 are Bessel functions of the first kind and of order zero and one, respectively. The parameter δ has a maximum at $\theta = 1$ so that

$$\delta_c = \frac{(j+1)\beta}{e} \qquad [16.6.39]$$

16.6.9 Model for an asymmetrical slab

Returning to the slab, an alternative situation is one face against a hot body and one exposed to the atmosphere. For this case, in addition to the heat transfer at the surface exposed to the atmosphere, it is necessary to consider different conditions at the hot face. One assumption is that there is a constant temperature at the hot face; another is that there is a constant heat flux at the hot face. The steady state temperature profiles for these two cases are shown in Figures 16.37 (b) and (c), respectively. For the asymmetrical slab the dimensionless ignition parameter is defined as

$$\delta = \frac{E}{RT_p^2}\frac{r^2}{k}Q'\rho A \exp\left(-E/RT_p\right) \qquad [16.6.40]$$

and the dimensionless temperature difference as

$$\theta = \frac{E}{RT_p^2}(T - T_p) \qquad [16.6.41]$$

The relevant equation is Equation 16.6.18 and the general solution is Equation 16.6.20 and in addition

$$\frac{d\theta}{dz} = -(2\delta C_2)^{\frac{1}{2}} \tanh\left[z(\delta C_2/2)^{1/2} + C_1\right] \qquad [16.6.42]$$

The case considered here is that where the hot face is at a constant temperature and the surface of the other face is at a much lower temperature. For this case the boundary conditions are

$$z = 0; \quad \theta = 0 \qquad [16.6.43a]$$

$$z = 2; \quad \theta = \theta_s \qquad [16.6.43b]$$

Then from boundary condition 16.6.43a

$$C_1 = \pm\cosh^{-1}\left(C_2^{1/2}\right) \qquad [16.6.44a]$$

$$C_2 = \exp\theta_m \qquad [16.6.44b]$$

where subscript m denotes maximum.

From boundary condition 16.6.43b

$$(2\delta)^{1/2} = \frac{\cosh^{-1}\left[\exp(\theta_m/2) \pm \cosh^{-1}[\exp(\theta_m/2)\cdot\exp(-\theta_s/2)\right]}{\exp(\theta_m/2)} \qquad [16.6.45]$$

Given that the temperature of the surface is much less than that of the hot face, so that $\theta_s < 0$, it can be shown that $z_m \rightarrow 0$ and $\theta_m \rightarrow 0$, and that

$$(2\delta)^{1/2} = \cosh^{-1}\,[\exp(-\theta_s/2)] \qquad [16.6.46]$$

For large $|\theta_s|$ Equation 16.6.46 provides a good estimate of δ_c so that

$$\delta_c = \frac{(2\ln 2 - \theta_s)^2}{8} \qquad [16.6.47a]$$

$$= \frac{(1.4 - \theta_s)^2}{8} \qquad [16.6.47b]$$

Equation 16.6.47 is a good approximation for $|\theta_s|$ values as low as 8.

This argument suggests that for large θ_s it is permissible to adopt the approximation used by Zeldovitch and Semenov that the maximum temperature occurs at the hot face. Physically this means that the hot face is a perfect insulator instead of a perfect conductor of infinite thermal capacity.

The boundary conditions at the hot face then become

$$z = 0; \quad \theta = 0 \qquad [16.6.48a]$$

$$z = 0; \quad \frac{d\theta}{dz} = 0 \qquad [16.6.48b]$$

There is now only one steady-state temperature profile, which is the critical one. With these boundary conditions

$$C_1 = 0 \qquad [16.6.49a]$$

$$C_2 = 1 \qquad [16.6.49b]$$

which gives Equation 16.6.47.

An alternative derivation in terms of the ambient temperature utilizes the boundary condition

$$z = 2; \frac{d\theta}{dz} = -\alpha(\theta_s - \theta_a) \qquad [16.6.50]$$

with

$$\theta_a = \frac{E}{RT_p^2}(T_a - T_p) \qquad [16.6.51]$$

and yields for $\theta_a < 0$ and large $|\,\theta_a\,|$

$$(2\delta_c)^{1/2}\tanh\left[(2\delta_c)^{1/2}\right] + 2\alpha\ln\left\{\cosh\left[(2\delta_c)^{1/2}\right]\right\} = -\alpha\theta_a \qquad [16.6.52]$$

For $\delta_c > 5$, Equation 16.6.52 simplifies to

$$\delta_c \approx \frac{1}{2}\left(\frac{\alpha}{1 + 2\alpha}\right)^2 (1.4 - \theta_a)^2 \qquad [16.6.53]$$

Equation 16.6.53 gives results of accuracy comparable to those of Equation 16.6.47 and simplifies to that equation as $\alpha \rightarrow \infty$.

For the assumption that the hot face is a perfect insulator, Equation 16.6.53 is valid for all values of α, but as an approximation to the more realistic case it fails at $\alpha = 0$.

16.6.10 Model for a hollow cylinder

Another important asymmetrical case is that of the hollow cylinder with the inner face at a constant hot temperature. For this case the dimensionless distances are defined as

$$Z = r/r_1 \qquad [16.6.54a]$$

$$z = r_1/r_1 = 1 \quad \text{Inner face} \qquad [16.6.54b]$$

$$z = r_2/r_1 = z_s \quad \text{Outer face} \qquad [16.6.54c]$$

The dimensionless temperature difference θ is defined by Equation 16.6.41 and the dimensionless ignition parameter as

$$\delta = \frac{E}{RT_p^2}\frac{r_i^2}{k}Q'\rho A\exp(-E/RT_p) \qquad [16.6.55]$$

The relevant equation is Equation 16.6.30 and the general solution is

$$\theta = \ln\left[\frac{2F^2 G z^{F-2}}{\delta(1 + Gz^F)^2}\right] \qquad [16.6.56]$$

where F and G are constants of integration.

The boundary conditions are

$$z = 1; \quad \theta = 0 \qquad [16.6.57a]$$

$$z = 1; \quad \frac{d\theta}{dz} = 0 \qquad [16.6.57b]$$

$$z = z_s; \quad \theta = \theta_s \qquad [16.6.57c]$$

From boundary condition 16.6.57b

$$F\frac{1 - G}{1 + G} = 2 \qquad [16.6.58]$$

From Equations 16.6.56 and 16.6.58

$$\delta_c = \frac{8G}{(1 - G)^2} \quad 0 < G < 1 \qquad [16.6.59]$$

From Equation 16.6.56 and boundary condition 16.6.57c

$$\theta_s = \ln\left[\frac{2F^2 G z_s^{F-2}}{\delta_c(1 + Gz_s^F)^2}\right] \qquad [16.6.60]$$

For the critical ignition parameter δ_c^* expressed in terms of the half thickness of the cylinder wall is

$$\delta_c^* = \delta_c\left(\frac{z_s - 1}{z}\right)^2 \qquad [16.6.61]$$

For a solid cylinder $F = 2$ and Equation 16.6.56 then reduces to Equation 16.6.31.

The model for the hollow cylinder may be applied to the problem of the self-heating of lagging on a pipe. The maximum, or critical, thickness of lagging to avoid self-heating may be calculated as follows. Calculate δ from Equation 16.6.55, assume that this is the critical value of δ ($\delta = \delta_c$), and calculate G and then F from Equations 16.6.58 and 16.6.59. Then assume a normalized outer radius z_s and calculate θ_s from Equation 16.6.60. If θ_s differs from that specified, assume a fresh value of z_s and recalculate.

Some illustrative calculations have been made by Gugan (1974a) and are summarized in Table 16.29. The results show that if the pipe temperature is increased, the thickness of lagging needs to be decreased in order to avoid self-heating. Thus the relation between pipe temperature and lagging thickness is the reverse of that required for heat insulation.

16.6.11 Critical parameters

The parameter is given by Equation 16.6.10, which may be written as

$$\delta = \frac{E}{RT_a^2}\frac{r^2}{k}Q(T_a) \qquad [16.6.62]$$

For a slab, Equation 16.6.62 may be rewritten utilizing Equation 16.6.14 and

$$\frac{V}{S} = r \qquad [16.6.63]$$

as

$$\delta = \frac{E}{RT_a^2}\frac{\alpha}{h}\frac{V}{S}Q(T_a) \qquad [16.6.64]$$

Further, since

$$\theta_o = \frac{E}{RT_a^2}(T_o - T_a) \qquad [16.6.65]$$

$$\delta = \theta_o\frac{r}{k}\frac{V}{S}\frac{Q(T_a)}{(T_o - T_a)} \qquad [16.6.66]$$

or

$$\delta = \theta_o\frac{\alpha}{h}\frac{V}{S}\frac{Q(T_a)}{(T_o - T_a)} \qquad [16.6.67]$$

Equation 16.6.67 can be extended to the other geometries by the generalization

$$\delta = (j+1)\theta_o\frac{r}{k}\frac{V}{S}\frac{Q(T_a)}{(T_o - T_a)} \qquad [16.6.68]$$

since

$$\frac{V}{S} = \frac{r}{2} \quad \text{Cylinder} \qquad [16.6.69a]$$

$$\frac{V}{S} = \frac{r}{3} \quad \text{Sphere} \qquad [16.6.69b]$$

or generally for the three principal symmetrical shapes

$$\frac{Sr}{V} = 1 + j \qquad [16.6.70]$$

These equations show that for these geometries the value of δ is a function of the surface/volume ratio S/V.

The relation between δ_c and S/V is illustrated in the table given in Section 16.6.6. As $\alpha \to 0$, δ_c is exactly proportional to S/V; while as $\alpha \to \infty$, δ_c lies within 10% of S/V.

There are a number of methods available for the estimation of the critical parameters δ_c and θ_o. One approximate analytical method has been developed by Boddington, Gray and Harvey (1971b). This method is based on the application of Equation 16.6.17 to any centrisymmetric convex body. The parameters are expressed in terms of an average radius R_o and of the shape factor j and procedures are given for determining these. At criticality, the following relations hold:

$$\delta_c(r) = \delta_c(R_o)\frac{r^2}{R_o^2} \qquad [16.6.71]$$

$$\theta_o = 2\ln[(j+7)/4] \qquad [16.6.72]$$

with

$$\delta_c(R_o) = 3F(j) \qquad [16.6.73]$$

$$F(j) = \frac{2j+6}{j+7} \qquad [16.6.74]$$

For the three principal symmetrical shapes the shape parameter has its usual values (0, 1 or 2) and

$$\frac{r^2}{R_o^2} = \frac{j+1}{3} \qquad [16.6.75]$$

Another approximate analytical method has been given by Hardee, Lee and Donaldson (1972). Other methods include expansion about the maximum temperature and use of a step function. Numerical solutions have also been obtained. In particular, results for the principal geometries have been given by Enig and co-workers (Enig, 1956; Enig, Shanks and Southworth, 1956). Results for some of the principal cases are summarized in Table 16.30.

The self-heating parameter δ is a function of the parameters of the reaction and solid mass and of the ambient temperature. There exists, therefore, a critical value of

***Table 16.30** Selected critical values of the ignition parameter δ_c and the center temperature θ_o without reactant consumption for centrisymmetric shapes*

[a] BGH, Boddington, Gray and Harvey method; FK, Frank–Kamenetsky formulation.

[b] Values of δ_c quoted are those given by Bowes (1984). The corresponding values of α are not given, but Parks gives results for the range $\alpha = 20–100$.

[c] Corrected by Boddington, Gray and Harvey (1971b) and quoted by Bowes (1984).

[d] Bowes gives the relation: $\delta_c \approx 2.0 + 0.84p^2$.

[e] Also referred to as a rectangular brick.

[f] Bowes gives the relation: $\delta_c \approx 2.0 + 0.84(1 + l/p^2 + l/q^2)$.

the ambient temperature that gives a critical value δ_c for the self-heating parameter. As the parameter $\alpha \rightarrow \infty$ there is a corresponding critical value of the surface temperature.

16.6.12 Oxidative self-heating

The self-heating reaction is usually, though not invariably, an oxidative one. Then the reaction will typically be governed by the reaction kinetics relation and by the diffusion of oxygen from the atmosphere.

There is relatively little information on the oxidation reactions which occur in self-heating. Models of the reaction frequently assume that it is first order with respect to oxygen concentration with a reaction index $n = 1$. For a number of reactions studied the value of the index n is about 0.7. Others are zero order over a wide range of oxygen concentrations. It is usual to assume that the Arrhenius equation applies, but Bowes warns that it is not always appropriate.

For oxidative self-heating it can be shown by a steady-state analysis that at critical conditions the value of the dimensionless temperature difference θ_o is given by

$$(1 + \epsilon\theta_o)^2 \left[1 + (n-1)\frac{\theta_o}{\xi}\right] = \theta_o\left(1 - \frac{\theta_o}{\xi}\right) \quad [16.6.76]$$

with

$$\theta_o = \frac{E}{RT_a}(T_o - T_a) \quad [16.6.77]$$

$$\xi = \frac{E}{RT_a}\frac{Q^* D_p C_o}{k} \quad [16.6.78]$$

where C_o is the concentration of oxygen in the atmosphere, D_p is the diffusion coefficient of oxygen in the pores, n is the index of the concentration term, Q^* is a modified heat release per unit mass, T_o is the temperature at the centre, θ_o

is the dimensionless temperature difference at the centre and ξ is a parameter.

16.6.13 Effect of water

Organic materials tend to be hygroscopic and commonly contain some 10–20% water as a condensed phase. Water can have a strong effect on self-heating but its effect is somewhat complex. Reviews have been given by Walker (1967) and Bowes (1984). Some of the effects are chemical. Water increases the rate of oxidation of many materials. In some cases, however, there can be an inhibiting effect.

Other effects are physical. Water has a high latent heat of vaporization and a correspondingly high heat of adsorption. During self-heating it vaporizes in the hotter regions and condenses again in the cooler regions. The net effect is an appreciable increase in the rate of heat transfer. The presence of water thus increases the effective thermal conductivity of the material. The increase may be by an order of magnitude.

The increase in temperature in the hotter region is retarded by the presence of water as vaporization takes place. The effect usually occurs at temperatures in the range 60–90°C, which is generally well below the temperature at which thermal ignition occurs. Thus this effect tends to manifest itself as an increase in the induction time.

If the vaporization of water occurs fairly uniformly over the temperature range as the material undergoes self-heating, the effect is to reduce the effective heat of reaction. In some cases this may result in the suppression of thermal ignition. This effect is seen in the case of 'overdried' materials. If a material is dried down to a very low water content, the reduction in the effective heat of reaction just described is no longer operative, and the material becomes more prone to thermal ignition.

There is also another effect of water on overdried material. When the material is first exposed to the atmosphere, water is adsorbed and heat is released. This may cause a temperature rise in cool material or may delay a temperature fall in hot material. In either case the base temperature from which any self-heating process starts is increased.

16.6.14 Unsteady-state model

The treatment of self-heating given so far has been based on the assumption of steady state. There are a number of situations in which this assumption breaks down and for which it is necessary to adopt an unsteady-state approach. These include:

(1) reactant consumption;
(2) induction period;
(3) autocatalytic reactions;
(4) hot spots and hot materials;
(5) high ambient temperature;
(6) varying ambient temperature.

The basic equation for self-heating is the unsteady-state Equation 16.6.1 with Equation 16.6.2. This latter equation may be modified to make explicit the dependence on reactant consumption, and then takes the form of Equation 16.6.81.

Consideration is now given to some of the principal aspects of the unsteady state, namely reactant consumption, induction period, autocatalytic reactions, and hot spots and hot materials.

16.6.15 Reactant consumption

In general the reaction equation will be of the form

$$\frac{\mathrm{d}C}{\mathrm{d}t} = -C^n A \exp(-E/RT) \qquad [16.6.79a]$$

$$\frac{\mathrm{d}C}{\mathrm{d}t} = -\psi(C) A \exp(-E/RT) \qquad [16.6.79b]$$

with

$$\psi(C) = C^n \qquad [16.6.80]$$

Then Equation 16.6.2 becomes

$$Q = C^n Q'' A \exp(-E/RT) \qquad [16.6.81a]$$

$$= \psi(C) Q'' A \exp(-E/RT) \qquad [16.6.81b]$$

where C is the concentration of oxygen, Q'' is the modified heat released per unit volume, ψ is a concentration function and n is an index. Then Equation 16.6.3 becomes

$$\rho c \frac{\partial T}{\partial t} = k\left(\frac{\partial^2 T}{\partial x^2} + \frac{j}{x}\frac{\partial T}{\partial x}\right) + C^n Q'' A'' \exp(-E/RT) \qquad [16.6.82]$$

Introducing the dimensionless concentration

$$\omega = C/C_{\mathrm{o}} \qquad [16.6.83]$$

where C_{o} is the concentration of oxygen in the ambient air and ω is the dimensionless concentration, and an alternative form of the dimensionless ignition parameter

$$\delta = \frac{E}{RT_{\mathrm{a}}} \frac{r^2}{k} C_{\mathrm{o}}^n Q'' A \exp(-E/RT_{\mathrm{a}}) \qquad [16.6.84]$$

Equation 16.6.82 becomes

$$\frac{\partial \theta}{\partial \tau} = \frac{\partial^2 \theta}{\partial z^2} + \frac{j}{z}\frac{\partial \theta}{\partial z} + \delta \omega^n \exp[\theta/(1+\epsilon\theta)] \qquad [16.6.85]$$

and Equation 16.6.79 becomes

$$\frac{\mathrm{d}\omega}{\mathrm{d}\tau} = -\frac{\delta}{B}\omega^n \exp[\theta/(1+\epsilon\theta)] \qquad [16.6.86]$$

with

$$B = \frac{E}{RT_{\mathrm{a}}^2} \frac{C_{\mathrm{o}} Q''}{\rho c} \qquad [16.6.87]$$

where B is a dimensionless parameter. The parameter B may be interpreted as a dimensionless adiabatic temperature rise.

For the three principal symmetrical shapes and for general case of finite α the usual boundary conditions for Equation 16.6.85 are

$$z = 0; \quad \frac{\mathrm{d}\theta}{\mathrm{d}z} = 0 \qquad [16.6.88a]$$

$$z = 1; \quad \frac{\mathrm{d}\theta}{\mathrm{d}z} = -\alpha\theta_{\mathrm{s}} \qquad [16.6.88b]$$

and the initial conditions are

$$\tau = 0; \quad \theta = 0; \quad \omega = 1 \qquad [16.6.89]$$

The behaviour of a self-heating mass may be characterized in terms of the parameters B and δ as shown in Figure 16.39. For large values of B, shown in Figure 16.39(a), the profiles of θ are sensitive to δ and there is a value of δ at which there is a relatively sharp transition to thermal explosion. For small values of B, shown in Figure 16.39(b), the profiles of θ are less sensitive, thermal explosion is less well defined and may not occur at all.

It is possible to derive a relation for the critical value as a function of B and n. Let $\delta(B)$ be the initial value δ and $\delta_c(\infty)$ be the critical value of δ at the end of the induction period for $B = \infty$. Then it can be shown that

$$\delta_c(B, n) = \frac{\delta_c(\infty)}{1 - 2.7(n/B)^{2/3}} \qquad [16.6.90a]$$

$$\delta_c(B, n) = \delta_c(\infty)(1 + 2.7(n/B)^{2/3}) \quad B \to \infty \qquad [16.6.90b]$$

The effect of reactant consumption has been studied, particularly for the three principal symmetrical shapes. Results for the centri-symmetric shapes obtained by Tyler and Wesley (1967) using numerical integration are shown in Table 16.31.

16.6.16 Induction period

It is possible to define a number of induction periods. One period of particular interest is the total time from the initiation of a situation leading to thermal explosion to the explosion itself. It is this induction period, which is considered here.

A treatment of the induction period, assuming no reactant consumption, has been given by Zinn and Mader (1960), who performed numerical integration of Equation 16.6.12 for the following case. A body at initial temperature T_i has its surface suddenly raised to a temperature T_s, which exceeds the critical value T_c for thermal explosion. They defined a dimensionless induction period τ_i such that

$$\tau_i = \frac{kt_i}{\rho c r^2} \qquad [16.6.91]$$

where t_i is the induction period and τ_i is the dimensionless induction period. They obtained for the three principal symmetrical shapes the results shown in Figure 16.40. The induction period decreases as the surface temperature increases.

If the surface temperature is raised to one greatly in excess of the critical value, the temperature rise in the solid occurs near the surface rather than at the centre. Zinn and Mader examined this situation also and obtained for the case of a 1 in. sphere of cyclotrimethylene trinitramine, or RDX explosive the results shown in Figure 16.41. It has been

shown that the values of for the transition from a central to an annular explosion are approximately as follows:

	δ
Plane slab	9.25
Cylinder	12.25
Sphere	14.25

16.6.17 Autocatalytic reactions

In some cases the self-heating reaction is an autocatalytic one. For this case the reaction may be expressed as

$$\frac{d\phi}{dt} = k(\phi^* + \phi)(1 - \phi) \qquad [16.6.92]$$

where ϕ is the fractional conversion and ϕ^* is the small fractional conversion necessary to initiate the reaction. A quantity χ may be defined as

$$\chi = \frac{\delta}{(1 + j)\alpha} \qquad [16.6.93]$$

where χ may be interpreted broadly as the ratio of the rate of heat generation to the rate of heat loss. The critical condition for thermal ignition is

$$\chi = \frac{4}{(1 + \phi^*)^2 e} \qquad [16.6.94a]$$

$$\approx \frac{4}{e} \qquad [16.6.94b]$$

and the value of the critical ignition parameter δ_c is

$$\delta_c = \frac{4}{(1 + \phi^*)^2} \frac{(1 + j)\alpha}{e} \qquad [16.6.95]$$

16.6.18 Thermal explosions of the second kind

As already described, there exist both stable and unstable steady states. A thermal explosion of the second kind involves passage through an unstable steady state. This situation can occur where there is an additional heat source or where there are certain initial conditions. A typical additional heat source might be a wander lamp left lying in a pile of material in a silo. Another form of additional heat source is a parallel reaction. The situation involving initial conditions of particular interest are those relating to hot spots, which are now considered.

16.6.19 Hot spots and hot materials

The topic of hot spots includes the following cases:

(1) reactive hot spots,
(2) inert hot spots and
(3) hot materials.

A hot spot is a limited volume in a mass of reactive material, which is at a temperature above that of the material. The hot spot may be reactive or inert. A hot material in this context is one in which the whole mass of the material is above ambient temperature. It may be

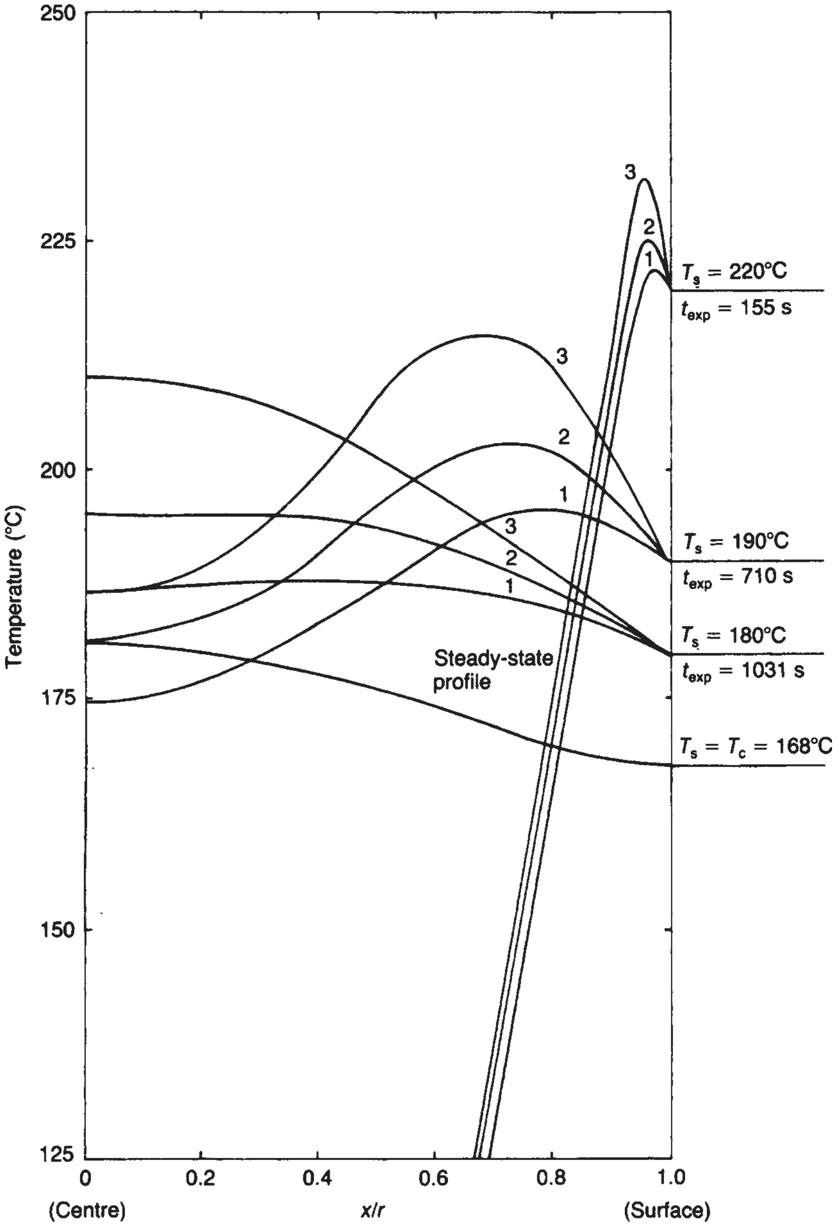

Figure 16.41 *Temperature profiles for a 1 in. sphere of RDX at times close to the end of the induction period (Zinn and Mader, 1960): (1) fraction of time to explosion 0.9; (2) fraction of time to explosion 0.95; (3) fraction of time to explosion 0.98. Initial temperature 25° C. The steady-state temperature profile at the critical temperature T_c is also shown (Courtesy of the Journal of Applied Physics)*

regarded as a form of reactive hot spot in which the hot region extends to the whole mass. The temperature profiles in a hot spot with a 'square' initial temperature distribution are shown in Figure 16.42. The initial temperature profile is given by outline A. An inert hot spot will lose heat to the surrounding medium and the temperature distribution in the early period may then be expected to take a form such as that shown in curve B. A reactive hot spot, however, will generate some heat and, assuming this is appreciable, its temperature distribution in the early period may be expected to take a form such as that shown by curve C.

For a reactive hot spot it has been shown by P.H. Thomas (1973a) that

$$\delta_c \approx \theta_o \psi'(\tau) \qquad [16.6.96]$$

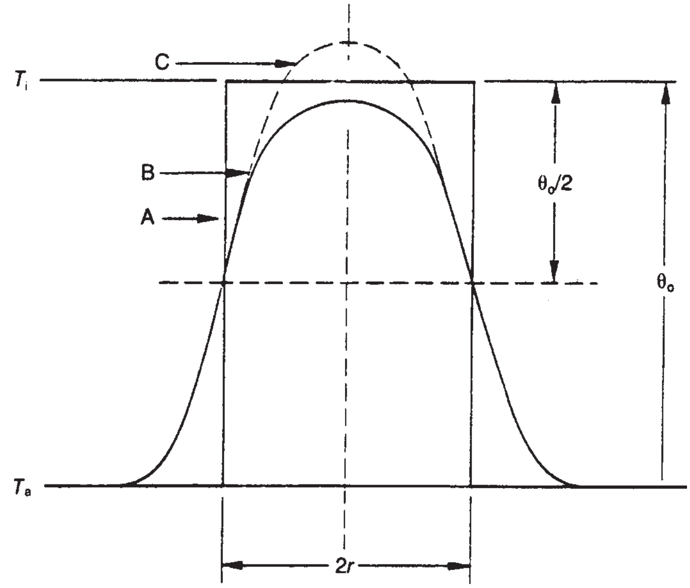

Figure 16.42 *Temperature profiles for a hot spot: A, initial temperature profile of hot spot, reactive or inert; B typical early temperature profile for inert hot spot; and C, typical early temperature profile for reactive hot spot*

with

$$\tau = 1/\delta_c \qquad [16.6.97]$$

where the parameters are defined in terms of the initial temperature T_i of the hot spot so that

$$\delta_c = \frac{E}{RT_i^2}\frac{r^2}{k}Q'\rho A\exp(-E/RT_i) \qquad [16.6.98]$$

$$\theta_i = \frac{E}{RT_i^2}(T_i - T_{im}) \qquad [16.6.99]$$

$$\psi = \frac{T_i - T}{T_i - T_{im}} \qquad [16.6.100]$$

$$\psi' = \frac{d\psi}{d\tau} \qquad [16.6.101]$$

where T_i is the initial temperature of the hot spot, T_{im} is the initial temperature of the medium, θ_i is the initial value of θ in the hot spot and τ is the dimensionless time.

Of particular interest is the solution of Equations 16.6.96–16.6.101 for hot material, where in effect the hot spot extends through the whole mass. In applying these equations use is made of the fact that in the early stages of cooling of an inert hot spot the temperature profiles all tend to intersect at a temperature $\theta_o/2$ as shown in Figure 16.42. Then the value of θ_o used in the treatments for hot materials is one-half of the value of θ_i as given by Equation 16.6.99.

Then for the case where $\alpha \to \infty$, P.H. Thomas (1972) has shown that

$$\psi'(\tau) \approx \frac{\exp(-1/4\tau)}{2\pi^{1/2}\tau^{3/2}} \quad \text{Plane slab} \qquad [16.6.102]$$

$$\psi'(\tau) \approx \frac{\exp(-1/4\tau)}{4\pi^{1/2}\tau^{3/2}} \quad \text{Sphere} \qquad [16.6.103]$$

$$\psi'(\tau) \approx \frac{3\exp(-1/4\tau)}{2\pi^{1/2}\tau^{3/2}}[\text{erf}(1/2\tau^{1/2})]^2 \quad \text{Cube} \qquad [16.6.104]$$

For this case the value of δ_c is obtained from Equation 16.6.96 utilizing Equations 16.6.102–16.6.104. At the other extreme, for $\alpha \to 0$ it can be shown that

$$\psi = 1 - \exp(-\alpha S r\tau/V) \qquad [16.6.105]$$

Then, differentiating Equation 16.6.105 and utilizing Equation 16.6.70 for the three principal symmetrical shapes it is readily shown that

$$\delta_c = \alpha(1 + j)\theta_o \exp[-\alpha(1 + j)/\delta_c] \qquad [16.6.106a]$$

$$\delta_c \approx \alpha(1 + j)\theta_o \quad \theta_o \gg 1; \delta_c \gg 1 \qquad [16.6.106b]$$

Treatments for the inert hot spot tend to be more complex.

16.6.20 Determination of model parameters

The self-heating properties of a porous solid may be characterized in terms of (1) the minimum ignition temperature, (2) the critical characteristic length, (3) the surface heat transfer coefficient and (4) the induction period.

The minimum ignition temperature may be obtained by exposing a body of the material in a defined shape to a series of successively higher temperatures using calorimetric methods and determining the temperature which is just high enough for ignition to occur.

For the critical characteristic length use is made of Equation 16.6.10 with the ignition parameter taken as the critical value δ_c and rearranged to give

$$\ln\left(\frac{\delta_c T_a^2}{r^2}\right) = M - \frac{P}{T_a} \qquad [16.6.107]$$

with

$$M = \ln(Q'\rho AE/Rk) \qquad [16.6.108]$$

$$P = E/R \qquad [16.6.109]$$

where R is the universal gas constant, T_a is the absolute temperature of the air and M and P are parameters.

Then if experiments are conducted with a range of slabs of different sizes and different surface temperatures, pairs of values of r and T_a are obtained. A plot of $\ln(\delta_c T_a^2/r^2)$ vs $1/T_a$ then gives the values of M and P.

Such experiments are in fact usually done using cubes rather than slabs. For a cube, δ_c is 2.6 so that the relation between the critical characteristic length for a cube r_{cb} and for a slab r_{sb} is

$$r_{sb} = r_{cb}(0.88/2.6)^{1/2} \qquad [16.6.110]$$

The commonly used test for the determination of the self-heating parameters M and P is to heat up a cube of the material in an oven under standard conditions and to measure the temperatures in the cube.

For the surface heat transfer coefficient, and hence the Biot number, use is made of Equation 16.6.5. The heat transfer coefficient for convection depends on the shape of the body and on whether the convection is natural or forced. For the case of natural convection and for a small sphere

$$\mathrm{Nu} \approx 2.0 + 0.6\,\mathrm{Pr}^{0.33}\mathrm{Gr}^{0.25} \qquad [16.6.111a]$$

For air, for which $\mathrm{Pr} \approx 0.7$, Equation 16.6.111a can be approximated by

$$\mathrm{Nu} \approx 2.0 + 0.6(\mathrm{Pr\,Gr})^{0.25} \qquad [16.6.111b]$$

$$= 2.0 + 0.6(\mathrm{Ra})^{0.25} \qquad [16.6.111c]$$

with

$$\mathrm{Nu} = \frac{dh_c}{k_f} \qquad [16.6.112]$$

$$\mathrm{Pr} = \frac{\nu}{\alpha_f} \qquad [16.6.113]$$

$$\mathrm{Gr} = \frac{gad^3\Delta T}{\nu^2} \qquad [16.6.114]$$

$$\mathrm{Ra} = \frac{g}{\nu\alpha_f} d^3 \frac{\Delta T}{T} \qquad [16.6.115]$$

$$a = 1/T \qquad [16.6.116]$$

where a is the volume coefficient of expansion, d is the diameter of the sphere, k_f is the thermal conductivity of the fluid, ΔT is the difference between the surface temperature and the ambient temperature $(T_s - T_a)$, is the thermal diffusivity of the fluid and ν is the kinematic viscosity of the fluid. Gr, Nu, Pr and Ra are the Grashof, Nusselt, Prandtl and Rayleigh numbers, respectively.

Then from Equations 16.6.111c, 16.6.112 and 16.6.115

$$h_c = \frac{k_f}{d}(2.0 + 0.6\,\mathrm{Ra}^{0.25}) \qquad [16.6.117]$$

The first term in the brackets in Equation 16.6.117 represents film conduction and the second term represents convection. The heat transferred by radiation q is

$$q = \frac{\epsilon_1\epsilon_2}{\epsilon_1 + \epsilon_2 - \epsilon_1\epsilon_2}\sigma(T_s^4 - T_a^4) \qquad [16.6.118]$$

where ϵ_1 is the emissivity of the surface and ϵ_2 is that of the surroundings.

Differentiating Equation 16.6.118 with respect to T_a, and linearizing

$$\frac{dq}{dT_a} = 4\frac{\epsilon_1\epsilon_2}{\epsilon_1 + \epsilon_2 - \epsilon_1\epsilon_2}\sigma T_a^3 \qquad [16.6.119a]$$

$$= h_r \qquad [16.6.119b]$$

As an approximation, the values of ϵ_1 and ϵ_2 in Equation 16.6.119a may be taken as unity. Bowes gives the following values for a sphere:

r (mm)	0.6 $\mathrm{Ra}^{0.25}$	h_c ($\mathrm{W/m^2\,K}$)	h_r ($\mathrm{W/m^2\,K}$)	α	δ_c
1.6	0.87	39	47	2.7	1.80
25.4	8.2	7.1	21	14.1	2.90
279	54	3.2	12.6	88	3.24

In Equation 16.6.117 for the convection heat transfer coefficient the dominant term is the film term at the smaller diameters and the convection term at the larger diameters.

The induction period may be determined by experiment. The results of a number of experiments follow the relation

$$t_i \propto r^2 \qquad [16.6.120]$$

Alternatively, the induction period may be estimated from Figure 16.40.

A material liable to self-heating is often a powder and its self-heating properties therefore depend on the particle size distribution. Experimental determinations of self-heating parameters are valid only for similar material.

16.6.21 Precautions against self-heating

Prevention of self-heating depends on recognition of the hazard, design features, and good housekeeping and adherence to procedures.

If a material may be liable to self-heating, tests may be done to determine first whether this is the case, and, if so, the critical size. Bowes gives the following broad rules of thumb for liability to self-heating in terms of the critical dimension r_c:

$r_c \geq 40$ m Material not liable to self-heating

$r_c \leqslant 10$ m Material liable to self-heating

Materials leaving the process hot can be cooled before being sent to storage. Self-heating of materials in storage and transport can be prevented by using smaller containers and/or by remixing the material periodically. Where oxidative self-heating is involved, measures can be taken to reduce the oxygen content of the ambient gas. One approach is the use of atmosphere control and, in particular, of inerting. Another method is the use of an oxygen barrier such as plastic liners inside paper bags. Polyethylene has been successfully used to prevent self-heating. It is not, however, a totally effective oxygen barrier and may be of limited use for more reactive materials.

Factors that tend to increase safety include the presence of antioxidants and the limitation of the residence time. Conversely, the safety margin is reduced if there is a loss of antioxidants that are normally present or a rise in the residence time above the normal value.

Some materials, such as freshly made activated carbon, heat up appreciably during the first 24 hours after manufacture. The processes involved are probably sorption and oxidation of the most reactive sites. Such materials can be 'weathered' by allowing the material to stand for a period in separate, freshly filled bags.

Self-heating of lagging can be minimized by measures to prevent leaks and by use of suitable lagging thicknesses.

Special measures are required to deal with situations where there is a possibility of a leak such as the EO leaks described in Section 16.6.2. Measures proposed following the investigation of these incidents include avoidance of dead leg pipework and other stagnant zones, reduction of the number of flanges and other possible leak points, measures to ensure leak-tight construction, use of non-absorbent lagging material if possible, inerting of regions at risk, provision of leak detection devices and regular testing for leak tightness and regular inspection for leaked materials. Large flanges may be installed without fire insulation but protected by sprinkler systems instead. The insulation used may be of the two-layer type with an inner material of close cell structure, such as cellular glass, and an outer layer of fire resistant material, with a vapour barrier between to prevent ingress of water and chlorides.

Good housekeeping can reduce self-heating caused by items such as waste rags or dust layers.

16.7 Static Electricity

Static electricity is an important source of ignition in process plants. There have been many apparently mysterious explosions the cause of which was eventually traced to static electricity. On the other hand there has been some tendency in investigations to attribute to static electricity ignitions for which no other cause could be found, even though the positive evidence for static was weak.

There is now much more information available both on the nature and on the prevention of static electricity. But despite this it remains a phenomenon which is often not well understood or appreciated. It is for this reason that a separate section is devoted here to static electricity rather than because it is a statistically dominant source of ignition.

Static electricity is a potential source of ignition wherever there is a flammable mixture of gas or of powder or dust. Accounts of static electricity are given in *Electrostatics in the Petroleum Industry* (Klinkenberg and van der Minne, 1958), *Handbuch der Raumexplosionen* (Freytag, 1965), *Handbook of Industrial Loss Prevention* (FMEC, 1967), *Electrostatic Hazards* (Haase, 1977), *Dust Explosions* (Cross and Fairer, 1982), *Electrostatics* (Cross, 1987), *Electrostatic Hazards and Powder Handling* (Glor, 1988) and *Understanding and Controlling Static Electricity* (Luttgens and Glor, 1989) and by R.V. Wright (1964), J.C. Howard (1964), N. Gibson (1969), J.R. Hughes (1970), Napier (1971) and K.N. Palmer (1973a).

The relevant British Standard is BS 5958: 1991 *Code of Practice for Control of Undesirable Static Electricity* Part 1: 1991 *General Considerations* and Part 2: 1991 *Recommendations for Particular Industrial Situations*. In the USA, NFPA 77: 2000 *Static Electricity* applies.

Selected references on static electricity are given in Table 16.32.

16.7.1 Static electricity in industrial processes

The industrial situations in which undesired static charges are generated are largely those in which two surfaces move

Table 16.32 *Selected references on static electricity*

relative to each other, with initial contact followed by subsequent separation. When the surfaces are separated, one body tends to be left with a positive charge and the other with a negative charge. If the bodies are good conductors of electricity, the charge moves quite freely and both bodies are effectively restored to their original uncharged state through the last points of contact at separation. But if one or both of the bodies are poor conductors, the charge does not flow freely and both bodies retain charge after separation.

There are many industrial processes that involve surface contact, movement and separation of poorly conducting materials. These processes may be classified in terms of: the phases involved, for example, gas-solid; the general type of system, for example, dusts and powders; or the particular type of process or equipment, for example, pneumatic conveying. Some systems in the process industries where static effects are important are listed, by the phases involved, in Table 16.33. The treatment given below is based on the general type of system. The hazard of static electricity occurs in the process industry in: fluid handling operations such as pipeline flow, settling of drops, agitation, filling of storage tanks, filling of tankers; powder and dust and powder handling operations such as grinding, sieving and pneumatic conveying; in sprays and mists such as in steam cleaning and steam leaks; moving equipment such as conveyor belts and bucket elevators; and the human body.

There are also industrial processes in which static electricity is exploited. They include electrostatic gas filtration and electrostatic spray coating. An account of these processes, which are of minimal interest here, is given by Cross (1987).

Table 16.33 *Some systems in the process industries where static electricity effects are important*

System	
Liquid–solid	Flow of liquid through pipes, filters Splash filling of tanks
Liquid–liquid	Mixing of immiscible liquids Settling of drops of one liquid through another
Gas–liquid	Cleaning with wet steam Spraying with water Leakage of wet steam
Gas–solid	Pneumatic conveying Fluidized beds
Solid–solid	Belt drives Conveyor belts Reeling of paper or plastics Human body

Static electricity is essentially a phenomenon of low current but high voltage. A low conductivity liquid flowing through a pipeline can generate charge at a rate of 10^{-8}–10^{-4} A. A powder coming out of a grinding mill can carry charge at a rate of 10^{-8}–10^{-4} A. At a charging rate of 10^{-6} A the potential of a container insulated from ground can rise at a rate of 1000 V/s. Potentials of 10,000 V or more are readily obtained in this way.

Objects that can become charged include process materials, process plant and the human body. As long as any of these can remain charged, the electrostatic hazard is not eliminated.

The static charge may discharge causing an incendive spark or it may give a less hazardous corona discharge or may leak away to ground. Sparks from good conductors are more incendive than are those from poor conductors.

The hazard of static electricity may be estimated by comparing the energy of an electrostatic charge with the MIE of flammable gas mixtures and powder or dust suspensions.

Static electricity is a complex phenomenon and it is emphasized that only an outline treatment is given here.

16.7.2 Static ignition incidents

In the past there has often been a tendency in incident investigation where the ignition source could not be identified to ascribe ignition to static electricity. Static is now much better understood and this practice is now less common.

In 1954, a large storage tank at the Shell refinery at Pernis in the Netherlands exploded 40 min after the start of pumping of tops naphtha into straight-run naphtha. The fire was quickly put out. Next day a further attempt was made to blend the materials and again an explosion occurred 40 min after the start of pumping. The cause of these incidents was determined as static charging of the liquid flowing into the tank and incendive discharge in the tank. These incidents led to a major program of work by Shell on static electricity.

An explosion occurred in 1956 on the *Esso Paterson* during loading at Baytown, Texas, the ignition being attributed to static electricity.

In 1969, severe explosions occurred on three of Shell's very large crude carriers (VLCCs): the *Marpesa*, which sank, the *Mactra* and the *King Haakon VII*. In all three cases tanks were being cleaned by washing with high pressure water jets, and static electricity generated by the process was identified as the ignition source. Following this set of incidents Shell initiated an extensive program of work on static electricity in tanker cleaning.

Explosions due to static ignition occur from time to time in the filling of liquid containers, whether storage tanks, road and rail tanks or drums, with hydrocarbon and other flammable liquids.

Explosions have also occurred due to generation of static charge by the discharge of carbon dioxide fire protection systems. Such a discharge caused an explosion in a large storage tank at Biburg in Germany in 1953, which killed 29 people. Another incident involving a carbon dioxide discharge occurred in 1966 on the tanker *Alva Cape*.

The majority of incidents have occurred in grounded containers. Grounding alone does not eliminate the hazard of static electricity.

These incidents are sufficient to indicate the importance of static electricity as an ignition source. Further incidents attributed to static electricity are described in Case Histories B36, B56 and B61.

16.7.3 Some basic relations

In work on static electricity it is often necessary to distinguish between the potential ϕ at a point and the potential difference, or voltage, V between two points. Where one point is grounded and the other is not, the potential and the voltage are the same.

Some of the fundamental relations of static electricity are as follows.

Ohm's law

Ohm's law states that

$$V = IR \qquad [16.7.1]$$

where I is the current (A), R is the resistance (Ω), and V is the potential difference, or voltage (V).

Definitions

The following relations are effectively definitions:

$$R = \frac{V}{I} \qquad [16.7.2]$$

$$G = \frac{1}{R} \qquad [16.7.3]$$

$$\rho = \frac{RA}{l} \qquad [16.7.4]$$

$$\kappa = l/\rho \qquad [16.7.5]$$

$$C = \frac{q}{V} \qquad [16.7.6]$$

$$\sigma = \frac{q}{A} \qquad [16.7.7]$$

$$s = \frac{q}{V_{\mathrm{cn}}} \qquad [16.7.8]$$

$$\epsilon = \frac{\epsilon_{\mathrm{a}}}{\epsilon_{\mathrm{o}}} \qquad [16.7.9]$$

where A is the area (m^2), C is the capacitance (F), G is the conductance (S), l is the length (m), q is the charge (C), s the space charge density (C/m^3), V_{cn} is the volume of the containment (m^3), ϵ is the relative permittivity, or dielectric constant, ϵ_{a} is the absolute permittivity (F/m), ϵ_{o} is the permittivity of free space (F/m), κ is the conductivity (S/m), ρ is the volume resistivity (Ω m) and σ is the surface charge density (C/m^2). The volume resistivity ρ is frequently referred to simply as the resistivity.

Field strength and force

The field strength E is defined as

$$E = -\frac{\mathrm{d}V}{\mathrm{d}x} \qquad [16.7.10]$$

or

$$E = -\frac{V}{x} \qquad [16.7.11]$$

where E is field strength (V/m) and x is the distance (m). Frequently the negative sign in Equation 16.7.11 is dropped, since it is only the magnitude of the voltage or field strength that is of interest.

The force F_{e} on a body due to the charge on it and to the field in which it is placed is

$$F_{\mathrm{e}} = qE \qquad [16.7.12]$$

where F_{e} is force (N). For a gravitational field

$$mg = qE \qquad [16.7.13]$$

where g is the acceleration due to gravity (m/s^2) and m is the mass of the body (kg).

Charge, energy and work

The charge accumulated on a body charged by a current is

$$\frac{\mathrm{d}q}{\mathrm{d}t} = \mathrm{I} \qquad [16.7.14]$$

The energy W on a charged body is

$$\frac{\mathrm{d}W}{\mathrm{d}q} = V \qquad [16.7.15]$$

$$= \frac{q}{C} \qquad [16.7.16]$$

where W is work, or energy (J).

Then, integrating Equation 16.7.16,

$$W = \frac{1}{2}\frac{q^2}{C} \qquad [16.7.17]$$

$$= \frac{1}{2}qV \qquad [16.7.18]$$

$$= \frac{1}{2}CV^2 \qquad [16.7.19]$$

Equation 16.7.19 also gives the energy of discharge when there is discharge of the full charge on a charged body. If there is a partial discharge from potential V_1 to potential V_2, the energy of discharge is

$$W = \frac{1}{2}C(V_1^2 - V_2^2) \qquad [16.7.20]$$

Surface charge density and displacement

The surface charge density *a* is proportional to the field-strength *E*. For a unidirectional field

$$\sigma \propto E \quad [16.7.21a]$$

$$= \epsilon_a E \quad [16.7.21b]$$

$$= \epsilon \epsilon_o E \quad [16.7.22]$$

For a bidirectional field

$$\sigma = \epsilon_1 \epsilon_o E_1 + \epsilon_2 \epsilon_o E_2 \quad [16.7.23]$$

where subscripts 1 and 2 denote the two fields.

Another quantity that is used is the displacement *D* which is defined as

$$|D| = \sigma \quad [16.7.24]$$

Then

$$D \propto E \quad [16.7.25a]$$

$$= \epsilon_a E \quad [16.7.25b]$$

$$= \epsilon \epsilon_o E \quad [16.7.26]$$

where *D* is the displacement (C/m^2).

Time constant

The time constant for charging and discharge of a liquid is

$$\tau = \frac{\epsilon \epsilon_o}{\kappa} \quad [16.7.27]$$

$$= \epsilon \epsilon_o \rho \quad [16.7.28]$$

where τ is the time constant (s).

16.7.4 Laws of Coulomb, Gauss and Poisson

Coulomb's law

It was shown by Coulomb that the force between two charged bodies is proportional to each of the charges on the two bodies and inversely proportional to the square of the distance between them. In electrostatic units:

$$F_e = \frac{qq'}{x^2} \quad [16.7.29]$$

where q is the charge on one of the bodies (C), q' is the charge on the other body (C) and x is the distance between them (m). In SI units

$$F_e = \frac{qq'}{4\pi\epsilon\epsilon_o x^2} \quad [16.7.30]$$

where F_e is the force (N), q is the charge on one of the bodies (C), and q' is the charge on the other body (C).

Coulomb's law was originally derived by experiment, but has subsequently been demonstrated theoretically.

It follows from Equations 16.7.12 and 16.7.30 that

$$E = \frac{q'}{4\pi\epsilon\epsilon_o x^2} \quad [16.7.31]$$

Gauss' law

Gauss' law may be stated as

$$\nabla D = s \quad [16.7.32]$$

which in Cartesian co-ordinates becomes

$$\frac{\partial V}{\partial x} + \frac{\partial V}{\partial y} + \frac{\partial V}{\partial z} = s \quad [16.7.33]$$

where *x, y* and *z* are the spatial co-ordinates (m). It may also be written for a cloud surface *S* as

$$\int D\,\mathrm{d}S = \sum q \quad [16.7.34]$$

or, from Equations 16.7.26 and 16.7.34,

$$\int E\,\mathrm{d}S = \frac{\sum q}{\epsilon\epsilon_o} \quad [16.7.35]$$

or for constant *E*

$$ES = \frac{\sum q}{\epsilon\epsilon_o} \quad [16.7.36]$$

Whereas Coulomb's law applies to a point source, Gauss' law is more widely applicable. It is used particularly to estimate capacitance and charge, given the limiting breakdown field strength of air. Several applications of Gauss' law are given below.

Poisson's law

Poisson's law, or equation, is

$$\nabla^2 V = -\frac{s}{\epsilon\epsilon_o} \quad [16.7.37]$$

which in Cartesian co-ordinates becomes

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = -\frac{s}{\epsilon\epsilon_o} \quad [16.7.38]$$

In general, applications of Poisson's equation tend to be relatively complex and often involve numerical solution. However, some applications of the equation are given below.

The laws of Coulomb, Gauss and Poisson are all formulations of the same physical law. They relate the charge, the potential and the field strength.

16.7.5 Charge

The charge on a body is expressed as the total charge q, the surface charge density σ or the space charge density s.

Sphere (uniform surface charge density)

For a sphere with uniform space charge density the charge is

$$q = 4\pi a^2 \sigma \quad [16.7.39]$$

where *a* is the radius of the sphere (m).

Sphere (uniform space charge density)
For a sphere with uniform space charge density the charge is

$$q = \frac{4}{3}\pi a^3 s \quad [16.7.40]$$

Cylinder (uniform space charge density)
For a cylinder with uniform space charge density the charge per unit length is

$$q = \pi r^2 s \quad [16.7.41]$$

Maximum surface charge
From Gauss' law, as given by Equation 16.7.36, and from Equation 16.7.22, the maximum surface charge on an insulating surface is

$$\begin{aligned}\sigma_{\max} &= \epsilon\epsilon_o E_b \\ &= 2.64 \times 10^{-5}\,\mathrm{C/m^2}\end{aligned}$$

where E_b is the breakdown field strength (V/m)

16.7.6 Capacitance

Given the charge on a body, the field strength, potential and capacitance may be obtained from Equations 16.7.6, 16.7.11 and 16.7.22. In this section the general approach to the determination of the capacitance of a system is illustrated for the cases of parallel plates and an isolated sphere and expressions are given for the capacitance of some other common systems. The capacitance of some common objects is also given. Field strengths are treated in the following section.

Parallel plates
For the capacitance of two parallel plates, Equation 16.7.22 yields

$$q = \epsilon\epsilon_o AE \quad [16.7.42]$$

and Equation 16.7.10 yields

$$V = Ex \quad [16.7.43]$$

where A is the area of each plate (m^2) and x is the distance between the plates (m). Combining Equations 16.7.42 and 16.7.43

$$q = CV \quad [16.7.44]$$

with

$$C = \frac{\epsilon\epsilon_o A}{x} \quad [16.7.45]$$

Isolated sphere
For the capacitance of an isolated sphere, Equation 16.7.22 yields

$$q = 4\pi r^2 \epsilon\epsilon_o E \quad [16.7.46]$$

and Equation 16.7.10 yields

$$V = -\int_{\infty}^{a} E\,\mathrm{d}r \quad [16.7.47]$$

where r is the radial distance (m).

Hence, substituting for E in Equation 16.7.47 and integrating gives

$$q = CV \quad [16.7.48]$$

with

$$C = 4\pi\epsilon\epsilon_o a \quad [16.7.49]$$

Concentric spheres
The capacitance of two concentric spheres is

$$C = 4\pi\epsilon\epsilon_o \frac{ab}{b-a} \quad [16.7.50]$$

where a and b are the radii of the smaller and larger spheres (m), respectively.

Sphere and plane
The capacitance of a sphere adjacent to a plane is

$$C = 4\pi\epsilon\epsilon_o a[\psi + 0.5\ln(2a/z)] \quad [16.7.51]$$

where z is the distance from the nearest point on the sphere to the plane (m) and ψ is Euler's constant. The value of Euler's constant is 0.577.

This system was originally studied by Russel (1909) and is treated by Cross (1987).

Coaxial cylinders
The capacitance of two coaxial cylinders is

$$C = \frac{\epsilon\epsilon_o 2\pi l}{\ln(r_2/r_1)} \quad [16.7.52]$$

where l is the length of the cylinders (m) and r_1 and r_2 are the radii of the inner and outer cylinders (m), respectively.

Parallel cylinders
The capacitance of two parallel cylinders is

$$C = \frac{\pi\epsilon\epsilon_o l}{\ln\left[\dfrac{a + (a^2 - r^2)^{\frac{1}{2}}}{r}\right]} \quad [16.7.53]$$

where a is the half-distance between the axes of the cylinders (m) and r is the radius of each cylinder (m).

Common objects
The capacitance of some common objects is given in Table 16.34.

16.7.7 Field strength and breakdown

Permittivity
The permittivity of a substance or medium is generally expressed in terms of its relation to the permittivity of free space. The relative permittivity, or dielectric constant, ϵ of a substance is the ratio of the absolute permittivity of that substance ϵ_a to the permittivity ϵ_o of free space, as given by Equation 16.7.9. Another notation that is quite widely used is to denote the absolute permittivity of a substance as ϵ and the relative permittivity as ϵ_r. The permittivity ϵ_o of free space is

$$\epsilon_o = 8.55 \times 10^{-12}\ \mathrm{F/m}$$

Table 16.34 *The capacitance of some selected objects*[a]

Object	*Capacitance*[b] (pF)
Single bolt	1
Tools	5
Small metal item (scoop, hose nozzle)	10–20
Flange (100 mm nominal)	12 (10–15)
Shovel	20
Small container (bucket, 50 l drum)	20 (10–100)
Medium container (250–500 l)	30–300
General plant item[c]	100–1000
Road tanker	1000
Human body	200 (100–300)

[a] *Sources*: N. Gibson (1969); BS 5958: Part 1: 1980; Expert Commission (1988); Glor (1988); Luttgens and Glor (1989).

[b] Approximate values.

[c] Item immediately surrounded by grounded structure.

The relative permittivity, or dielectric constant, of air is about 1, that of hydrocarbons about 2, and that of water about 80.

Parallel plates

From Equation 16.7.42 the field strength between two parallel plates with one at potential V and the other at zero potential is

$$E = \frac{q}{\epsilon\epsilon_o A} \qquad [16.7.54]$$

where A is the area of each plate (m^2).

Isolated sphere

From Equation 16.7.46 the field strength at the surface of an isolated sphere is

$$E = \frac{q}{4\pi\epsilon\epsilon_o a^2} \qquad [16.7.55]$$

where a is the radius of the sphere (m).

Infinite parallel plates (uniform space charge density)

The maximum field strength between two infinite parallel plates with a uniform charge density between them and with both at zero potential occurs at the boundary and is

$$E = \frac{sx}{\epsilon\epsilon_o} \qquad [16.7.56]$$

where x is the half-distance between the plates (m).

Sphere (uniform space charge density)

The maximum field strength in a sphere with a uniform space charge density and with zero potential at the boundary is

$$E = \frac{sa}{3\epsilon\epsilon_o} \qquad [16.7.57]$$

where a is the radius of the sphere (m).

This equation is often applied to systems that approximate a sphere such as a cubic storage tank.

For a sphere with a uniform space charge density exerting fields both inside and outside the sphere the field strengths are

$$E = \left(\frac{s}{3\epsilon\epsilon_o}\right) r \quad r \le a \qquad [16.7.58a]$$

$$E = \frac{s}{3\epsilon\epsilon_o}\frac{a^3}{r^2} \quad r > a \qquad [16.7.58b]$$

where r is the radial distance (m).

It can be shown by Gauss' law that the field strength outside a sphere is the same if the total charge q is (1) concentrated at one point, (2) uniformly distributed in space in the sphere and (3) uniformly distributed over the surface of the sphere.

The relation between the field strength and the potential on a sphere is as follows. From Equation 16.7.10, for the sphere

$$V = \int_a^\infty E\,dr \qquad [16.7.59]$$

Then from Equations 16.7.40, 16.7.58 and 16.7.59

$$E = V/a \qquad [16.7.60]$$

Cylinder (uniform space charge density)

The maximum field strength in an infinite cylinder with a uniform space charge density and with zero potential at the boundary is

$$E = \frac{sr_c}{2\epsilon\epsilon_o} \qquad [16.7.61]$$

where r_c is the radius of the cylinder (m). This equation is often applied to pipes.

For a cylinder with a uniform space charge density exerting fields both inside and outside the cylinder the fields' strengths are

$$E = \left(\frac{s}{2\epsilon\epsilon_o}\right) r \quad r \le r_c \qquad [16.7.62a]$$

$$E = \frac{s}{2\epsilon\epsilon_o}\frac{r_c^2}{r} \quad r \ge r_c \qquad [16.7.62b]$$

Coaxial cylinders (uniform space charge density)

The field strengths at the surfaces of the inner and outer cylinders in a system of two coaxial cylinders with a uniform charge density in the space between them are, respectively

$$E_i = \frac{sr_o}{4\epsilon\epsilon_o}\left[2\beta + \frac{1 - B^2}{B \ln B}\right] \qquad [16.7.63]$$

$$E_o = \frac{sr_o}{4\epsilon\epsilon_o}\left[2 + \frac{1 - B^2}{B \ln B}\right] \qquad [16.7.64]$$

with

$$B = r_i/r_o \qquad [16.7.65]$$

where E_i and E_o are the field strengths at the surfaces of the inner and outer cylinders (V/m) and r_i and r_o are the radii of the inner and outer cylinders (m). If $r_i \ll r_o$

$$E_i = \frac{sr_o}{4\epsilon\epsilon_o}\frac{1}{B \ln B} \qquad [16.7.66]$$

$$E_o = \frac{sr_o}{2\epsilon\epsilon_o} \qquad [16.7.67]$$

These equations have been applied to the case of a cable hanging inside a storage tank.

Tanks fully and partially filled

A detailed treatment of the field strengths in fully and partially filled tanks is given by Hinkenberg and van der Minne (1958) and further treatments are described below.

Field breakdown

The breakdown field strength E_b of air at atmospheric pressure is usually given as

$$E_b = 3 \times 10^6\,\text{V/m} = 3000\,\text{kV/m} = 3\,\text{MV/m}$$

In fact, the breakdown field strength is a function of the electrode gap. Klinkenberg and Van der Minne give the following data for the critical field strength between large parallel electrodes in air at atmospheric pressure:

Electrode gap (mm)	*Critical field strength* (kV/m)
0.6	5220
10	3150
100	2650
Large gap	2240

Figure 16.43 gives the breakdown field strength in air over a somewhat wider range.

According to a relationship usually known as Paschen's law, the breakdown field strength is a function of the product Pl of the pressure P and the gap l, where P is pressure (bar) and l is gap width (m). Figure 16.44 shows the breakdown voltage V for air as a function of Pl. For values of $Pl > 10^{-3}$ bar m, this graph is consistent with a constant breakdown field strength of 3000 kV/m.

16.7.8 Electrostatic charging

The conditions for a significant accumulation of electrostatic charge are that there occurs some process, which generates the charge, and that any process of charge dissipation is sufficiently slow.

There are a number of mechanisms by which an electrostatic charge can build up. The mechanisms of principal interest here are (1) contact and separation, (2) induction, (3) double layer separation and (4) charge sharing. Other mechanisms include (5) corona charging, (6) diffusion charging, and (7) particle capture.

Most accounts of the generation of static electricity begin with a discussion of the electrostatic phenomena involved in the contact and separation of surfaces, in the first instance solid surfaces. If two different materials are rubbed together, so that there is first contact and then separation of their surfaces, charges build up on the surfaces of the two materials, one material having a charge of one polarity and the other a charge of opposite polarity.

Modern theory, stemming from work on solid-state physics, treats electrostatic phenomena in terms of electron transfer. If the temperature of a surface is high enough, electrons are emitted from it. This emission is characterized by the electron work function. The work function is lower in conducting materials and higher in insulating ones.

If the surfaces of two different materials at the same temperature are brought into contact, electron transfer occurs. The material with the lower work function is the donor and that with the higher work function the acceptor. Electrons migrate from the former to the latter, so that the acceptor acquires a negative charge and the donor a positive one. At equilibrium the potential difference due to the difference in the two work functions is equal to that due to the charge transfer. The proportion of electrons transferred is very small, at most eight in a million.

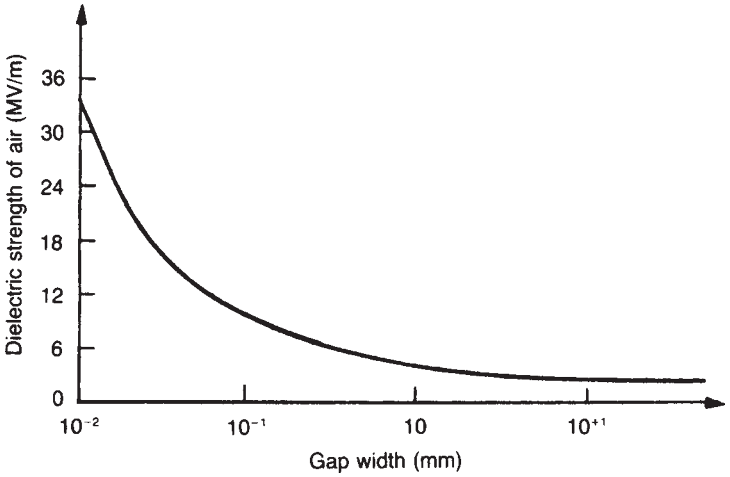

Figure 16.43 *Dielectric strength of air (Glor, 1988): effect of gap width (Courtesy of Research Studies Press)*

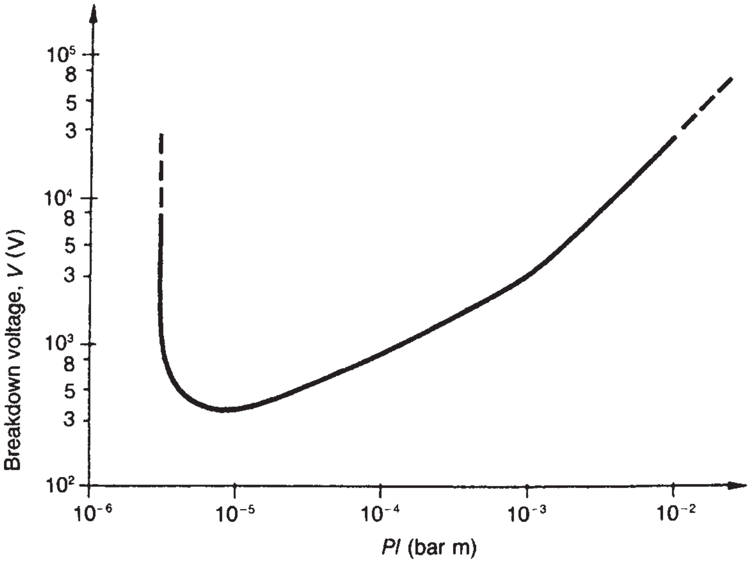

Figure 16.44 *Dielectric strength of air (Glor, 1988): the effect of group Pl (Courtesy of Research Studies Press)*

If the two surfaces are then separated, charge separation also occurs. Provided charge dissipation is limited, one material retains a negative charge and the other a positive charge. The two processes of contact and separation comprise the process of charge generation.

Charge is also generated between two surfaces of the same material at different temperatures.

The nature of the charges depends on the permittivity of the two materials. According to Coehn's (1898) laws':

(1) the body with the higher permittivity has the positive charge;
(2) the magnitude of the charge is a function of the difference in the permittivities of the two materials.

These laws' are, however, controversial. For one thing, as just stated, charge generation can occur between surfaces of the same material.

Materials may be ranked in a triboelectric series. Charge generation is larger for two materials far apart in the series. However, there is no standard triboelectric series, different versions being given by different authorities. Before separation the distance between the surfaces will be very small, of the order of 10^{-9} m. After separation the capacitance is greatly decreased due to the large increase in the distance between the surfaces. The charge remains constant. The voltage is therefore greatly increased ($q = CV$). The energy is also greatly increased ($W = qV/2$). Energy is supplied to the system as work done in moving the two charges apart.

The model just given is a highly simplified one. In particular, it is based exclusively on electron transfer and takes no account of ion transfer. There are some phenomena that are more readily explained by ion transfer. For example, glass may acquire a negative or a positive charge, depending on whether it has previously been in contact with acid or with alkali. An account of ion transfer is given by Cross (1987).

In discussing charging by contact and separation, Cross draws a distinction between contact and friction charging and states that the failure to distinguish between them has been the cause of much confusion. Friction charging can occur even between identical materials. It is probably a surface temperature effect.

However, some workers prefer to avoid the terms 'contact' and 'friction' altogether. There is no dispute that actual charge accumulation happens when separation occurs, and to this extent the term 'separation charging' may be preferred. Liittgens and Glor (1989) argue that 'friction charging' is also a misnomer in that charge accumulation has nothing to do with friction *per se*, but is an effect of surface temperature.

Some of the factors which influence the magnitude of charge accumulation in separation charging include (1) the temperature of the surfaces, (2) the permittivity, (3) the number and density of contact points, (4) the electrical conductivity, (5) the speed of separation and (6) changes in the condition of the materials.

The temperature of the surfaces is a fundamental factor determining the extent of electron transfer.

Coehn's laws, as already discussed, describe the effect of permittivity.

The number and density of contact points depends on the force on the two surfaces. Work on a series of metals and polymers has been done by Haenen (1976), who obtained the relation

$$q \propto F_c^n \qquad [16.7.68]$$

where F_c is the force (N/m^2), q is the charge generated (C) and n is an index. The value of n was in the range 0.3–1.0.

The higher the conductivity of the materials, the greater the extent to which any charge generated is neutralized.

If both bodies are poor conductors, both will become charged. Of one body is a good conductor and grounded, the charge on that body will flow to ground. If one body is a good conductor but not grounded, the charge will distribute itself over the body. In this way a considerable charge may build up.

The speed of separation is another factor governing the extent of charge neutralization. The higher the speed of separation, the less time there is available for charge neutralization to occur.

Physical changes in the condition of the materials, such as expansion and compression, must have some effect, but are not well documented. Another important mechanism of charging is induction. Induction charging occurs only where the body is a conductor. If a body that is an isolated conductor is placed in an electrical field, charges of different polarity are induced on opposite sides. If then a grounded electrode touches, or even approaches close to, this body, the charges close to the electrode flow away, leaving the body with a charge of opposite sign.

This effect may be illustrated by the situation shown in Figure 16.45. In Figure 16.45(a) the man, wearing non-conducting footwear approaches a positively charged conveyor belt. A negative charge is induced on the upper part of his body on the side nearer the belt, and a positive charge on the lower part. In Figure 16.45(b) he touches a grounded point on the conveyor and the negative charge leaks to ground. In Figure 16.45(c) he is left with a positive charge, which equalizes over his body.

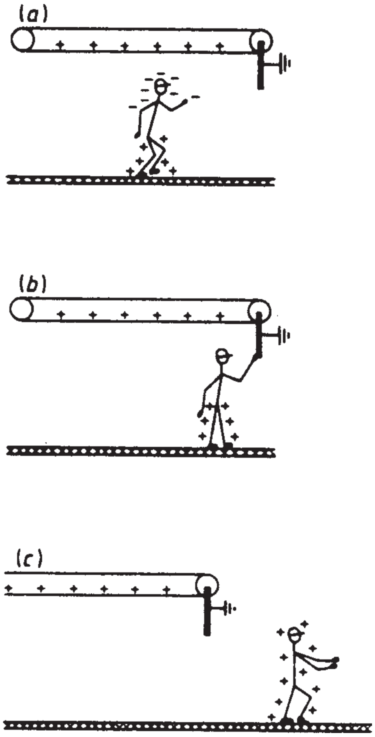

Figure 16.45 *Inductive charging of the human body (Cross, 1987): (a) the charge separates in the field due to the charged belt; (b) the charge from top of the body flows to ground; and (c) the body is left with a net charge (Courtesy of Adam Hilger)*

Liquids also can be charged by induction. A charging mechanism that is particularly important for liquids is double layer separation. If an ionic substance is dissolved in a liquid of high dielectric constant, the ions are dissociated and in an electrical field they move in opposite directions. An example of such a situation is sodium chloride ions in water. At an interface such as a pipe wall ions of one charge will be held strongly, while those of the other charge will be held less strongly and will form a diffuse layer. For a liquid with conductivity as high as that of water, the diffuse layer will be only a few molecules thick. Liquids such as hydrocarbons, however, also contain some ions. For these liquids, which have much lower conductivity, the diffuse layer will be much thicker.

There are a number of models of the double layer, as shown in Figure 16.46. The original model was that of Helmholtz (1879). In the Helmholtz model, shown in Figure 16.46(a), the layer of counter ions is compact, in the Guoy-Chapman model (Guoy 1910, 1917; Chapman, 1913), shown

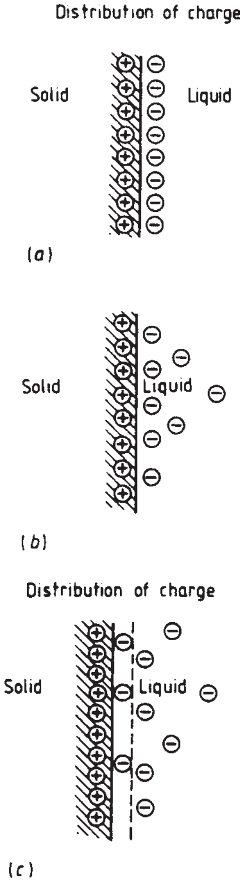

Figure 16.46 *Double layer at a solid-liquid interface (Cross, 1987): (a) Helmholtz model; (b) Gouy-Chapman model; and (c) stem model (Courtesy of Adam Hilger)*

in Figure 16.46(b) the layer is more diffuse, while in the Stern model (Stern, 1924), shown in Figure 16.46(c), the layer of counter ions partly compact and partly diffuse. If the liquid moves through the pipe, the diffuse layer moves with the liquid and charge separation occurs.

Some of the factors that influence the magnitude of charge accumulation in liquid double layer separation include (1) permittivity, (2) electrical conductivity and (3) speed of separation. The effects of these variables are discussed below.

Charge accumulation over time is not necessarily a simple monotonic process. There are three principal patterns of charge accumulation, as shown in Figure 16.47. The charge may either (1) rise to a maximum and stay there, (2) rise to a maximum and then stabilize at a lower plateau, or (3) rise to a maximum, fall to zero and then stabilize at a plateau of opposite sign.

The time taken to reach the maximum value may be characterized by the half-life, which is a function of the materials.

Charge sharing occurs when two bodies, at least one of which is charged, come into contact and charge passes from one to the other. It is relevant particularly to mists and dusts.

Corona charging can be used to create a defined charge on a body for experimental purposes. An account is given by Cross (1987).

Diffusion charging of particles occurs as a result of collisions between particles and ions in a gas. Particle capture, particularly the capture of small particles by larger ones, is another mechanism of charging.

In certain situations it is possible to calculate the limiting charge density. The limiting factor is the charge, which gives an electric field strength equal to the breakdown field strength of air. Gauss' law, given below, may be used to determine the limiting surface charge densities and also the limiting volume charge densities.

Little has been said so far about the polarity of the charge. This is important in some applications, as described below.

Processes in which charge separation occurs include: (1) flow of liquids, (2) transfer of liquids, (3) size reduction, (4) transfer of powders, (5) reeling processes and (6) rotation of belts.

16.7.9 Electrostatic charge accumulation, retention and relaxation

The charging processes described lead to an accumulation of charge in the system. In the general case this input of charge is balanced by an output. This output may take various forms. Charge may be carried away in material leaving the system or it may leak away to ground. The equivalent electrical diagram such as that shown in Figure 16.48 commonly represents this situation.

One common case is where the charging current on an object is balanced by the leakage current so that the system is at steady state. Then the voltage V of the object is then related to the charging current I and the resistance R to ground by Equation 16.7.1 (Ohm's law).

This situation is relevant to grounding. If the charging current is known, it is possible to ensure that the voltage does not exceed a specified limit by ensuring a suitable resistance to ground. The limit on the voltage is generally set in order to avoid an incendive spark. The limiting factor may be the need to avoid a field strength, which causes breakdown or the need to avoid an accumulation of energy that equals the MIE of the flammable mixture. The energy accumulated also depends on the capacitance of the object. Table 16.35 gives typical electrostatic potentials and spark energies quoted for charged objects.

Another common case is where material undergoes a transition from a situation where it was being charged to one where the charging reduces or ceases. It is then able to dissipate this charge, usually by leakage to a containment and so to ground. This process is known as relaxation. It is relevant particularly to liquids. Where a liquid has acquired a charge, arrangements may be made to allow the charge to relax. In a flow system these take the form of providing residence time, while in a storage or tanker system they involve allowing time to elapse before operations are undertaken.

Some of the relations commonly used for the charging and discharge of a system are as follows.

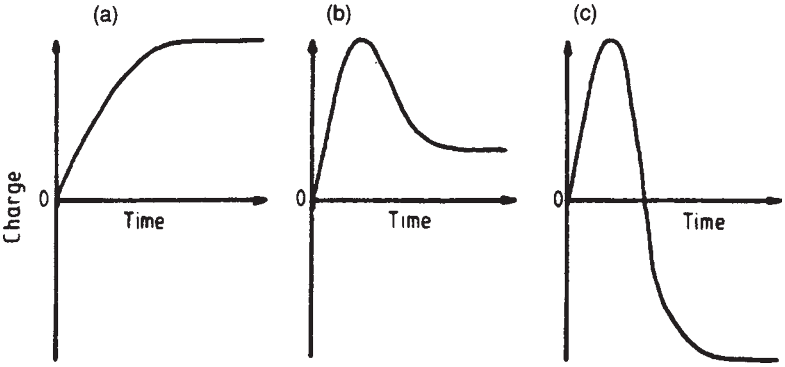

Figure 16.47 A streaming current in a liquid flowing in a pipe (Cross, 1987; aftter Coste and Pechery, 1977): (a) monotonic rise; (b) initial peak followed by a fall to a plateau; and (c) initial peak followed by a fall to a plateau, with reversal of sign (Courtesy of Adam Hilger)

Charging of a condenser

The relations for the charging of, and discharge from, a simple resistance–capacitance (RC) circuit provide the basis for analysis of more complex systems. For the charging of such a circuit

$$\frac{dq}{dt} = I \qquad [16.7.69]$$

$$I = \frac{1}{R}(V_o - V) \qquad [16.7.70]$$

From Equations 16.7.6, 16.7.69 and 16.7.70 the unsteady-state charge balance on the capacitance gives

$$\tau \frac{dV}{dt} = V_o - V \qquad [16.7.71]$$

with

$$\tau = RC \qquad [16.7.72]$$

Integrating Equation 16.7.71

$$V = V_o[1 - \exp(-t/\tau)] \qquad [16.7.73]$$

Multiplying Equation 16.7.73 by C and applying Equation 16.7.6

$$q = q_o[1 - \exp(-t/\tau)] \qquad [16.7.74]$$

Differentiating Equation 16.7.74 and utilizing Equation 16.7.69

$$I = I_o \exp(-t/\tau) \qquad [16.7.75]$$

where I_o is the current at the start of charging (A), q_o is the charge equivalent to the impressed voltage, or the charge at the end of charging (C), and V_o is the voltage across the circuit, or the voltage at the start of charging (V).

Discharge of a condenser

For the discharge of the circuit the unsteady-state charge balance is, from Equations 16.7.1, 16.7.6 and 16.7.69

$$\tau \frac{dV}{dt} = -V \qquad [16.7.76]$$

Integrating Equation 16.7.76

$$V = V_o \exp(-t/\tau) \qquad [16.7.77]$$

Multiplying Equation 16.7.77 by C and applying Equation 16.7.6

$$q = q_o \exp(-t/\tau) \qquad [16.7.78]$$

Differentiating Equation 16.7.78 and utilizing Equation 16.7.69

$$I = I_o \exp(-t/\tau) \qquad [16.7.79]$$

Charging of a tank

For the charging of a tank into which liquid is being pumped, from Equation 16.7.4

$$R = \frac{\rho h}{A} \qquad [16.7.80a]$$

$$R = \frac{h}{\kappa A} \qquad [16.7.80b]$$

where h is the height of liquid in the tank (m). The relationships for the time constant τ are given by Equations 16.7.27, 16.7.72 and 16.7.80.

The initial and final charges in the tank contents are $q = 0$ and $q = q_o$. The initial rate of change of charge is the charge current in the liquid entering the tank, or streaming current I_o:

$$\left(\frac{dq}{dt}\right)_{t=0} = I_o \qquad [16.7.81]$$

The unsteady-state charge balance on the tank is

$$\tau \frac{dq}{dt} = q_o - q \qquad [16.7.82]$$

From Equations 16.7.81 and 16.7.82

$$q_0 = I_0\tau \qquad [16.7.83]$$

Integration of Equation 16.7.82 gives, for tank charging, Equation 16.7.74.

Relaxation of a tank

Equation 16.7.78 is applicable for the relaxation of charge in a liquid in a tank into which pumping has just stopped. The rate of decay in this case may be defined in terms of the relaxation time τ or of the charge half-life $t_{1/2}$. The relationship between the two is

$$\frac{t_{1/2}}{\tau} = \ln 2 = 0.693 \qquad [16.7.84]$$

where $t_{1/2}$ is the half-life (s). The charge decays during relaxation to 50% of its original value in 0.69τ, 37% in $1\,\tau$ and 5% in $3\,\tau$.

16.7.10 Electrostatic discharge

When an electrostatic charge has accumulated, it may discharge either by leaking away, usually to ground, or by a specific mode of discharge. There are a number of mechanisms by which an electrostatic charge can discharge. Those of principal interest here are (1) spark discharge, (2) brush discharge, (3) corona discharge, (4) propagating brush discharge and (5) bulking brush discharge.

A corona discharge can cause ignition of a flammable gas mixture but its incendivity is borderline; it is sometimes stated to be non-incendive to flammable gases or dusts. Essentially it is incendive only to gases with very low MIEs such as hydrogen and carbon disulfide. The other modes of discharge can be incendive, except that it has not been demonstrated that a brush discharge can ignite dusts.

A corona discharge occurs over a longer time than a spark discharge and may give a faint glow and a sound of hissing.

Streaming currents for substances such as petroleum products are of the order of 10^{-6}–10^{-5} A. Corona currents can be much larger. The existence of a corona may therefore dissipate the charge due to the streaming current and lead to a lower steady-state electrostatic potential.

In discussion of discharges it is usual to speak of the bodies the surfaces of which act as points of discharge as electrodes. In this sense the human body may act as an electrode.

A spark discharge is one that occurs between two conductors isolated from each other and involves two electrodes. Typically one of the conductors is isolated from ground and the other is grounded. Spark discharges are also called capacitor discharges, since any system of two conductors isolated from each other is effectively a capacitor. A spark discharge can occur between a fixed isolated object and a grounded object. Alternatively, one or even both of the objects may be moving.

If the resistance between the origin of the spark and all other points on the conductor is less than about $10^6\,\Omega$, a spark discharge can occur. The resistance above that such a discharge will not occur cannot be stated with any precision.

The value of the breakdown electric field strength usually quoted for air is that applicable to two parallel plates. If the surfaces are not parallel, the breakdown field strength can be lower. There are numerous industrial situations in which there are two objects in combination which constitute a capacitor and which therefore may have the potential for a spark discharge.

A spark discharge occurs in a fraction of a second and gives a short, sharp, crackling sound.

A brush discharge is one that occurs on a single electrode and the discharge ends in space. The electrode is a grounded conductor. A charged insulator or a charged conductor may create the electric field. Most accounts of brush discharges deal mainly with the former.

Some industrial situations in which a brush discharge can occur are as follows. The grounded conductor may be a fixed metal object, a sampling device or the human body. The charged object may be a plastic pipe, a drum or a bag, a conveyor belt, a flowing liquid or a powder or a cloud of spray or dust.

Where the second object, like the first, is a conductor, a spark discharge is also possible, and brush and spark discharges may be in competition. The nature of the discharge depends on the shape of the objects.

A corona discharge is similar to a brush discharge but occurs where the electrode is more pointed. The radius of curvature limits quoted are >5–50 mm for a brush discharge and <1 mm for a corona discharge. A corona discharge may persist over a long period.

There are a number of situations in which a propagating brush discharge may occur. These are where there is (1) a non-conducting film suspended parallel to a conductor, (2) a non-conducting film on a conductor, or (3) a non-conductor. The situation may be explained by reference to Figure 16.49, where Figure 16.49(a) shows an isolated

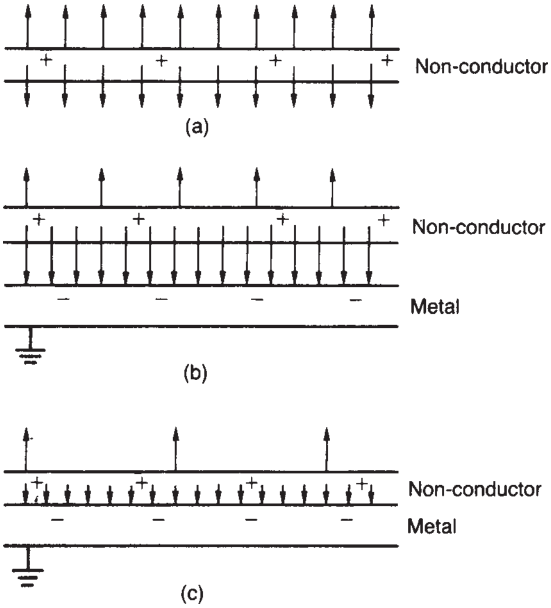

Figure 16.49 *Electric field strength due to an electrically charged sheet (BS 6958: Part 1 1980): (a) isolated sheet; (b) sheet adjacent to a metal plate grounded on the opposite side; and (c) sheet backed by an grounded metal plate (Courtesy of the British Standards Institution)*

non-conducting film in free space and Figures 16.49(b) and (c) show the first two cases mentioned; the third case is similar to the second as far as the field is concerned. The strength of the electric fields is proportional to the density of the arrows. For the isolated film in free space the breakdown field strength of air sets a limit on the surface charge density. For case 1 the presence of the grounded conductor causes a redistribution of the field so that much of it is directed towards the conductor. In this situation a much higher charge density can be accommodated before field breakdown occurs. For case 2 even greater redirection occurs and an even greater charge density can be accommodated. Case 3 is similar to case 2 except that now there is a single non-conducting object.

A propagating brush discharge can occur if there is a short circuit between the insulating film and the conductor or, in case 3, between one side and the other of the non-conductor. One way in which this can occur is if the film is perforated by mechanical damage. Alternatively, if an electrode approaches the non-conducting surface the field may be altered so that a brush discharge occurs on the electrode; the central channel may extend to that surface and damage it. In either case the change in direction of the field gives a very high field strength across the surface and ionization occurs, so that the whole non-conducting surface then discharges into the original channel.

A suitable colouring powder may be used to effect visualization of the discharge patterns on the insulator surface. These patterns are characteristic and are called lichtenberg figures. Propagating brush discharges are referred to as Lichtenberg discharges.

Propagating brush discharges have also been reported on insulating film not backed by a conductor. Although propagating brush discharges have traditionally been explained in terms of a non-conducting film adjacent to or on a conducting surface, the more important practical case is that of a non-conducting envelope such as a pipe or container.

Some industrial situations in which a propagating brush discharge can occur include: the flow of a low conductivity liquid or a powder through a pipe or into a container which is either non-conducting or has an insulating internal coating, and rotation of a conveyor belt with a conductive coating on one side.

A bulking brush discharge is a type of brush discharge that can occur on a heap of powder in a silo. Non-conductive, relatively coarse powders are the most susceptible. The discharge spreads over the surface of the powder, starting at the wall and moving to the centre.

Reference should also be made to lightning-like discharges. These have been observed in the ash and dust clouds over volcanoes and at one time it was supposed that such discharges might occur in industrial operations. There is, however, no evidence of this.

The four types of discharge described, other than bulking brush discharge and lightning discharge, are shown in Figure 16.50.

16.7.11 Liquids

Charge generation

Static electricity effects in liquids may usefully be considered in terms of the classical theory of the electrical double layer at an interface. This has been described by Stern as comprising two parts: a compact or Helmholtz layer near the interface and a diffuse or Guoy layer extending further into the liquid.

According to this model, if a liquid such as oil is at rest and in contact with another immiscible liquid such as water or with a solid such as a container wall, there builds up in that liquid an electrical double layer. This electrical double layer may be represented in convenient, though over-simplified, form as one layer of positive ions and one of negative ions. The phenomenon is illustrated schematically in Figures 16.51(a) and (b) for these two cases. There is no significance in the fact that the ions nearest the interface are positive; they could equally well be negative.

If, in the system described, the oil is a poor conductor and there is a relative movement between the surface of the oil and that of the water or of the container, the ions closest to the interface tend to adhere to it so that the oil loses some ions of one particular sign and thus becomes electrostatically charged. Situations in which such charge separation may occur are the pipeline flow of an oil, the settling of water droplets through an oil and the splashing of oil droplets onto the side of a tank, as illustrated in Figures 16.51(c) and (d), (e) and (f), and (g) and (h), respectively.

The classical electrochemical models describe some of the situations mentioned. The equations are useful at least as a guide to the factors that are important. In some cases they have been further developed to give relations more applicable to industrial situations.

The extent of charge separation is dependent on the resistivity of the liquid. If its resistivity is low, charge separation is easy, but so is charge recombination through the liquid, while if its resistivity is so high as to be effectively infinite, no charge separation occurs. If the liquid has high resistivity, however, there may be appreciable charge separation without immediate recombination. It is the handling of high resistivity liquids, therefore, which tends to generate static electricity. Examples of low resistivity liquids are water, ethanol and crude oil, and examples of high resistivity liquids are gasoline, kerosene, naphtha, benzene and other white oils.

Charge discharge

A hazard occurs with a liquid if charge is able to accumulate and if this charge undergoes rapid discharge rather than gradual dissipation. This hazard depends to a large extent on the container in which the liquid is held. Broadly, such containers are (1) containers made of conducting material and grounded, (2) containers made of conducting material and insulated from ground and (3) containers made of non-conducting material.

In process plants the container is usually made of metal and is grounded. If the liquid has low conductivity, it is possible for a large charge to accumulate in the container. The relaxation time for dissipation of the charge may be long. A discharge may occur between the liquid and the grounded container. Thus, in this situation, grounding of the container is not sufficient to eliminate the hazard. The comment has already been made that the majority of ignition incidents have occurred in grounded containers.

It is easier for charge recombination to occur if one, or both, of the two oppositely charged objects is pointed. Thus any metal object which protrudes into a tank and which is electrically connected to it acts as a path for the discharge current. Such an object is known as a ‘grounded probe’. Objects that can act as grounded probes include dipsticks and ullage tapes, tank washing machines and metallic objects floating on the liquid surface.

An activity that causes particular risk of discharge is level gauging. If a man standing on a tank inserts a

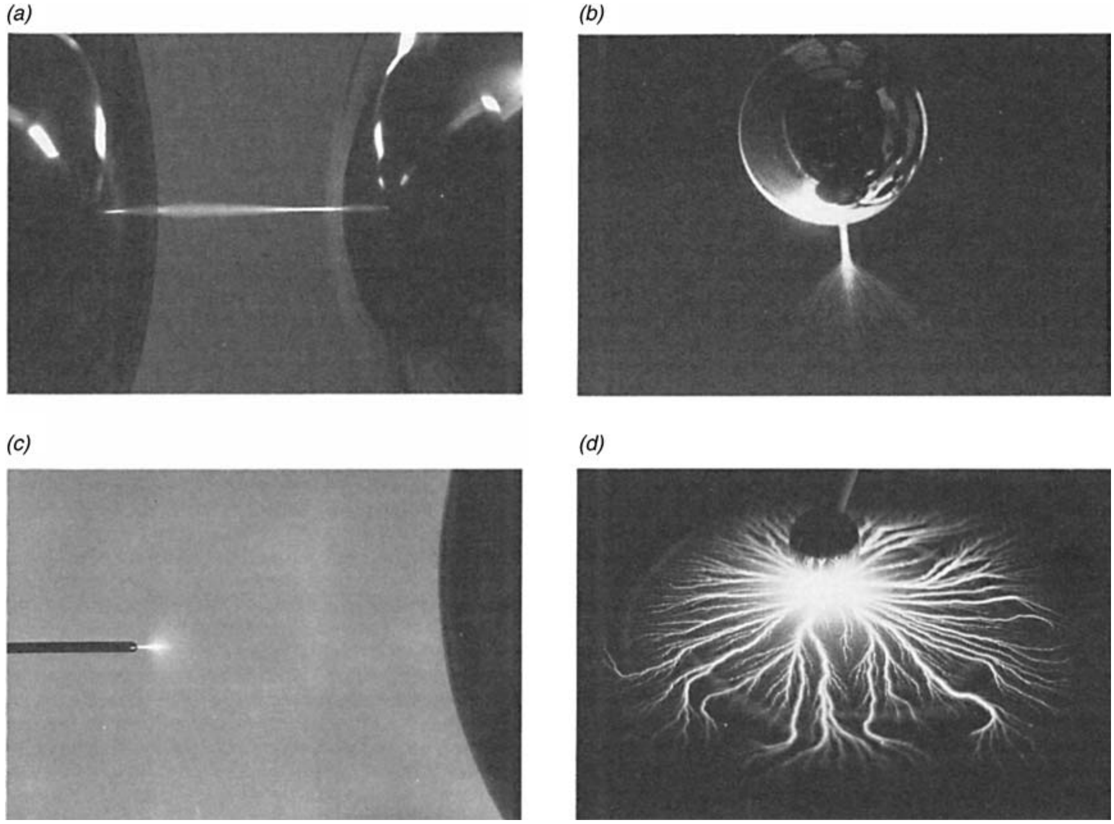

Figure 16.50 Four types of electrostatic discharge (Lüttgens and Glor, 1989): (a) spark discharge; (b) brush discharge; (c) corona discharge; and (d) propagating brush discharge (Courtesy of Expert Verlag)

conducting ullage tape into the liquid in the tank and the liquid is charged, a discharge may occur between the liquid and the tape. This may happen in two ways. If the tape is connected to ground via the man, or otherwise, it can act as a grounded probe. Alternatively, if it is insulated from ground but inserted in the liquid there may be a discharge across to the grounded tank.

A container may be made of metal but insulated from ground. In this case a large charge may accumulate in the liquid and on the container. Then if a path to ground is created there may be a discharge.

A similarly large charge may accumulate in a liquid held in a container made of insulating material, and again discharge may take place if a path to ground occurs.

Another configuration which gives rise to the possibility of discharge is that of an isolated conductor. The conductor may become charged and then give a discharge. Isolated conductors in plant may occur not only in vessels but also in pipework. A section of non-conductive material in metal pipework may constitute an isolated conductor.

If the charged object is a good conductor, it may be treated in the conventional way as an electrical capacitance. The energy available for discharge is given by Equation 16.7.19. The energies calculated in this way may be compared with the MIEs of flammable gas mixtures and of dust suspensions (as described in Section 16.2 and Chapter 17, respectively) in order to determine the probability that a spark discharge may have sufficient energy to cause ignition.

If the charged object is a poor conductor, no similar calculation of the energy available to produce a spark is possible, because the charge is generally not uniformly distributed and the resistance to its flow is high.

16.7.12 Some electrolytic relations

The model of a hydrocarbon electrolyte which is most often used in work on static electricity is that of a binary, monovalent electrolyte. For such an electrolyte some basic relations are as follows. The number of charges z is

$$z = |z_+| = |z_-| \qquad [16.7.85]$$

where z is the number of elementary charges per particle.

The ionic mobility u is assumed to be

$$u = u_+ = -u_- \qquad [16.7.86]$$

where u is the ionic mobility (m^2/Vs). The ionic velocity v is

$$v = uE \qquad [16.7.87]$$

where v is the ionic velocity (m/s).

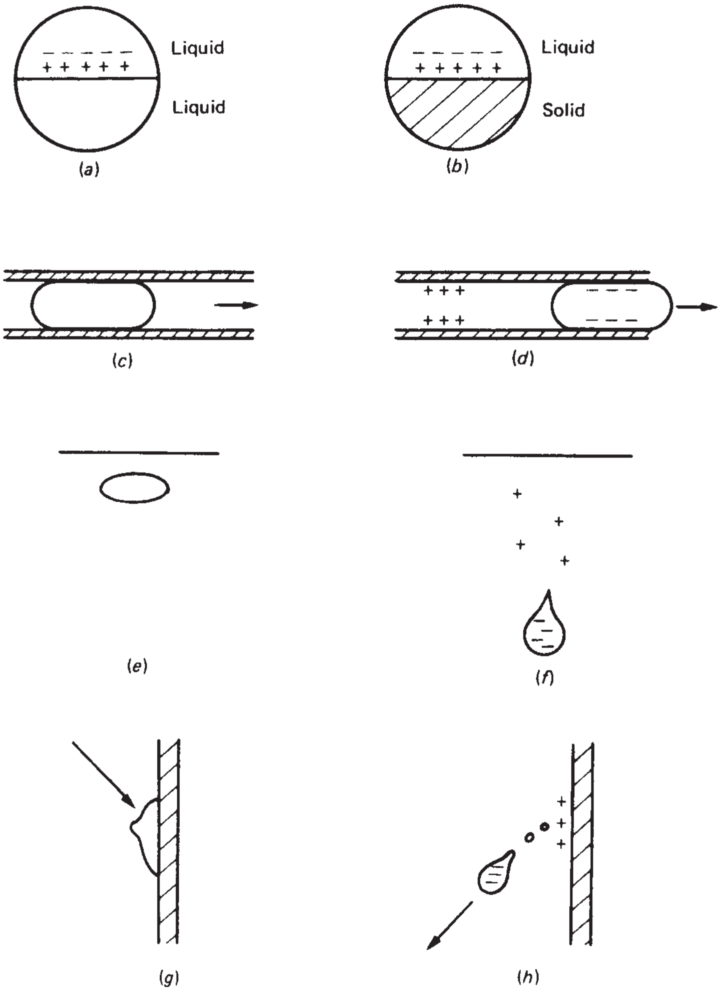

Figure 16.51 *Generation of static electricity in liquid systems: (a) electrical double layer at a liquid–liquid interface; (b) electrical double layer at a liquid–solid interface; (c, d) charge separation as oil flows through a pipeline; (e, f) charge separation as a water drop falls through oil; and (g, h) charge separation as oil spashes onto a tank wall*

The charge flux j for each ionic species with concentration n is

$$j = z\frac{n}{N}Fv \quad [16.7.88]$$

$$j = z\frac{n}{N}FuE \quad [16.7.89]$$

where F is the charge per kilomole equivalent (C/kmol), j is the charge flux (A/m^2), n is the number of ions per unit volume (ions/m^3), and N is the number of molecules per kilomole (molecules/kmol). F is Faraday's constant ($= 9.65 \times 10^7$) and N is Avogadro's number ($= 6.02 \times 10^{26}$).

The concentration c of each ionic species is

$$c = \frac{n}{N} \quad [16.7.90]$$

The force F_e due to the electric field is

$$F_e = zeE \quad [16.7.91]$$

where e is the charge on a proton (C) ($= 1.6 \times 10^{-19}$) and F_e is force (VAs/m). The electric charge is given by

$$ne = cF \quad [16.7.92]$$

The total concentration of ions is

$$c_+ + c_- = 2c \quad [16.7.93]$$

The current density J is

$$J = 2nvze \quad [16.7.94]$$

$$= 2cvzF \qquad [16.7.95]$$

$$= 2cuzFE \qquad [16.7.96]$$

$$= \kappa E \qquad [16.7.97]$$

with

$$\kappa = 2nuze \qquad [16.7.98]$$

$$= 2cuzF \qquad [16.7.99]$$

where J is the current density (A/m^2). In terms of the ionic concentrations, the conductivity is

$$\kappa = (c_+ - + c_-)uF \qquad [16.7.100]$$

where c_+ is the concentration of positive ions (kmol/m^3) and c_- is the concentration of negative ions (kmol/m^3). The space charge density is

$$s = (c_+ - c_-)F \qquad [16.7.101]$$

The relation between the ionic velocity and the diffusion coefficient is

$$D_m = \frac{kTu}{ze} \qquad [16.7.102]$$

where D_m is the molecular diffusion coefficient (m^2/s), k is Boltzmann's constant (kg m^2/s^{2}K) and T is the absolute temperature (K).

The relation between the concentration and the conductivity is

$$\kappa_\pm = \frac{c_\pm z^2F^2D_m}{RT} \qquad [16.7.103]$$

$$\kappa = \kappa_+ + \kappa_- \qquad [16.7.104]$$

$$\kappa = \frac{(c_+ + c_-)z^2F^2D_m}{RT} \qquad [16.7.105]$$

$$\kappa = \frac{2cz^2F^2D_m}{RT} \qquad [16.7.106]$$

where R is the universal gas constant (kJ/kmol K).

For a liquid from which all the ions of one sign have been removed, Equations 16.7.100 and 16.7.101 become

$$\kappa = cuF \qquad [16.7.107]$$

$$s = cF \qquad [16.7.108]$$

The thickness δ of the double layer is derived as follows. It has been shown by Debye and Huckel that

$$\delta = \left(\frac{\epsilon\epsilon_o kT}{2nz^2e^2}\right)^{1/2} \qquad [16.7.109]$$

where k is the Boltzmann constant (J/K) and δ is the thickness of the double layer (m).

From Equations 16.7.98, 16.7.102 and 16.7.109 it can be shown that

$$\delta = (D_m\tau)^{1/2} \qquad [16.7.110]$$

The surface charge density σ at the electrical double layer is given by

$$\sigma = \frac{\epsilon\epsilon_o V_d}{\delta} \qquad [16.7.111]$$

where V_d is the potential difference across the double layer (V).

Another important parameter is the zeta potential. This is the potential at the plane of slip between the surface and a liquid moving across it. The zeta potential is

$$\zeta = \frac{\eta u}{\epsilon\epsilon_o} \qquad [16.7.112]$$

or

$$\zeta = \frac{\eta v}{\epsilon\epsilon_o E} \qquad [16.7.113]$$

where ζ is the zeta potential (V) and η is the viscosity of the liquid (kg/m s).

16.7.13 Liquid conductivity

The electrical conductivity of a liquid is due to the presence of ions. This is true for hydrocarbons as well as for aqueous solutions. Addition of ions increases the conductivity and removal of ions decreases it.

It has been found by a number of investigators that the electrical conductivity of hydrocarbon liquids is not a true constant but may vary. It is therefore usual to speak of a 'rest' conductivity, which is the intrinsic property, and an 'effective' conductivity, which depends on the conditions.

Douwes and van der Waarden (1967) showed that when the dc electrical conductivity of hydrocarbons was measured under different conditions so that there were different decay times, extrapolation back to zero time gave conductivities equal to each other and equal to the ac conductivity. They concluded that it was this zero time dc conductivity, which is the intrinsic property.

A discussion of fundamental aspects of liquid conductivity has been given by Klinkenberg (1967a).

According to Schön (1967), the effective conductivity κ_e and rest conductivity κ_r (S/m) may vary by a factor of 10. In general, the difference increases as the charge density increases.

Britton and Smith (1988) give relations for the effect of charge density on the conductivity and for the effect of temperature on the effective conductivity. They quote the work of H. Kramer and Schön (1973) on the effect of charge density:

$$\kappa_e = k_1 + k_2 s \qquad [16.7.114]$$

where k_1 and k_2 are constants. The constant k_2 is positive for liquids with low rest conductivity (<1 pS/m) and negative for liquids with a higher rest conductivity. Kramer and Schön obtained a maximum value of 4 for the ratio κ_r/κ_e. For the effect of temperature Britton and Smith quote an equation of P.I. Mason (1975):

$$\log_{10}(\kappa_2/\kappa_1) = k_3(T_2 - T_1) \qquad [16.7.115]$$

where k_3 is a constant and subscripts 1 and 2 refer to states 1 and 2, respectively. For liquids such as kerosene, the value of the constant k_3 is about 0.015°C^{-1}. H. Kramer and Schön (1975) give some experimental data showing the effective conductivity to be, on average, half the rest value. W.D. Rees (1975) reports measurements in which the effective conductivity varied between one-tenth and one-half of the rest value.

The above relations also indicate that for low conductivity liquids the effective conductivity is greater than the rest value. This is important, because the relaxation times for low conductivity liquids are long and any feature that reduces them is helpful. Thus Vellenga and Klinkenberg (1965) have derived a model of charge relaxation in a liquid in which the assumption is that the conductivity is proportional to the charge density and which gives a hyperbolic rather than an exponential decay. Another model has been given by M.D. Foster (1967).

The range of conductivities that occur in practice is very wide. According to Klinkenberg and van der Minne (1958), the conductivity of a crude oil may be 10^7 times that of a light fraction. There tend to be large differences between the conductivity of pure and commercial chemicals. For example, the conductivity of pure heptane has been given as 0.03 pS/m and that of the commercial product as 10–100 pS/m.

The electrical conductivity, dielectric constant and relaxation time of selected liquids are shown in Table 16.36. Relaxation times vary from very small fractions of a second for some crude oils up to minutes or even hours for some highly purified products.

One broad classification of liquid conductivity (Expert Commission, 1988) is that liquids with a conductivity of less than 10^{-8} S/m are classed as non-conductive and those with a conductivity exceeding this are classed as conductive. Examples quoted of non-conductive liquids are aliphatic and aromatic hydrocarbons, ethers and methane derivatives, and examples of conductive liquids are hydrocarbons with polar groups, alcohols, aldehydes, ketones, acids, esters (except those of higher acids), nitriles, amides, amines and nitro compounds.

Two liquid conductivities that are commonly taken as demarcation values are 1 pS/m and 50 pS/m. A conductivity less than 1 pS/m is commonly classed as very low and one in the range 1–50 pS/m as low. The conductivity criterion of 50 pS/m appears to derive in large part from the work at Shell (e.g. Klinkenberg and van der Minne, 1958). It is quoted as a demarcation value in codes such as NFPA 77: 1988 and BS 5958: 1991.

The greatest danger occurs where the liquid conductivity is in the intermediate range, that is, not so low that there is little charge generation and not so high that charge equalization is very rapid. Figure 16.52 illustrates the zone of particular hazard.

Mention is made in the literature of the possibility of prostatic agents and of 'hot fluids', but usually only in passing.

A note on the units of conductivity/resistivity is given in the notation at the end of this chapter.

16.7.14 Liquid flow in pipes

One of the most important situations in which static electricity may be generated by a liquid is in flow through a pipe into a receiver such as a storage tank or a road or rail tanker. The flow of liquid results in a charging, or streaming, current that then transports charge into the receiver.

Factors that affect the charge generation in liquid flow in pipes include the pipe diameter and material, the liquid viscosity and electrical conductivity, and the liquid velocity. Impurities, including water, are also important. Figure 16.53, from Leonard and Carhart (1970), illustrates the variation of charging current with conductivity.

The charge generated by a liquid flowing in a pipe is greatly increased if the liquid contains water. An increase in the charge generated by a factor of up to 50 is quoted by Klinkenberg and van der Minne (1958). Many accidents attributed to static electricity have involved wet liquids.

Charge generation by liquid flow in pipes has been modelled by a number of workers and some success has been achieved in explaining theoretically the charging currents generated in small diameter pipes, but there has

Table 16.36 *Electrical conductivity, dielectric constant and relaxation time of selected liquids*

A Electrical conductivity, dielectric constant and relaxation time

	Electrical conductivity (S/m)	*Dielectric constant*	*Relaxation time* (s)
Highly purified hydrocarbons	10^{-15}	2	1.8×10^4
White products	$10^{-13} - 10^{-10}$	2	$1.8 \times 10^{-1} - 10^2$
Crude oil	$10^{-9} - 10^{-7}$	2	$1.8 \times 10^{-4} - 1.8 \times 10^{-2}$
Demineralized water	10^{-5}	80	7.1×10^{-5}

B Dielectric constant

Hexane	1.9
Heptane	2.0
Benzene	2.3
Toluene	2.4
Cyclohexane	2.0
Ethyl ether	4.3
Acetone	21.0
Methanol	33.7
Ethanol	25.7

Sources: Klinkenberg and van der Minne (1958); Eichel (1967); Napier (1971).

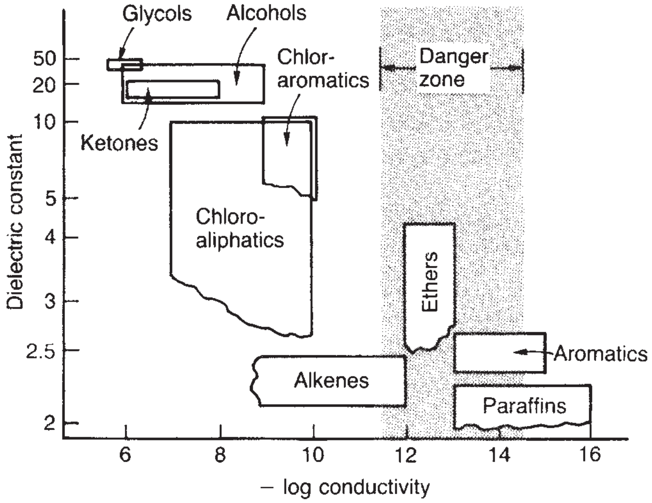

Figure 16.52 Liquid electrical conductivity (Saletan, 1959b): conductivity ranges of selected liquids (Courtesy of Chemical Engineering)

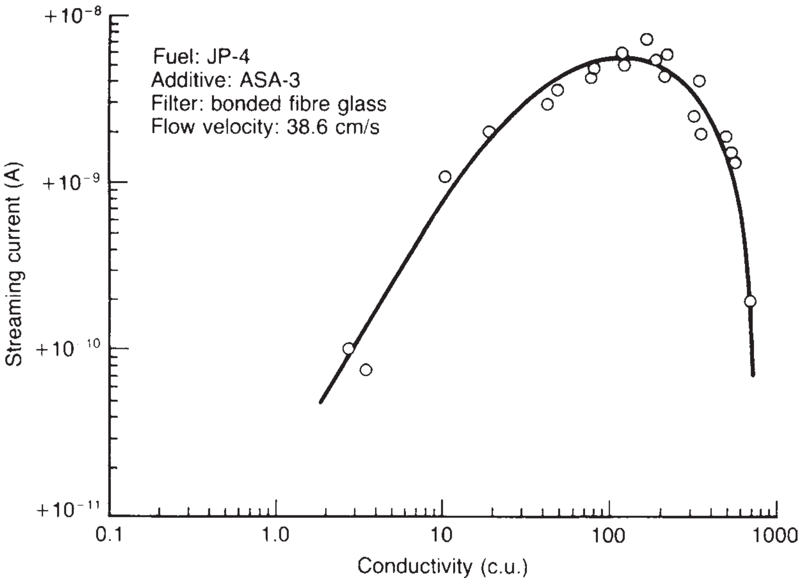

Figure 16.53 Streaming current for liquid flow in a pipe (Leonard and Carhart, 1970): effect of liquid electrical conductivity (Courtesy of the Journal of Colloid and interface Science)

been less success with large pipes and for these it is necessary to rely on empirical correlations. Empirical correlations are generally of the form

$$I \propto u^m d^n \qquad [16.7.116]$$

where d is the pipe diameter (m), I is the streaming current (A), u is the velocity of the liquid (m/s) and m and n are indices.

Most of the work on liquid flow in pipes refers to metal pipes, but there is a limited amount of work on non-conducting pipes. Obstructions in the pipe may cause appreciable charge generation. Filters are the main case in point, but other items such as ball valves have also received attention.

16.7.15 Early models

Early theories of charge generation by a liquid flowing in a pipe were given by W.F. Cooper (1953a) and Boumanns

(1957). In Boumanns' theory charge is generated as the flow of liquid entrains ions from the double layer. But this mechanism, while capable of giving a transient, does not fully explain the existence of a steady-state current. Boumanns therefore introduced the concept of a 'wall current'.

Another early model was that of Schön, given in unpublished work quoted by Hampel and Luther (1957). This work is also referred to by Klinkenberg and van der Minne (1958).

16.7.16 Klinkenberg and van der Minne model

A model for the streaming current and the streaming potential for the flow of liquid in a pipe has been given by Klinkenberg and van der Minne (1958). The assumptions of the model are that (1) the electrical double layer is thin compared with the pipe diameter, (2) this layer is also thin compared with the laminar sublayer, (3) the streaming current is independent of the pipe length, and (4) the shear stress is constant throughout the electrical double layer. The charging current I is

$$I = \pi d_p \int sv \mathrm{d}x \qquad [16.7.117]$$

where d_p is the pipe diameter (m) and x is the distance from the pipe wall (m). The shear stress τ_s in the electrical double layer is

$$\tau_s = \eta \frac{\mathrm{d}v}{\mathrm{d}x} \qquad [16.7.118]$$

where η is the viscosity of the liquid (kg/m s) and τ_s is the shear stress (N/m^2). Then, since the shear stress is assumed constant throughout the layer,

$$\tau_{so} = \frac{\eta v}{x} \qquad [16.7.119]$$

where τ_{so} is the shear stress at the wall (N/m^2).

Applying Poisson's equation, Equation 16.7.38, in one dimension

$$s = -\epsilon\epsilon_o \frac{\mathrm{d}^2 V}{\mathrm{d}x^2} \qquad [16.7.120]$$

Hence from Equations 16.7.117–16.7.120

$$I = -\frac{\pi d_p \tau_{so} \epsilon\epsilon_o}{\eta} \int x \frac{\mathrm{d}^2 V}{\mathrm{d}x^2} \mathrm{d}x \qquad [16.7.121]$$

Integrating Equation 16.7.121 between the wall ($x = 0$) and the plane where the potential gradient is zero ($\mathrm{d}V/\mathrm{d}x = 0$)

$$I = -\frac{\pi d_p \tau_{so} \epsilon\epsilon_o}{\eta} \left(x \frac{\mathrm{d}V}{\mathrm{d}x} - \int \frac{\mathrm{d}V}{\mathrm{d}x} \mathrm{d}x \right)_{x=0}^{\mathrm{d}V/\mathrm{d}x=0} \qquad [16.7.122]$$

For the limit just given the first term in the integration in Equation 16.7.122 is zero. The second term may be replaced by the zeta potential. Hence

$$I = -\frac{\pi d_p \tau_{so} \epsilon\epsilon_o \zeta}{\eta} \qquad [16.7.123]$$

Eliminating the shear stress by using a force balance which introduces the pressure drop

$$\pi d_p l \tau_{so} = A_p \Delta P \qquad [16.7.124]$$

where A_p is the pipe cross-sectional area (m^2), l is the pipe length (m) and ΔP is the pressure drop (N/m^2). Hence from Equations 16.7.123 and 16.7.124

$$I = -\frac{A_p}{l} \frac{\epsilon\epsilon_o \zeta}{\eta} \Delta P \qquad [16.7.125]$$

The streaming potential V_s is obtained by equating the streaming current to minus the leakage current through the liquid in the pipe:

$$I = -\frac{V_s}{R_p} \qquad [16.7.126]$$

where R_p is the resistance of the liquid in the pipe (Ω) and V_s is the streaming potential (V). Then from Equations 16.7.4, 16.7.5 and 16.7.126

$$I = -\frac{A_p \kappa}{l} V_s \qquad [16.7.127]$$

Equating Equations 16.7.125 and 16.7.127 yields

$$V_s = \frac{\epsilon\epsilon_o \zeta}{\kappa \eta} \Delta P \qquad [16.7.128]$$

16.7.17 Koszman and Gavis model

Another theoretical model, or rather suite of models, is that of Koszman and Gavis (Gavis and Koszman, 1961; Koszman and Gavis, 1962a,b). They postulate that electrolytic oxidation-reduction reactions can occur in hydrocarbons, that in effect a cell reaction occurs in the pipe, and that the current flow is associated with this reaction. With current flow, concentration polarization will occur. They thus avoid the need to assume a wall current of unspecified origin. The current is explicitly described as a diffusion current due to the concentration polarization. The Koszman and Gavis models are given in cgs units and these units are retained for these models here.

The first model derived is for a low conductivity liquid. The mechanisms of charge transport are diffusion, convection and electrical conduction. The basic equation for charge transport, or current, is

$$I = -D_m \nabla q - \kappa \nabla \phi + vq \qquad [16.7.129]$$

where D_m is the diffusion coefficient (cm^2/s), I is the streaming current (A), q is the charge (C), v is the local velocity (cm/s), κ is the electrical conductivity of the liquid (Ω^{-1} cm^{-1}) and ϕ is the potential (V). The solution of the charging current equation is

$$I = \frac{2\pi r_p u D_m \tau F (c_o - c_s)}{\delta_m n_t} [1 - \exp(-L/u\tau)] \qquad [16.7.130]$$

where c_o is the concentration of the discharging ion in the bulk fluid (mol/cm^3), c_s is the concentration of the discharging ion at the pipe wall (mol/cm^3), F is Faraday's constant (= 96,500 C/mol), L is the length of tube (cm), n_t is the transference number, r_p is the pipe radius (cm), u is the average velocity (cm/s), δ_m is the thickness of the diffusion layer (cm) and τ the relaxation time (s).

The total transport of charge across the diffusion layer includes normal conduction transport under the influence of the potential difference between the tube and the bulk liquid, and it is therefore necessary to include the transference number n_t of the ions of charge opposite to those being discharged.

The thickness of the diffusion layer is given by

$$\delta_m = 2r_p/\mathrm{Nu} \qquad [16.7.131]$$

Then from Equations 16.7.106, 16.7.130 and 16.7.131

$$I = I_\infty[1 - \exp(-L/u\tau)] \qquad [16.7.132]$$

with

$$I_\infty = \frac{\pi\epsilon\epsilon_o RTu}{2n_t F}\mathrm{Nu}(1 - c_s/c_o) \qquad [16.7.133]$$

From the correlation for the Nusselt number Nu

$$\mathrm{Nu} = 0.0223\ \mathrm{Re}^{7/8}\mathrm{Sc}^{1/4} \qquad [16.7.134]$$

with

$$\mathrm{Re} = \frac{(2r_p)u}{v} \qquad [16.7.135]$$

where v is the kinematic viscosity (cm^2/s). Then from Equations 16.7.133 and 16.7.134

$$I_\infty = \frac{0.035\epsilon\epsilon_o RTu}{n_t F}\ \mathrm{Re}^{7/8}\ \mathrm{Sc}^{1/4}(1 - c_s/c_o) \qquad [16.7.136]$$

Sc is the Schmidt number.

The concentration c_s should be sensitive to the surface materials, but since these are found to have only a small effect it is possible to assume $c_s \ll c_o$.

As described below, Equation 16.7.132 has had some success in describing the current generation in hydrocarbon liquids of low conductivity, but not for high conductivity hydrocarbon liquids. Koszman and Gavis utilizing the model of Klinkenberg and Van der Minne have therefore extended the treatment. Starting with Equation 16.7.123, and introducing the Reynolds number

$$\mathrm{Re} = \frac{ud_p\rho_1}{\eta} \qquad [16.7.137]$$

where η is the viscosity of the liquid (g/cm s) and ρ_1 is the density of the liquid (g/cm^3), the friction factor f

$$f = \frac{\tau_{so}}{2\rho_1 u^2} \qquad [16.7.138]$$

and the correlation for the friction factor

$$f = 0.079\ \mathrm{Re}^{-0.25} \qquad [16.7.139]$$

yields

$$I = 0.04\pi\epsilon\epsilon_o\ \mathrm{Re}^{3/4}u\zeta \qquad [16.7.140]$$

The authors then write Equation 16.7.140 as

$$I = \frac{0.02\pi r_p\kappa\zeta}{G} \qquad [16.7.141]$$

with

$$G = \frac{4r_p^2}{\mathrm{Re}^{7/8}\tau v} \qquad [16.7.142]$$

From Equation 16.7.141 they derive

$$I = \frac{0.04I_\infty\ \mathrm{Re}^{-1/8}\ \mathrm{Sc}^{-1/2}}{G^{1/2}} \qquad [16.7.143]$$

where I_∞ is given by Equation 16.7.133.

The high conductivity model of Equation 16.7.141 does not include a term, which corrects for pipe length comparable to that in Equation 16.7.132, because the relaxation time is so short that the equilibrium current is reached in a very short distance.

The Koszman and Gavis model for low conductivity is Equations 16.7.132 and 16.7.133, and that for high conductivity is Equations 16.7.141 and 16.7.142.

Some features of the low conductivity model are:

$$I = f(\kappa) \quad \text{Short pipes} \qquad [16.7.144a]$$

$$I_\infty \neq f(\kappa) \quad \text{Long pipes} \qquad [16.7.144b]$$

$$I_\infty \propto u^{1\frac{7}{8}} \qquad [16.7.145]$$

$$I_\infty \propto (2a)^{7/8} \qquad [16.7.146]$$

Koszman and Gavis performed experiments to study the charge generation in small diameter pipes. The experiments confirmed relations 16.7.144–16.7.146. They then plotted the group $(I_\infty/u^{1\frac{7}{8}}(2a)^{7/8})$ against G, as shown in curve A of Figure 16.54. The graph shows that in the low conductivity region the group $(I_\infty/u^{1\frac{7}{8}}(2a)^{7/8})$ is independent of G, as predicted by theory. This held for a wide range of liquid electrical conductivities, liquid velocities and a rather smaller range of pipe diameters and materials. The main exception was platinum pipes, which gave a much higher current generation, as shown in curve B of Figure 16.54. The authors attributed this to a surface roughness effect.

The low conductivity model is not applicable, however, in the high conductivity region. Its range of applicability is for values of $\log_{10}G < -5$. For higher conductivities the current predicted is higher than that observed. At high conductivities the high conductivity model, Equation 16.7.141, was used. It gave the predicted values shown in curves C and D of Figure 16.54. The two curves are for the two extreme values of the Reynolds number used (2100 and 45,000).

N. Gibson (1971) has cast the Koszman and Gavis model in the form

$$Y = Kf(G) \qquad [16.7.147]$$

with

$$Y = \frac{I_\infty}{u^{1.88}d^{0.88}} \qquad [16.7.148]$$

$$G = \frac{d^2}{\mathrm{Re}^{1.75}\tau v} \qquad [16.7.149]$$

$$K = \frac{0.35RT\epsilon\epsilon_o}{n_t F_v^{0.88}}\mathrm{Sc}^{0.25}f(C)$$

where f(C) is a concentration function.

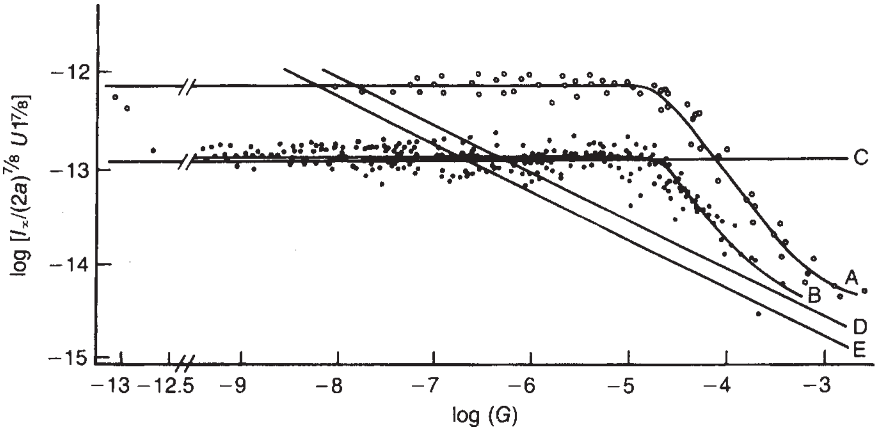

Figure 16.54 *Streaming current for liquid flow in a pipe (Koszman and Gavis, 1962b): A, B experimental curves for platinum, stainless steel tubes respectively. C, theoretical line for low conductivity liquids; D, theoretical line for high conductivity liquids, Re = 2100; and E, theoretical line for high conductivity liquids, R_e = 45 000 (Courtesy of Chemical Engineering Science)*

Equation 16.7.147 applies to liquids of all conductivities. For the case of liquids of low conductivity in turbulent flow

$$f(G) = 1 \qquad [16.7.151]$$

The model of Equation 16.7.147 gives exponents for the pipe diameter d and the liquid velocity u, which may be compared with values obtained in empirical correlations.

16.7.18 Schön model

Schön (1965) carried out experiments using pipe diameters in the range 2.5–20 cm and 'motor spirit' (resistivity $10^{-14} - 10^{-11}$ Ω cm) and obtained the correlation

$$I_\infty = \beta(ur)^n \qquad [16.7.152]$$

where r is the pipe radius (cm), u is the liquid velocity (cm/s), β is a constant and n is an index. The value of n was in the range 1.8–2.0. The author states that the experimental scatter was such that a value of 2 may be taken for n. For this value of n the constant $\beta = 1.5 \times 10^{-13}$.

Equation 16.7.152 has been given by Klinkenberg (1967c) in SI units:

$$I_\infty = Cu^2d^2 \qquad [16.7.153]$$

where d is the pipe diameter (m), u is the liquid velocity (m/s) and C is a constant. The value of the constant C is given as 3.75×10^{-6} As^2/m^4.

Schon states that Equation 16.7.152 is intended to give an upper limit. It has been widely quoted in the literature and thus evidently is widely used.

A critique of Equation 16.7.152 has been given by Britton and Smith (1988), who indicate that it is not conservative in all cases and propose a revised value of C of 2.5×10^{-5} As^2/m^4.

16.7.19 Gibson and Lloyd model

Another set of experiments are those of N. Gibson and Lloyd (1967, 1970b), who utilized pipe diameters in the range 1.62–10.9 cm with toluene and toluene with ASA additive as a conductivity modifier.

They found that the Koszman and Gavis model broke down for these larger pipe diameters. They correlated their results using the equation

$$I_\infty = ku^m d^n \qquad [16.7.154]$$

where d is the diameter of the pipe (cm), u is the velocity of the fluid in the pipe (cm/s), k is a constant and m and n are indices. The indices m and n were somewhat variable, as was the constant, but N. Gibson (1971) has given Equation 16.7.154 as

$$I_\infty = ku^{2.4}d^{1.6} \qquad [16.7.155]$$

and the values of k given by N. Gibson and Lloyd (1970b) are then of the order of 10^{-14}.

The variability of the indices is taken into account in the alternative equation given by N. Gibson and Lloyd (1967) as follows:

$$I = 2.24 \times 10^{-11} d^{1.8} u^{1.45} + 0.01d \exp(0.4 \log_{10} d \log_{10} u) \qquad [16.7.156]$$

where d is the pipe diameter (cm) and u is the liquid velocity (cm/s).* Equation 16.7.156 is another equation which is often quoted.

N. Gibson and Lloyd (1970a) also studied the effect of contamination on charge generation. They found that the presence of contaminant in the toluene could affect the charge generated, but that the values of the streaming current never exceeded those of pure toluene by a factor of more than 10. They attributed this effect to the influence of the contaminant on the electrical conductivity of the liquid.

---

*In the original paper, and in the first edition of this book, a negative sign incorrectly preceded the index of d in Equation 16.7.156.

16.7.20 Other models

There are a number of other models for the charging current in liquid flow through pipes. They include those by Gibbings (1967) and Gibbings and Hignett (Gibbings and Hignett, 1966; Hignett and Gibbings 1968), Goodfellow and S Graydon (1968a,b), Walmsley (1982, 1983a–c) and Walmsley and Woodford (1981a,b), and Abedian and Sonin (1982).

16.7.21 Liquid flow in non-conducting pipes

Most of the work done on streaming currents has been for metal pipes, but a small amount of work has been done on non-conducting, or insulating, pipes. In this context a non-conducting pipe is one made of a material such as glass, rubber or plastic. However, the point is often made that these materials can conduct the very low currents, which occur in static electrification.

Work using 12 mm diameter polyethylene pipe with kerosene has been described by N. Gibson (1971). The main difference compared with results for metal pipes was that for a low conductivity liquid (resistivity 10^{10}–10^{12} Ω cm) the streaming current passed through a transient, decreasing with time to a constant value. For a high conductivity liquid the current was constant with time, as is the case for liquids of all conductivities in metal tubes. This decrease of current was attributed to the fact that the charge, which separates to the pipe surface, is unable to migrate along it sufficiently fast and impedes charge separation.

Work on the electrification of xylene in a glass pipe has been described by Cross, Haig and Cetronio (1977). These workers found a number of features that had a marked effect. There were high charge levels at bends and constrictions compared with straight pipe. Current flowing to metal flanges and to metal bands placed around the pipe varied both in magnitude and polarity. The state of the pipe surface was difficult to control and had a strong effect. For example, baking the pipe at 400°C effected a change in polarity.

16.7.22 Carruthers and Marsh model

Carruthers and Marsh (1962) have developed a model for the streaming current that is applicable to both conducting and insulating pipes. The model was developed as part of a study of the fuelling of aircraft where a filter in the pipe is liable to generate a large amount of charge. The model assumes that the liquid entering the system is already charged and deals with its subsequent behaviour. It does no itself provide an estimate of the streaming current in the liquid entering the pipe. The simple model initially used was

$$I_o = I_i \exp(-t/\tau) + I_p[1 - \exp(-t/\tau) \qquad [16.7.157]$$

where I_i is the current entering the pipe (A), I_p is the current generated in the pipe (A), I_o is the current leaving the pipe (A) and t is the residence time in the pipe (s).

This model proved inadequate, however, and the following more complex model was developed. A conductance ratio B was defined as

$$B = \frac{\text{Conductance per unit length of liquid in pipe}}{\text{Conductance per unit length of liquid in pipe} + \text{pipe wall}} \qquad [16.7.158]$$

so that

$$B = 0 \quad \text{Conducting pipe} \qquad [16.7.159a]$$

$$B = 1 \quad \text{Insulating pipe} \qquad [16.7.159b]$$

Then the general expression derived is

$$I = [I_i e^{-\lambda} + I_p(1 - e^{-\lambda}) + B(I_i - I_p)\left[\left(\frac{1 - e^{-\lambda}}{\lambda}\right) - e^{-\lambda}\right] \qquad [16.7.160a]$$

with

$$\lambda = t/\tau \qquad [16.7.160b]$$

For the two extreme cases

$$I_o = I_i f(\lambda) + I_p[1 - f(\lambda)] \qquad [16.7.161]$$

with, for conducting pipe

$$f(\lambda) = e^{-\lambda} \quad B = 0 \qquad [16.7.162a]$$

and for insulating pipe

$$f(\lambda) = \frac{1 - e^{-\lambda}}{\lambda} \quad B = 1 \qquad [16.7.162b]$$

where f is the fraction of the charge unrelaxed.

The authors conducted experiments with 0.47 cm diameter pipe and *iso*-octane. Some of their results are shown in Figure 16.55. Figure 16.55(a) gives experimental data for copper pipe and Figure 16.55(b) data for PTFE pipe. They regarded these results as reasonable confirmation of the model.

Larger scale experiments using a 2.5 in. rubber hose were also performed and here the performance of the model using a rest conductivity was less good. However, the fit improved when an effective conductivity some 13 times lower than the rest value was used.

16.7.23 Liquid flow through filters and ball valves

Obstruction and filters in pipes can cause considerable increases in charge generation. Filters, in particular, can be prolific charge generators. For example, H. Kramer and Schön (1975) quote charge densities as high as 1000 C/m^3 obtained at filters. N. Gibson (1969) states that the current generated by a filter can be as high as 10^{-6}–10^{-5} A.

Factors that affect the charge generation at a filter include the porosity and pore diameter, the electrical conductivity of the liquid, and the superficial velocity of the liquid.

Experimental investigations of charge generation in filters include those of Gavis and Wagner (1967), Masuda and Schön (1967), Leonard and Carhart (1970) and Huber and Sonin (1975). The latter workers also give a model for the charge generation. The filters used by these various investigators were somewhat different and the original work should be consulted for the correlations obtained. The model of Carruthers and Marsh for the relaxation of charge after a charge generator such as a filter has already been described.

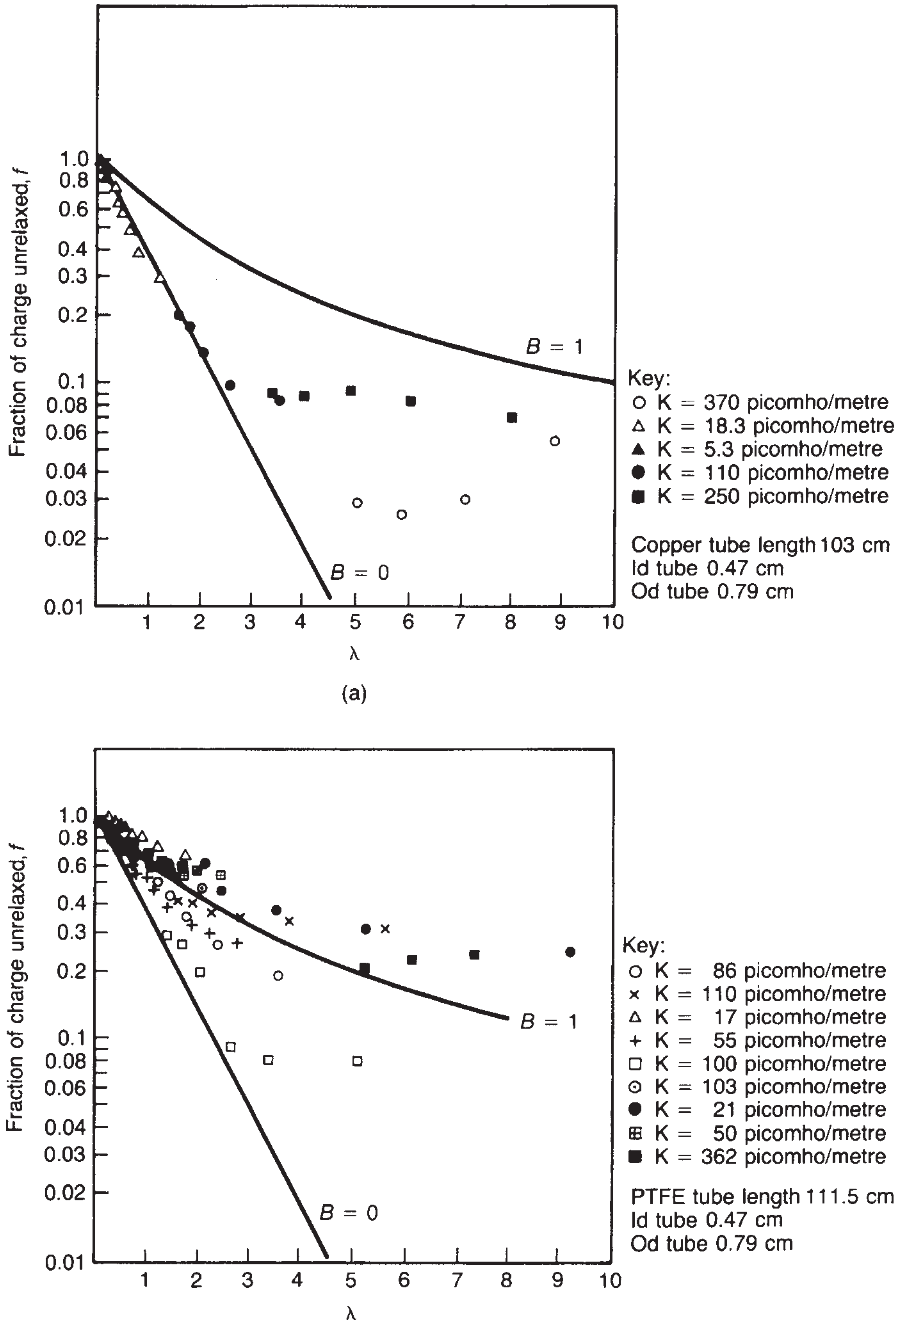

Figure 16.55 *Streaming current for liquid flow in a pipe (Carruthers and Marsh, 1962): non-conducting pipe: (a) charge relaxation in a copper pipe; and (b) in a PTFE pipe (Courtesy of the Institute of Petroleum)*

Work on charge generation in ball valves has been carried out by N. Gibson and Lloyd (1975). They performed experiments in a 10.9 cm stainless steel pipe with a 4 in. bore stainless steel ball valve with toluene and with toluene + water. Parameters investigated were the liquid velocity, the water content in the range 0–5% v/v and the fractional opening of the valve. Charge densities in the liquid increased with liquid velocity and with water content, the latter increase being marked for water contents above 0.1–0.2% v/v. Of the openings investigated, a fractional opening of 0.13 gave the highest charge generation. The highest charge density obtained in the work was 623 C/m^3 at a liquid velocity of 10 m/s with a water content of 5% v/v and a fractional opening of 0.13.

In addition to the effect such charging may have on a liquid flowing into a receiver, there is also a hazard of an incendive discharge at the valve itself. Gibson and Lloyd state that incidents have occurred where the valve body has been insulated by PTFE support rings and packing, and discharges have been observed during the flow of liquid. The capacitance of ball valves in the range 2–20 cm has been measured as 2–150 pF and the resistance to ground in the range 10^8–10^{14} Ω. The authors take a potential of 1 kV as the minimum likely to give an incendive spark, and use a MIE of 0.2 mJ. They are then able to compute the charging current required to give an incendive spark for different values of the valve capacitance, resistance to ground and potential using Equations 16.7.1, 16.7.6 and 16.7.19.

16.7.24 Liquid droplet settling

Klinkenberg and van der Minne (1958) have also given a treatment for liquid droplet settling, based on earlier work by von Smoluchowski (1921). For the settling of a drop of immiscible liquid, such as water, or of a solid particle, the downwards-acting force in an electric field is

$$F_e = \frac{4}{3}\pi a^3 g\Delta\rho + qE \qquad [16.7.163]$$

The upwards-acting force is

$$F_e = 6\pi\eta a u \qquad [16.7.164]$$

where a is the diameter of the liquid droplet (m), u is the settling velocity (m/s) and $\Delta\rho$ is the density difference between the droplet and the continuous liquid phase (kg/m^3). Following Stokes' law, and equating these two forces

$$u = \frac{\frac{4}{3}\pi a^3 g\Delta\rho + qE}{6\pi\eta a} \qquad [16.7.165]$$

The current caused by the transported charge is the sum of that from the falling droplets ($un_d q$) and that from conduction (κE). At equilibrium there is no net current and hence

$$un_d q + \kappa E = 0 \qquad [16.7.166]$$

where n_d is the number of droplets per unit volume (droplets/m^3) and q is the charge on a droplet (C). But

$$n_d = \frac{X}{4/3\pi a^3} \qquad [16.7.167]$$

where X is the volume fraction of the dispersed phase (v/v). From Equations 16.7.165–16.7.167

$$E = -\frac{qXg\Delta\rho}{6\pi\eta a\kappa\alpha} \qquad [16.7.168]$$

with

$$\alpha = 1 + \frac{n_d q^2}{6\pi\eta a\kappa} \qquad [16.7.169]$$

Also, the settling velocity is

$$u = \frac{2a^2 g\Delta\rho}{9\eta\alpha} \qquad [16.7.170]$$

$$= \frac{u_{st}}{\alpha} \qquad [16.7.171]$$

where u_{st} is the Stokes velocity (m/s) and α is a correction factor.

Equation 16.7.168 contains the charge term q which is generally not known. It is more convenient to reformulate it in terms of the zeta potential, which can be estimated. From Equations 16.7.6 and 16.7.47

$$q = 4\pi\epsilon\epsilon_o a\zeta \qquad [16.7.172]$$

Hence from Equations 16.7.168 and 16.7.172

$$E = -\frac{2}{3}\frac{\epsilon\epsilon_o}{\kappa}\frac{Xg\Delta\rho\zeta}{\alpha\eta} \qquad [16.7.173]$$

with

$$\alpha = 1 + \frac{2X_\kappa}{\eta}\left(\frac{\epsilon\epsilon_o\zeta}{\kappa a}\right)^2 \qquad [16.7.174]$$

The settling potential gradient V_{set} is equal to the field strength E. The charge q_{ves} in the vessel is

$$q_{ves} = n_d q V_{ves} \qquad [16.7.175]$$

where q_{ves} is the charge in the vessel (C), V_{set} is the settling potential gradient (V/m) and V_{ves} is the volume of the vessel (m^3).

The foregoing gives the field strength in the liquid. The field strength in the vapour space may be obtained by equating the potential differences so that

$$E_v = \frac{Eh_1}{H - h_1} \qquad [16.7.176]$$

where E_v is the field strength in the vapour space (V/m), h_1 is the height of liquid in the tank (m) and H is the height of the tank (m).

As an illustration, consider the estimate made by Howells (1993 LPB 114) for the settling of droplets of water from a foam blanket injected onto the top of a hydrocarbon fuel in a floating roof storage tank, as described in Section 16.28. He uses the following values of the parameters: $\epsilon = 2$, typical of hydrocarbons; $\epsilon_o = 8.85 \times 10^{-12}$ F/m; $\Delta\rho = 300$ kg/m^3, typical for the density difference between water and hydrocarbons; $\zeta = 0.04$ V, typically in the range 0.01–0.1 V;

$\eta = 5 \times 10^{-4}$ Ns/m^2, typical of hydrocarbons; $\kappa = 0.1$ pS/m, typical of a very low conductivity product; $\alpha = 1$, constant dependent on particle size, which can be taken as unity for particles over a few hundred microns diameter; and $g = 9.81$ m/s. The value of X is obtained on the assumptions that a 0.3 m blanket of foam with an expansion ratio of 5 and a 25% drainage time is applied to the surface and that the foam breaks down into 750 μm droplets; this gives $X = 2.7 \times 10^{-4}$. Equation 16.7.173 then yields an electric field of 9 kV/m. Applied to a tank filled with liquid to a depth of 3 m grounded at the bottom, the liquid surface potential obtained is 27 kV.

16.7.25 Liquid sprays and mists

Another situation that can give rise to the generation of static charge is the break-up of a liquid to form a spray or mist. This can occur in two main ways: (1) discharge through an orifice, or (2) splashing against a surface.

The charge on a liquid droplet resides on the surface and exerts an outward force, which is countered by surface tension. There is thus an upper limit to the amount of charge on a droplet, which was determined by Lord Rayleigh (1882), and is known as the Rayleigh limit. This may be written as

$$q = (64\pi^2 \epsilon\epsilon_o \gamma a^3)^{1/2} \qquad [16.7.177]$$

or

$$\left(\frac{q}{m}\right)_{\max} = \left(\frac{36\epsilon\epsilon_o\gamma}{a^3\rho_l}\right)^{1/2} \qquad [16.7.178]$$

with

$$m = \frac{4\pi a^3 \rho_l}{3} \qquad [16.7.179]$$

where a is the radius of the droplet (m), m is the mass of the droplet (kg), q is the charge (C), γ the surface tension of the liquid (N/m), ρ_l is the density of the liquid (kg/m^3) and the subscript max denotes the maximum. The Rayleigh limit is higher than the Gauss limit.

If a droplet is charged to the Rayleigh limit it disrupts. Work by Schweizer and Hanson (1971) on n-octanol showed that such a droplet then forms one particle with some 95% of the mass and some 77% of the charge, and a number of other, much smaller particles.

N. Gibson (1971) has reported work on the electrification of kerosene and of kerosene with 5% water released as a jet from a 3 mm pipe. Some results of this work are shown in Figure 16.56. The presence of relatively small amounts of water produced a 1000-fold increase in the space charge density.

Napier and Rossell (1973) studied the charge in a spray from a jet of xylene from a 0.25 mm tube. Space charge densities of 0.6×10^{-3} C/m^3 were measured. They comment that the conductivity of the liquid may have been increased by small amounts of water (up to 0.1%), oxidation products and dissolved metals.

After separation the liquid droplets retain their charge until they settle out or until a discharge occurs. A mist containing enough energy to give an incendive spark can be created by a high-pressure jet, but the conditions under which discharge occurs are not well defined. Discharges observed have tended to be of the non-incendive corona type rather than spark discharges.

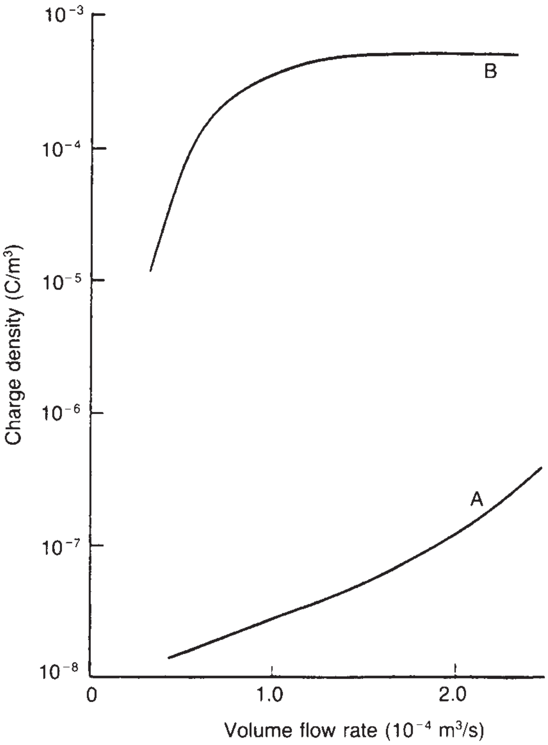

Figure 16.56 *Charge generated in a liquid jet (N. Gibson, 1971): A, kerosene; B, kerosene plus 5% water (Courtesy of the Institute of Physics)*

N. Gibson (1971) has given a simple model that treats the mist as a sphere containing uniformly sized droplets. The maximum field strength occurs at the periphery of the sphere and is

$$E_{\max} = \frac{s a_{\mathrm{ms}}}{3\epsilon_{\mathrm{ms}}\epsilon_o} \qquad [16.7.180]$$

while the total energy of such a spherical mist cloud isolated in space is

$$W = \frac{2\pi s^2 a^5 \mathrm{ms}}{9\epsilon_o}\left(\frac{1}{\epsilon_{\mathrm{ms}}} + \frac{1}{\epsilon_{\mathrm{ar}}}\right) \qquad [16.7.181]$$

where a_{ms} is the radius of the mist cloud (m), E is the field strength at the edge of the cloud (V/m), s is the space charge density of the mist (C/m^3), W is the energy in the cloud (J), ϵ_{ar} is the dielectric constant of air and ϵ_{ms} is the dielectric constant of the mist.

Another situation that can occur is where the jet impinges on a conducting object insulated from ground. A charge may accumulate on the object and then give a discharge.

These electrostatic effects occur when steam is let down from a high pressure so that it comes out wet from the orifice, as with a leak on a steam main. The principal hazard with such a leak is generally that presented by a conducting object insulated from ground.

An electrostatic charge can accumulate in droplets in steam. There is a static electricity hazard, therefore, when steam is used for cleaning or purging of equipment that has contained flammables.

Similarly, charge generation can occur when a vapour, such as propane, containing some small liquid droplets is let down through a jet.

Charge is also generated when a gas containing solid particles issues from an orifice. Thus a carbon dioxide jet being directed from a fire extinguisher into a vessel containing a flammable atmosphere may contain small particles of solid carbon dioxide and may generate enough charge to ignite the mixture.

The splashing of liquid falling onto, or directed against, a surface also results is charge generation. This has been studied by Iribane and Mason (1967), Jonas and Mason (1968), Levin and Hobbs (1971) and Vos (1971).

Levin and Hobbs showed that the main charging mechanism is disruption of the double layer at the liquid-air interface. Most of the charge is associated with the ejection of droplets of some 20 μm diameter from the liquid surface.

Vos obtained for aqueous solutions the following relation for the charging current

$$I = c^{*}u^{2} \qquad [16.7.182]$$

where c^{*} is the charging tendency (As^2/m^2), I is the charging current (A) and u is the velocity of the jet impinging on the surface (m/s).

16.7.26 Liquid agitation

The agitation of liquids can generate charges of the same order of magnitude as charging by liquid flow in a pipe. Vos *et al.* (1974) have described work undertaken following several fires involving agitation to effect the dissolution of epoxy resin in xylene. With epoxy resin flakes of 0.3–4 mm and with a liquid conductivity of 50 pS/m, the charge density increased from below 30 $\mu C/m^3$ at a stirrer speed of 250 rpm to 450 $\mu C/m^3$ at a speed of about 1250 rpm. Increasing the conductivity to 2000 pS/m led to a reduction in charge density to 10 $\mu C/m^3$. The charge density decreased with increase in temperature to an extent that could not be accounted for simply by the effect of temperature on conductivity. Further studies of agitation charging have been described by H. Kramer (1981). Blowing gas through the liquid may also effect agitation. This also is liable to generate charge. Static electricity is also generated by splash filling of tanks.

16.7.27 Liquid storage tanks

Charge accumulation and relaxation are particularly important in relation to the filling of liquid storage tanks and of road and rail tankers. The storage tank problem has a number of different aspects: charge accumulation and relaxation; field strengths and potentials; and the generation of sparks, particularly incendive sparks. Some of the work in this field has been associated with the fueling of aircraft.

16.7.28 Klinkenberg and van der Minne model

Klinkenberg and van der Minne (1958) have given a number of expressions for the electric field strength in storage tanks. For a full spherical tank, Equation 16.7.57 is applicable and they also suggest its use for tanks that are cubic in shape. For long shallow tanks they refer to Equation 16.7.56.

For a partially full tank with a uniform charge density in the liquid but otherwise no liquid surface charge and zero charge density in the vapour space, they give the following relation for the field strength in the vapour space

$$E_{\mathrm{v}} = \frac{s h_{\mathrm{l}}^{2}}{2\epsilon_{\mathrm{o}}(\epsilon_{\mathrm{v}} h_{\mathrm{l}} + \epsilon_{\mathrm{l}} h_{\mathrm{v}})} \qquad [16.7.183]$$

where E_{v} is the field strength in the vapour space (V/m), h_{l} is the depth of liquid (m), h_{v} is the height of the vapour space (m), ϵ_{l} is the dielectric constant of the liquid and ϵ_{v}, is the dielectric constant of the vapour.

16.7.29 Vellenga model

Vellenga (1961) obtained a model for the electric field strength inside a rectangular tank. He assumes that the charge is uniformly distributed and that the dielectric constant of the liquid and of the vapour are the same, the difference between them being in practice a factor of about 2. He obtained for the general case the expression

$$E_{\gamma} = \frac{1}{2}\frac{sc}{\epsilon\epsilon_{\mathrm{o}}}\left[w^{2} - \sum_{n=1}^{n=\infty} A_{\mathrm{n}}(\cos \pi n w - 1)\cos \pi n \gamma\right] \quad \gamma > w \qquad [16.7.184]$$

with

$$A_{\mathrm{n}} = \frac{4}{\pi^{2}}\frac{1}{n^{2}\cosh(n\pi/2\beta)} + \frac{16}{\pi^{3}}\sum_{m=1}^{m=\infty} \sin(m\pi/2)/[mp^{2}\cosh(p\pi/2\alpha)] \qquad [16.7.185]$$

$$\alpha = c/a \qquad [16.7.186]$$

$$\beta = c/b \qquad [16.7.187]$$

where *a, b* and *c* are the length, width and height of the tank (m), respectively, E_{γ} is the field strength at the fraction of the tank height γ (V/m), w is the fraction of the height filled with liquid, α and β are shape parameters, and γ is the fraction of the tank height at which the field strength is measured.

For the particular case of a tank whose height is small relative to its lateral dimensions, Vellenga obtains

$$E = \frac{1}{2}\frac{scw^{2}}{\epsilon\epsilon_{\mathrm{o}}} \qquad [16.7.188]$$

16.7.30 Carruthers and Wigley model

Carruthers and Wigley (1962) developed a model for the field strength and potential in a partially filled rectangular metal storage tank filled with uniformly charged liquid. They then extended this model to give the fields produced by a charge on the surface of the liquid and in the mist in the vapour space above it.

The space charge density s is given by

$$s = \frac{I_{\mathrm{o}}\tau}{V_{\mathrm{ves}}t} \quad t \gg \tau \qquad [16.7.189]$$

where I_o is the current entering the tank (A), t is the time of filling (s) and V_{ves} is the volume of the liquid in the tank (m^3).

For a point in the vapour space with the co-ordinate x, y, z as measured from the top of the tank, the approximate field strength in the z direction E_z is

$$E_z = \frac{16s}{\epsilon_o \pi^3 (1/a^2 + 1/b^2)^{1/2}} \times \frac{(\cosh \beta d - 1) \cosh \beta z \sin(\pi x/a) \sin(\pi y/b)}{\epsilon_v \cosh \beta p \sinh \beta d + \sinh \beta p \cosh \beta d} \qquad [16.7.190]$$

with

$$\beta = \pi^2 \left(\frac{1}{a^2} + \frac{1}{b^2} \right) \qquad [16.7.191]$$

where a is the length of the tank (m), b is the width of the tank (m), d is the height of the liquid (m), p is the height of the vapour space (m), ϵ_l is the dielectric constant of the liquid and ϵ_v is the dielectric constant of the vapour.

The authors also derive the space charge densities and field strengths for any mist existing in the vapour space in the tank. They consider two cases: (1) a tank filled with mist and (2) a tank half filled with liquid and half with mist. In this treatment they assume a cubical tank of length a. For the first case the field strength is at a maximum at the centre of each wall and is

$$E_{mf} = \frac{64}{3} \frac{a s_{mf}}{\epsilon \epsilon_o \pi^4} \qquad [16.7.192a]$$

$$E_{mf} = 6.79 \frac{a s_{mf}}{\epsilon \epsilon_o \pi^3} \qquad [16.7.192b]$$

where E_{mf} is the maximum field strength with the tank full of mist and s_{mf} is the space charge density with the tank full of mist. For the second case, from Equation 16.7.190 and setting $d = p = a/2$, the maximum field strength in the vapour space is

$$E_{mh} = 2.84 \frac{a s_{mh}}{\epsilon \epsilon_o \pi^3} \qquad [16.7.193]$$

where E_{mh} is the maximum field strength in the vapour space with the tank half full of liquid (V/m) and s_{mh} is the space charge density with the tank half full of liquid (C/m^3).

It can then be shown that in some circumstances a charged mist may produce a field strength of the same order as that of a charged liquid. Thus, assuming that in the first case all the liquid entering the tank in a time equal to the relaxation time τ forms a mist, the space charge density is

$$s_{mf} = \frac{I_o \tau}{a^3} \qquad [16.7.194]$$

while in the second case the space charge density is

$$s_{mh} = \frac{2 I_o \tau}{a^3} \qquad [16.7.195]$$

From Equations 16.7.192 and 16.7.194 for the first case and Equations 16.7.193 and 16.7.195 for the second, the maximum field strengths are, respectively,

$$E_{mf} = 6.79 \frac{I_o \tau}{\epsilon \epsilon_o \pi^3 a^2} \qquad t = \tau \qquad [16.7.196]$$

and

$$E_{mh} = 5.68 \frac{I_o \tau}{\epsilon \epsilon_o \pi^3 a^2} \qquad t \gg \tau \qquad [16.7.197]$$

16.7.31 Vellenga and Klinkenberg model

As already mentioned, there is frequently an appreciable difference between the effective and rest conductivities of the liquid. One consequence of this is that during the relaxation of charge in a liquid following the filling of a tank, the relaxation time constant, given by Equation 16.7.27, is not in fact constant and the decay of the charge does not then follow the exponential decay given by Equation 16.7.78.

Vellenga and Klinkenberg (1965) have derived an alternative expression for charge decay based on the assumption that the conductivity of the liquid is proportional to the charge density. Considering a small element of volume V with space charge density s and hence a charge Vs, application of Gauss law, Equation 16.7.34, gives

$$\int D_n \mathrm{d}A = sV \qquad [16.7.198]$$

where D_n is the component of D normal to an element of surface dA. The rate of loss of charge from dA is the current density J_n, and that from the whole element is the current density J. Then from Equations 16.7.26, 16.7.27, 16.7.97 and 16.7.198

$$\frac{1}{\tau} \int D_n \mathrm{d}A = -\frac{\mathrm{d}(sV)}{\mathrm{d}t} \qquad [16.7.199]$$

Integrating Equation 16.7.199 gives

$$\frac{\mathrm{d}s}{\mathrm{d}t} = -\frac{s}{\tau} \qquad [16.7.200]$$

Taking the limiting case where all the ions of one sign are removed, as described in Section 16.7.12, and substituting from Equations 16.7.107 and 16.7.108 in Equation 16.7.200

$$\frac{\mathrm{d}s}{\mathrm{d}t} = -\frac{us^2}{\epsilon_o \epsilon} \qquad [16.7.201]$$

Integrating Equation 16.7.201 yields

$$s = \frac{s_o}{1 + t/\tau_o} \qquad [16.7.202]$$

where s_o is the initial charge density and τ_o is the initial relaxation time.

Equation 16.7.202 is a hyperbolic equation and the authors describe it as the hyperbolic law of relaxation. Another hyperbolic decay model is that of M.D. Foster (1967). A number of workers have reported decay of charge in tanks, which approximates more closely to the hyperbolic than to the exponential law.

16.7.32 Kramer and Schön model

H. Kramer and Schön (1975) have carried out a series of fundamental studies of the static electricity hazard in storage tanks, including the charging current entering the tank, the distribution of charge in the liquid, the field strength in the liquid and in the vapour space and the effect of bodies which distort this field, the incendivity of sparks produced and development of rules for tank filling.

With regard to the charge distribution, the authors postulate that the charge is not uniformly distributed within the liquid but is concentrated in a charge cloud. They estimate the volume of this charge cloud as

$$V_e = Q\tau \qquad [16.7.203]$$

where Q is the volumetric flow of liquid (m^3/s) and V_e is the volume of the charge cloud (m^3), this volume being that at the surface of which the charge density has decayed to $1/e$ of its original value. This model is based on laminar flow. For turbulent flow the cloud would be somewhat larger.

Kramer and Schön made measurements in a 15 m^3 tank, near the fill pipe outlet and at the far end of the tank, of the relative field strength, or field strength divided by total charge in the tank, at different filling rates, and plotted the relative field strengths at these two points vs the volume of the charge cloud. Whereas the relative field strength at the fill pipe was virtually constant, that at the far side of the tank was constant at high charge cloud volumes but fell off rapidly for charge cloud volumes below 2 m^3. The authors suggest that these results indicate that the effective charge cloud volume was some five times the nominal value given by Equation 16.7.203.

A further detailed study of the space charge cloud is given by Schön and Masuda (1969) and Schön and Kramer (1971).

H. Kramer and Schön (1975) then discuss the problem of field strength. They comment that the model of Carruthers and Wigley may not be applicable to large tanks containing high conductivity liquids. In any event, features such as the fill pipe distort the field, and this is crucial.

They treat the fill pipe as a cylindrical object. For such a configuration the relation between the potential and the field strength is

$$\phi_{\max} = Er_1 \ln(r_2/r_1) \qquad [16.7.204]$$

where r_1 and r_2 are the radii of the inner and outer cylinders (m) and $\phi_{\max}$ is the maximum potential in the center of the tank in the absence of the fill pipe (V). The inner cylinder is the radius of the fill pipe and the outer one may be equated with a suitable lateral dimension of the tank.

They measured the field strength at the fill pipe in a large tank and a tank truck as

$$E = 7.5 \times 19^9 q \qquad \text{Large tank} \qquad [16.7.205a]$$

$$E = 30 \times 10^9 q \qquad \text{Tank truck compartment} \qquad [16.7.205b]$$

where q is the charge (C).

Then from Equation 16.7.204 they obtained the maximum potential $\phi_{\max}$ as

$$\phi_{\max} = 1.9 \times 10^9 q \qquad \text{Large tank} \qquad [16.7.206a]$$

$$\phi_{\max} = 5.0 \times 10^9 q \qquad \text{Tank truck compartment} \qquad [16.7.206b]$$

The smaller tank therefore had the higher maximum potential. The authors state that the Carruthers and Wigley model gives the maximum potential as inversely proportional to the diagonal of the mid-height cross-sectional area, and that their results confirm this.

They then consider the incendivity of discharges. For an incendive discharge there is a critical radius of curvature below which an incendive spark is unlikely. This radius is about 5 mm. For small radii of curvature above this value

$$E_e r = 35{,}000 \qquad 5 \times 10^{-3} \leq r \leq 12 \times 10^{-3} \qquad [16.7.207]$$

where E_e is the field strength for the onset of incendive discharge (V/m) and r is the radius of curvature (m). For larger radii

$$E = 3{,}000{,}000 \qquad r > 12 \times 10^{-3} \qquad [16.7.208]$$

With a small probe the potential distribution in the vicinity of the probe is changed only locally. The undisturbed potential ϕ at the probe determines the field strength E at the surface of the probe according to the relation

$$Er \approx \phi \qquad [16.7.209]$$

Then from Equations 16.7.207–16.7.209 an incendive spark is unlikely as long as the maximum potential in the vapour space is kept below 35 kV.

Kramer and Schön consider two limiting cases: (1) a tank with a probe and (2) a tank with a fill pipe only. These two cases correspond, therefore, to field strengths for the onset of an incendive discharge of 35 kV and 3000 kV, respectively.

For the first case, from relations 16.7.207–16.7.209 and taking account of the empirical factor of 0.6 for the maximum potential

$$0.6\,\phi_{\max} \leq 35{,}000 \qquad [16.7.210]$$

The streaming current entering the tank and the total charge in the tank are

$$I_o = \frac{\pi d^2 u s_o \epsilon \epsilon_o}{4\kappa_e} \qquad [16.7.211]$$

$$q = I_o \epsilon \epsilon_o / \kappa_e \qquad [16.7.212]$$

where d is the diameter of the fill pipe (m), I_o is the charging current in the liquid entering the tank (A), s_o is the charge density of that liquid (C/m^3), u is the liquid velocity (m/s) and κ_e is the effective conductivity of the liquid (S/m). Then from Equations 16.7.206 and 16.7.210–16.7.212

$$\frac{s_o u d^2}{\kappa_e} \leq 2.2 \times 10^6 \qquad \text{Large tank} \qquad [16.7.213a]$$

and

$$\frac{s_o u d^2}{\kappa_e} \leq 0.83 \times 10^6 \qquad \text{Tank truck compartment} \qquad [16.7.213b]$$

For the second case

$$E_e \approx 3{,}000{,}000 \qquad [16.7.214]$$

and assuming that the field strength at the fill pipe is

$$E \propto 1/d \qquad [16.7.215]$$

Equations 16.7.205, 16.7.211, 16.7.212 and 16.7.214 yield

$$\frac{s_0 ud}{\kappa_e} \leq 1.2 \times 10^8 \qquad \text{Large tank} \qquad [16.7.216a]$$

$$\frac{s_0 ud}{\kappa_e} \leq 0.6 \times 10^8 \qquad \text{Tank truck compartment} \qquad [16.7.216b]$$

The relationship between the effective conductivity and the rest conductivity proposed by the authors in this context is

$$\kappa_e = \kappa_r/2 \qquad [16.7.217]$$

From these relations the authors give the limiting filling criteria shown in the table at the bottom of the page.

Where, for a container of lateral dimensions a and b, L is the length of the diagonal, calculated from $L = (a^2 + b^2)^{1/2}$.

The relation for other tank sizes utilizes scaling based on the diagonal of the mid-height-cross-sectional area. These are limiting criteria that do not include a safety factor. The authors also quote the following German safety rule:

$$u^2 d \leq 0.64 \qquad [16.7.218]$$

For liquids with very low conductivities the treatment described may be too restrictive. The streaming current is likely to be lower and may not reach its steady-state value. The authors state that experimental evidence suggests that a limiting rest conductivity of 0.8 pS/m may be applied.

This treatment is applicable only to conditions where there are no generators of unusually large amounts of charge, such as a liquid velocity above 7 m/s, water in the liquid or a filter in the inlet pipe. Also the treatment applies to tank sizes up to those of a tank car. For larger tanks the assumption of a uniform charge density breaks down, because the effective relaxation volume is small compared with the tank volume.

Filling condition			*Projections permitted*
Tank truck	*Rail tank car*	*Other tanks*[a]	
$u^2 d \leq 6.2 \times 10^{12} \kappa_r$	$u^2 d \leq 12.4 \times 10^{12} \kappa_r$		Fill pipe only; outlet fully covered by liquid
$ud \leq 0.29 \times 10^6 \kappa_r$	$ud \leq 0.47 \times 10^6 \kappa_r$	$ud \leq = 0.17 \kappa_r^{1/2} L^{1/2}$	Projections of all kinds permitted

[a] Where, for a container of lateral dimensions a and b, L is the length of the diagonal, calculated from $L = (a^2 + b^2)^{1/2}$.

16.7.33 Road and rail tankers

As described in Section 16.7.2, a large proportion of the incidents attributed to ignition by static electricity have involved road tankers and rail tank cars. The work of H. Kramer and Schön (1975) on tanks in general and road and rail tankers in particular was described in Section 16.7.32.

An early study of the static ignition hazard in filling road tankers was made by Herzog, Ballard and Hartung (1961). They considered three paths for a discharge: (1) between two points on the liquid surface, (2) between the liquid surface and the tank wall and (3) between the liquid surface and a probe. They concluded that the latter was the principal hazard.

These authors developed the concept that the approach of a grounded probe can cause a very high charge to build up on the liquid surface. A system composed of a liquid surface and a probe is a capacitor. Capacitance is inversely proportional to separation. Therefore as the probe approaches the liquid surface, or rather as the liquid surface during filling approaches the probe, with the charge initially being constant, the liquid surface potential at the point near the probe will drop according to Equation 16.7.6. The difference in liquid surface potentials thus created will cause the charge to move in order to equalize the potentials. They carried out experimental work and found that at lower flow rates there was little difference in potential between a point near the probe and one some distance away, so that there was a degree of charge concentration, but that at higher flow rates a potential difference developed and the charge concentration was less; they attributed this latter condition to the increased turbulence.

They found that the design of the fill pipe had a marked effect on its capacitance. The pipe capacitance decreased linearly with the separation between the pipe and the liquid surface up to a separation of 0.1 in. The lowest separation at which capacitances were measured was 0.02 in. but capacitance values were extrapolated back to a separation of 0.0025 in. The pipe design with the lowest capacitance at 0.0025 in. was one with a 45° slant end, with a capacitance of 140 pF. Other designs were, in ascending order of capacitance, an open pipe end, a T deflector and a cone deflector, the latter having the highest capacitance at 470 pF. The liquid surface potentials measured in this work were up to 10 kV.

Mahley and Warren (1968) carried out an investigation in which the effect of the following parameters was studied: (1) fill tube design, (2) liquid velocity, (3) compartment height, (4) fill tube height, (5) liquid conductivity, (6) liquid wetness, (7) air bleed and (8) filter.

They found that the design of the fill tube had a marked effect on the potential of the liquid surface. The lowest potential was obtained with the 45° slant end pipe. The ranking of the other devices was generally, in ascending order of potential, an open pipe end, a T deflector and a cone deflector.

Drop heights of <2, 30 and 60 in. were used. The difference in liquid surface potential between the first two drop heights was minimal, but use of a 60 in. drop height gave much higher potentials.

The liquid surface potential increased with liquid velocity, with water content and with the use of a filter. The increase in potential with liquid velocity was more than proportional and the magnitudes were much higher for fill tube designs other than the slant end one. The increase in potential when a filter was used was large.

The effect of liquid conductivity was somewhat complex. The conductivity range studied was 2.5–100 cu (pS/m). In this range, use of a conductivity additive caused the liquid surface potential to decrease with the resultant increases in liquid conductivity. But the results for undoped liquid did not show this regular variation. A liquid with 16 cu gave a higher potential than one with 2.5 cu.

The effect of an air bleed, which might occur due to equipment malfunction upstream, was simulated using a nitrogen bleed, but this appeared to have a minimal effect on the liquid surface potential.

The account of this work just given is necessarily simplified. There was considerable interaction between the different variables, with mutually enhancing or reducing effects.

The liquid surface potentials measured in this work were up to almost 50 kV, the latter value being obtained-with a liquid conductivity of 16 cu, a liquid velocity of 30 ft/s, a fill tube with cone deflector and a drop height of 60 in.

Tank truck loading has been studied by Ginsburgh and co-workers (L. Wright and Ginsburgh, 1963; Bulkley and Ginsburgh, 1968) with special reference to charge relaxation and discharge incendivity.

L. Wright and Ginsburgh (1963) investigated discharges. They present a model that shows that the controlling features of the discharge are the potential of the liquid surface and the geometry of the probe. They report experiments on discharges induced by applying power between a liquid surface and a probe, including a 3 in. diameter vertical pipe, a vertical plate and a horizontal plate. For the pipe the potentials for onset of a discharge were 25 kVat a separation of 0.5 in. and 50 kVat one of 1 in. When power was applied the liquid rose towards the probe, and for separations of less than 0.5 in. it touched the probe.

Bulkley and Ginsburgh (1968) continued this work on discharges. The MIE normally quoted, say >0.25 mJ for hydrocarbons, applies only to a spark gap of optimal shape and separation and to a near-stoichiometric mixture. They suggest that, in practice, the energy required to give an incendive spark is at least an order of magnitude greater.

The spark between a liquid surface and a probe is quite different from that between two metal electrodes. Although concentrated at the probe, it branches over a relatively large part of the liquid surface.

The authors state that most of the sparks obtained in the work of Wright and Ginsburgh did not possess enough energy to be incendive. For an incendive spark to occur the liquid surface potential must exceed 20 kV, which requires a charge density of 30 μC/m^3. They propose that a charge density of 15 μC/m^3, incorporating a safety factor of 2, be taken as the safety limit.

Bulkley and Ginsburgh point out that over the years, oil products have become much purer so that their conductivity is much less, with corresponding increases in relaxation times from seconds to minutes. One consequence of this is that the residence time of typically 30 s in tanks, provided to allow relaxation, is no longer adequate.

16.7.34 Strawson and Lyle model

Strawson and Lyle (Lyle and Strawson, 1971, 1972, 1973; Strawson and Lyle 1975a,b) have reported an extensive program of work by Shell on the safe loading of road and rail tankers.

Lyle and Strawson (1971) conducted experiments in which they studied discharges between a charged liquid surface and a fill pipe when a tank is filled with charged fuel. The fuel was gas oil with a conductivity of 2–7 pS/m. The locus of the liquid inlet charge density limit curve for onset of discharge ranged from an inlet liquid charge density of about 200 μC/m^3 at low liquid inlet velocities down to less than 20 μC/m^3 at high velocities. The discharge energies were determined to be about 0.005 mJ.

A separate experiment was conducted to determine the energy in an incendive discharge between a liquid surface and a probe. The liquid used was kerosene with a propane–air mixture in the vapour space around the probe. Liquid entering the tank was given a high charge by passing it through a filter. The energy required to achieve ignition was 4.7 mJ. This compares with the normal MIE of 0.2 mJ.

In an extension of this work, Strawson and Lyle (1975b) performed experiments in three metal tanks of 1.2, 2.3 and 5 m^3 volume and with overhead and bottom filling pipes. They investigated the conditions for discharge between the liquid surface and the fill pipe or a gauge marker. They developed a model for the discharge conditions. In addition to determining the locus of the liquid inlet charge density limit curve for the onset of discharge as a function of liquid inlet velocity for a fixed tank length, they also obtained both experimentally and theoretically the locus of that curve as a function of tank length for a fixed liquid inlet velocity. The locus passed through a minimum for a tank length of about 2 m. For this tank length the authors determined the limiting liquid inlet charge density as 20 μC/m^3.

The authors state that no sparks were obtained with liquids with conductivities greater than 4 pS/m.

Strawson and Lyle went on to consider the parameters that might be taken as the basis of safety, the field strength and the potential. In particular they discuss the criterion of field strength at the filling tube used by Kramer and Schb'n (Schön and Kramer, 1971; H. Kramer and Schön, 1975). This model is based on a charge distribution in the liquid around the fill pipe. They argue that the charge distribution is more likely to be relatively uniform. At the high filling rates, which are of prime interest, turbulence will tend to equalize the charge density. Moreover, Kramer and Schön have shown that for a low conductivity liquid the charge density is uniform even in large tanks.

The alternative is to use the potential of the liquid surface. Strawson and Lyle conclude that this is the better criterion. They assume that the charge is uniformly distributed and define the relevant potential as that existing in the absence of any protrusion. Various limiting values of this potential have been proposed. Mahley and Warren (1968) have proposed 1 kV, based apparently on the work of Herzog, Ballard and Hartung (1961), but the authors regard this as too low. They refer to the value given by Kramer and Schön of 35 kV. They state that in their own work the minimum potential for incendive discharge was 45 kV, and propose this as the limit value.

A model was developed for the potential of the liquid surface that gives

$$\phi \propto s_t f \text{ (tank dimension, liquid depth)} \qquad [16.7.219]$$

where s_t is the space charge density in the liquid in the tank (C/m^3) and ϕ is the potential of the liquid surface (V).

The charge density in the tank is in turn related to that in the liquid entering the tank according to the relation

$$s_t = \frac{s_o Q \tau}{V_{ves}}[1 - \exp(-t/\tau)] \qquad [16.7.220]$$

where Q is the volumetric flow of the liquid entering the tank (m^3/s), s_o is the space charge density of the liquid entering the tank (C/m^3), and V_{ves} is the volume of liquid in the tank (m^3).

From Equations 16.7.219 and 16.7.220, the authors derive their guideline for safe filling conditions:

$$ud \leq \left[\frac{\kappa u}{s_o} f(L)\right]^{1/2} \qquad [16.7.221]$$

where d is the fill pipe diameter (m), L is the length of the tank (m), s_o is the inlet charge density ($\mu C/m^3$), u is the liquid inlet velocity (m/s), κ is the liquid conductivity (pS/m) and k is a constant.

In subsequent work, Strawson and Lyle (1975a) obtained limiting values of the group $s_o/\kappa u$. Their results are shown inFigure 16.57, which gives the following limits:

$s_o/\kappa u$ ($\mu C/s(pS\ m^3)^{-1}$)	
≤ 1.8	Tests at filling stations
≤ 3.3	Experiments
≤ 12.5	Experiments with partially blocked filter

Also shown in Figure 16.57 are the limit lines given by the model of Schön (1962a) for charge generation in a pipe, which are a function of the residence time in the pipe, and hence of the pipe length. From this work Strawson and Lyle propose a limiting value for the group $s_o/\kappa u$ of 12.5.

Using this limit value in Equation 16.7.221 together with appropriate values of $kf(L)$, the authors obtain the following guidelines for safe filling:

Filling mode	*Tank length*			
	≤ 2 m		>2 m	
	$kf(L)$	ud	$kf(L)$	ud
Top filling	3.1	≤ 0.50	$3.1\,(L/2)^{1/2}$	$0.50\,(L/2)^{1/2}$
Bottom filling	1.6	≤ 0.36	$1.6\,(L/2)^{1/2}$	$0.36\,(L/2)^{1/2}$

The criteria for bottom filling allow for a central protrusion from the roof. In addition, a further overall limit is imposed to limit the field created by the jet:

$$ud \leq 0.77 \qquad [16.7.222]$$

This treatment contains a number of assumptions, which are therefore the conditions for its applicability. Three of these are: that the charge distribution in the liquid is uniform; that the charge generation due to splashing can be neglected; and that any charge density transient at start-up can be neglected. The authors regard these criteria as being confirmed experimentally. With regard to the conductivity of the liquid, it is assumed that the ratio of the effective to the rest conductivity is the same as in the experiments and that the inlet liquid charge density is proportional to the liquid conductivity. Further restrictions are the absence of high charge generation conditions, specifically water in the liquid or a filter in the pipe, and absence of insulated conductors in the system or tank.

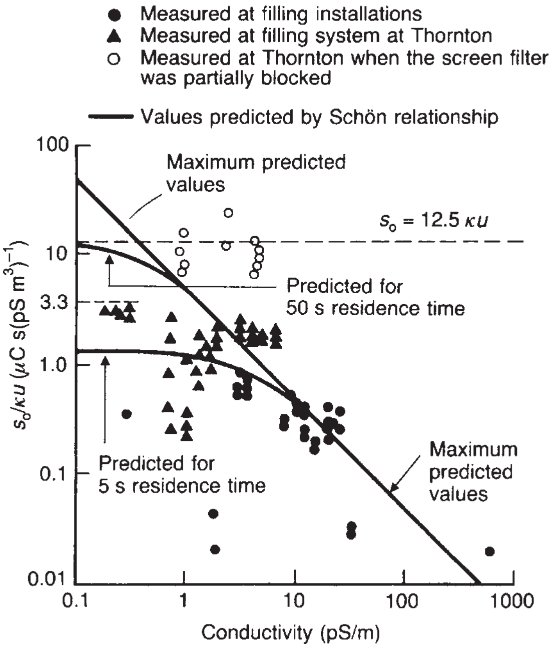

***Figure 16.57** Charge generated at filling stations (Strawson and Lyle, 1975a) (Courtesy of the Institution of Electrical Engineers)*

16.7.35 Kramer and Schön model

The work of Kramer and Schon on the filling of tanks in general and of road and rail tankers in particular, was described in Section 16.7.32. This work provides another set of guidelines for tanker filling.

16.7.36 Rees model

Another extensive program of work on the safe loading of road and rail tankers is that carried out by BP, as described by W.D. Rees (1981). Rees describes experimental work on discharges between a charged liquid surface and a metal probe. In this work it proved relatively easy to obtain discharges, which would ignite a propane–air mixture with negatively charged liquids at liquid surface potentials as low as 25 kV, but ignition did not occur with positively charged liquids even at potentials as high as 80 kV. It was found that a charge transfer in the discharge of at least 75 nC was required for ignition. The shape and dimensions of the probe affected ignition. The shape most favourable to ignition was a sphere, then a hemisphere and then a rod.

Using a 28 mm sphere with the most ignitable propane–air mixture the probability of ignition was close to unity, provided the charge transfer exceeded 75 nC.

Rees summarizes the principal guidelines for safe filling as follows. The criterion of the Physikalische Technische Bundesanstalt (PTB) is

$$ud < 0.38 \qquad [16.7.223]$$

The Shell criteria are

$$ud < 0.50 \qquad [16.7.224]$$

and

$$s_o/\kappa u < 12.5(\mu\text{C s(pS m}^3)^{-1}) \qquad [16.7.225]$$

The criterion given by Equation 16.7.224 is criticized insofar as the work described on incendive discharges has shown that critical values of the group $s_o/\kappa u$ can be less than 12.5. The critical values depend on the pipe diameter, the liquid conductivity and the liquid inlet velocity; values down to 2.4 are quoted.

Rees refers to four incidents that have occurred in Canada with a loading limit $ud < 0.5$, and two in Germany with a loading limit $ud < 0.37$.

Rees states the BP view that it is not possible to determine a loading velocity that is completely safe, but that it can be said that reducing the velocity reduces the risk. The PTB guideline is preferred and, in order to avoid proliferation of guidelines, is the one adopted.

However, he also puts forward for discussion the following proposals for loading limits:

Liquid conductivity (pS/m)	*Loading rate, ud*
$\kappa \geq 10$	≤3500 l/min
$5 \leq \kappa \leq 10$	≤0.5
$\kappa < 5$	≤0.38

16.7.37 Oil and chemical tankers

As described in Section 16.7.2, some of the most serious incidents attributed to ignition by static electricity have involved oil tankers. An early study of the problem is that of Bustin (1963). Following the *Esso Paterson* explosion in 1956 the company adopted a set of safety rules to reduce the static ignition hazard. The investigation described was to assess the effectiveness of these safety rules.

Bustin considers the following conditions: (1) loading of product, (2) steam cleaning, (3) water washing, and (4) ventilation.

He describes an extensive series of tests on the loading of tankers. Charge densities of up to 0.2 μC/m^3, liquid surface potentials of 10 kV and field strengths of 4 kV/m were calculated from these tests. The author states that while at these potentials discharge would not occur to normal tank internals, it might well to a pointed probe. He therefore lays emphasis on ensuring that there are no grounded probes or insulated conductors.

The cleaning of tanks using steam has been associated with a number of explosions. Tests by BP some years previously showed that if the steam-cleaning machine was not grounded, or lost its ground connection, a high potential could build up on it and, in the event of a discharge, the spark was likely to incendive. Isolated conductors in particular are a hazard in this respect. With regard to the steam cloud itself, faint discharges were detected. The highest field strength determined was 60,000 V/m, which indicates that a volume of steam equivalent to a sphere some 1.25 m diameter would need to discharge to give an incendiary spark. The author states that steam cleaning is to be avoided; in fact it is frequently banned. The main method of cleaning tanks is water washing. The author regards this as safe.

Rapid ventilation may be used for gas freeing. But there was concern that charge generation could occur due to the presence of rust particles or fuel droplets in the air. Tests were performed in which the conditions in a ventilation pipe were measured. At 510 cfm of air, an air velocity of 170 ft/s and a dust loading of 0.016 lb/ft^3 the charging current was 5×10^{-6} A and the calculated field strength at the pipe wall was 50 kV/m. This was considered close to the region where discharges might occur, though not necessarily incendive ones. In fact even abnormally high dust loadings did not lead to ignition unless an insulated conductor was present.

Bustin states that neither water washing nor ventilation necessarily ensure the elimination of a flammable mixture.

Following the three tanker explosions in 1969, a major program of work was undertaken by Shell. Some of the results were described in a set of papers by van der Meer (1971), van der Weerd (1971), Smit (1971) and Vos (1971).

The work described by van de Weerd (1971) was concerned with water washing. A typical washing machine operates at 10 bar giving 180 m^3/h of water with a jet velocity of 40 m/s. The jet diameter is 4 cm at the nozzle increasing to 1–3 m at the wall. Quite large amounts of air are entrained. The mist formed has a density of about 1 g/m^3. Mist formed by impact at the wall is charged.

The factors studied were (1) number and type of washing devices, (2) jet velocity, (3) water temperature, (4) type of water, (5) impurities, (6) wall conditions and (7) tank size. It was found that the number of water guns had relatively little effect. The type of water, the water temperature and impurities in the water and presence of crude oil or sludge on the wall affected the sign and magnitude of the charge, but in an unpredictable way.

In a series of tests on water washing of tanks a typical value obtained for the charge density of the mist was 3×10^{-8} C/m^3. For a 12 m-radius tank in the absence of a protrusion this translates using Equation 16.7.57 to a field strength of 13.5 V/m. The field strength at a probe comprising a 2.5 cm cylinder was calculated to be 600 kV/m. The maximum field strength measured was 400 kV/m and the maximum space potential was estimated as 40 kV.

Experiments were conducted to investigate discharges and their incendivity. Tests are described in which a 28 mm hemispherical probe was inserted into a steam mist with a maximum space potential of 36 kV and a field strength of 330 kV/m. Discharges were obtained and were measured as groups of pulses. The discharges were of relatively long duration, some tens of milliseconds, which contrasts with a duration for metal to metal discharges of about 10^{-7} s. The energy dissipation in the first millisecond at this potential was some 0.04 mJ. The author comments that such energy dissipation may be a better measure of incendivity than energy accumulation.

The charging of insulated conductors inside a tank was also studied. The charging mechanisms include charge induction, charge transfer from mist droplets, and corona charging. It was found that with a space potential of 30 kV a cord lowered by a man standing insulated on the deck charged up to about half the space potential within seconds once his resistance to ground exceeded $10^{10}\Omega$. A man wearing normal footwear on a well-painted deck would have a resistance to ground in excess of this.

In another study a 13 mm diameter rod was dropped through a mist with a maximum space potential of 37 kV and the rod acquired a charge of some 2×10^{-7} C. Laboratory tests showed that such an object could have given an incendive spark.

Smit (1971) describes models for potential distribution developed in support of this work, and Vos (1971) describes work on the generation of a charged mist by an impacting jet, as already described.

J.F. Hughes *et al.* (1973) give an account of related work on water mists. One study dealt with periodic discharges at a probe that were found to be associated with the departure of a water droplet from the probe. These were corona discharges and were not incendive to a propane–air mixture. Another phenomenon investigated was a slug of water falling through the cloud. Slugs of water were made to fall on a trajectory spaced 0.1–0.4 cm from a grounded probe. The discharges obtained were incendive.

A number of mechanisms for incendive discharges in water washing were investigated by van de Weerd (1975), in particular discharges from a falling water slug. Washing machines can give water slugs some 4 cm diameter by 50 cm long. The maximum space potential during tank washing is at least 30 kV. Work was done to determine the fraction of the energy of the charge induced on the slug, which participates in the discharge when the slug approaches a protrusion on the tank, and this fraction was estimated as 0.2–0.4. Taking a figure of 0.2 gives a discharge energy of 1.5 mJ. This compares with a minimum ignition energy of some 0.5 mJ for a hydrocarbon–air mixture in this situation, van de Weerd concludes that such discharges are incendive.

H.R. Edwards (1983) addresses the rather different matter of chemical tankers. The background was a proposal to extend to chemical tankers the Safety of life at Sea (SOLAS) regulations which are applicable to oil tankers. There is a problem with this in that inerting by combustion products is not acceptable for chemicals, while the use of nitrogen is expensive.

He describes trials on five chemical tankers in respect of loading, steam cleaning and water washing. It was found that the liquid electrical conductivities were relatively high, being in the range 20–80 pS/m. These are the conductivities of the industrial chemicals as loaded. For example, Analar quality benzene has a conductivity of 0.8 pS/m, but the conductivity for benzene loaded in the trials was 40 pS/m. The highest value measured for the liquid surface potential was 3.4 kV for benzene. The Carruthers and Wigley model was used to confirm that the liquid surface potential would not give rise to incendive sparks.

In steam cleaning tests the maximum space potential in the steam mist in smaller tanks of 300 m^3 was about 4 kV, but tanks above 1000 m^3 gave potentials above 10 kV, the maximum recorded value being 18 kV.

Edwards details the procedures used in water washing. He gives data on the maximum space potentials in the water mist. Except for esters, the maximum space potential was 7.9 kV. For esters it exceeded 10 kV in several cases, the highest value being 11.7 kV for ethyl acetate. As already described, some of the space potentials given by Edwards are based on his model. He refers to 10 kV as the safety criterion. He lists a number of factors that suggest that, in practice, there is a safety margin. One is the safety margin in the 10 kV criterion itself. Another is the fact that chemical tankers use smaller washing machines, which tend to give smaller water slugs. He suggests that for these the hazard threshold is closer to 15 kV. Another factor is that the maximum space potential is near the centre of the vapour space, which is not the location of protrusions.

The problem of a falling water slug has been investigated further by M.R.O. Jones and Bond (1984, 1985), in the context of chemical tankers. The situation envisaged is a slug falling from the jet of the washing machine and approaching a grounded wall. The authors refer to work by Bustin (1973–74) on the size of water slugs from washing machine jets. They state that the hazardous conditions are often taken to be a space potential of at least 10 kV near the washgun and a slug of at least 0.5 m, but that there is no firm foundation for this.

Jones and Bond refer to the empirical finding of van der Weerd that the effective ignition energy required for a discharge between a water slug and a metal conductor is about twice that for a metal-to-metal discharge. They describe a model for the limiting hazardous conditions in terms of the tank centre space potential (TCSP) and the slug length. They compare their model with data given by H.R. Edwards (1983) on space potential in chemical tankers, described below. The crude data need to be converted to give the TCSP using a suitable model. In their initial work Jones and Bond accept Edwards' model for the calculation of the TCSP, but in the second paper replace this with their own model. The highest TCSP in the test data set is calculated to be some 20 kV. The initial treatment revealed no case in which the safety margin between the observed potential and the hazard threshold value was exceeded, but in some cases the difference was small, whereas in the revised treatment it is considerably larger.

Jones and Bond give a number of recommendations for the conduct of water washing of tanks, including limits on the number of washing machines and the water supply pressure.

J.S. Mills and Haighton (1983) have studied the charging of tanks by the flue gas used for inerting. The charge is generated in the boiler and carried by soot particles. Charge dissipation occurs by drift of soot particles to the walls and by corona discharge. The purpose of the work was to determine whether incendive discharges could be produced and to study the decay of the charge. Tests were done in which discharges from a charged cloud to a projection were simulated by discharges from an electrode. An electrode with a 25 mm diameter tip gave ignition most easily. The lowest space potential at which this electrode would give ignition was estimated as 70 kV. In subsequent shipboard trials the maximum space potential obtained was about 55 kV. The time for decay to 10 kV was about 5.5 h. It was concluded that the maximum space potentials were not such as to give incendive brush discharges, but that spark discharges from isolated conductors were a possibility and more stringent measures should be taken to exclude these.

J.S. Mills and Oldham (1983) review the hazard of static ignition in tankers. They quote the potentials required to give an incendive brush discharge as 45 kV for a liquid surface potential and 70 kV for the space potential of a mist, both these potentials being negative. They refer to work that has shown mist space positive potentials of 40 kV in open cycle washing and 120 kV in closed cycle washing. These authors also discuss the static hazards of the use of glass reinforced plastic (GRP) pipes in tankers.

16.7.38 Discharges incendive in gas and liquid systems

As far as concerns ignition by an electrostatic discharge, what matters is the incendivity of the discharge. Non-incendive discharges can in some cases be helpful in dissipating charge that might otherwise participate in an incendive discharge. For a discharge to be incendive, a minimum voltage and a minimum energy are required. It is usually reckoned that for a spark discharge from a conducting object into a flammable mixture the minimum voltage is 1000 V, or 1kV.

As far as the energy of the discharge is concerned, the incendivity of the discharge is generally assessed by comparing the energy of the discharge with the MIE of the flammable mixture. For a flammable gas or vapour mixture this is the MIE of the gas. For hydrocarbons the figure most often quoted is that for a propane–air mixture which is given as 0.2 mJ. The figure appears to derive in the first instance from Lewis and von Elbe. This MIE is that measured for a spark discharge at metal electrodes. It is effectively a minimum figure.

Certain substances have a lower MIE. Hydrogen and carbon disulfide are the gases generally mentioned in this context. The MIE of carbon disulfide is 0.009 mJ and that of hydrogen is about 0.011 mJ. Substances with such low MIEs are therefore treated as sensitive substances.

In order to assess the incendivity of a discharge, therefore, it is necessary to know any minimum potential required, the energy of the discharge and the efficiency of that energy in effecting ignition relative to the energy in the spark discharge between the metal electrodes used in the measurement of MIEs. For a spark discharge various values are given for the minimum potential, but these often incorporate a safety factor. One commonly quoted value of this kind is 100 V. Britton and Smith (1988) give a value of 1000 V, or 1 kV, which they relate to the minimum gap required to avoid quenching.

The energy in a spark discharge depends on the potential and on the capacitance of the conductor. The energy is therefore variable, but there are many situations that will give an incendive spark discharge. For a brush discharge a minimum potential is not usually quoted, but may be obtained from field breakdown considerations.

With regard to the energy of a brush discharge use is made of the equivalent energy as proposed by N. Gibson and Lloyd (1965). If a flammable gas has a given MIE and a brush discharge is just able to ignite the appropriate mixture for that gas, the discharge is said to have an equivalent energy equal to the MIE value. Glor quotes values of the equivalent energy of brush discharges in the range 1–3.6 mJ and gives a theoretical treatment for a particular configuration that gives an actual energy of 4 mJ.

A brush discharge is incendive to most flammable gases. A series of studies on brush discharges has been made by Heidelberg (1959, 1967, 1970a).

For a propagating brush discharge there is a minimum voltage across the non-conducting layer for breakdown to occur. This is shown in Figure 16.58 (Maurer *et al.*, 1987). For layers of about 10 μm the minimum voltage is 4 kV, this value rising to 8 kV for layers of about 200 μm.

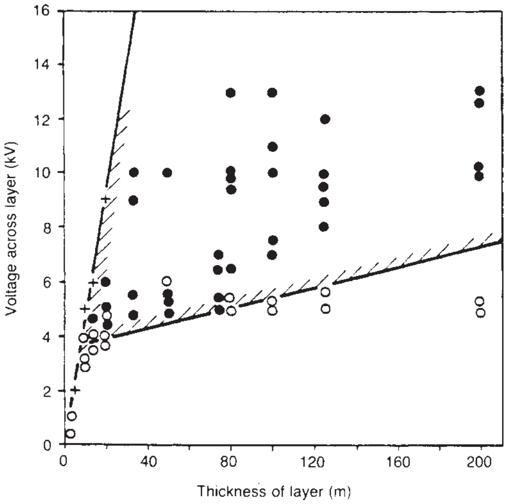

Figure 16.58 *Voltage across dielectric layers for generating a propagating brush discharge: (●) Propagating brush discharges; (O) no propagating brush discharges; (+) breakdown voltage (Maurer et al., 1987) (Courtesy of the Institute of Physics)*

Other conditions governing propagating brush discharges have been determined by Heidelberg (1967, 1970a), who found that such discharges occur only if the surface charge density exceeds 2.7×10^{-4}C/m^2 and that they do not occur if the non-conducting layer is more than 8 mm thick.

The energy in a propagating brush discharge is very high. It depends essentially on the participating area and the surface charge density. The high energies in propagating discharges may be explained as follows. As explained in Section 16.7.5, the normal maximum surface charge density, given that the permittivity of free space is $\epsilon_0 = 8.85 \times 10^{-12}$ F/m, the dielectric strength of air is $\epsilon = 1$ and the breakdown field strength of air is $E_b = 3 \times 10^6$ V/m, is given by Equation 16.7.22 as 2.64×10^{-5} C/m^2. For a configuration capable of giving a propagating brush discharge the relevant quantity to replace the breakdown field strength ϵ_b is the dielectric strength. Then for a typical non-conducting material of dielectric strength 2.7×10^7 V/m and dielectric constant 2–4, the maximum surface charge density becomes 5×10^{-4} C/m^2. This is nearly 20 times the previous figure. A propagating brush discharge is incendive to most flammable gases.

The energy in the four main types of discharge and their incendivity to gases and dusts is illustrated in Figure 16.59 (Glor, 1988).

As described in Sections 16.7.27–16.7.39, investigations of liquid storage tanks, road and rail tankers and oil and chemical tankers have often included studies of the incendivity of discharges in these systems. In addition, there has been some work specifically directed to this topic.

In the context of aircraft fuelling, Bruinzeel (1963) carried out experiments on discharges during the filling of a liquid storage tank with kerosene. The tank was 4 × 1 × 0.75 m divided into four compartments. Discharges were

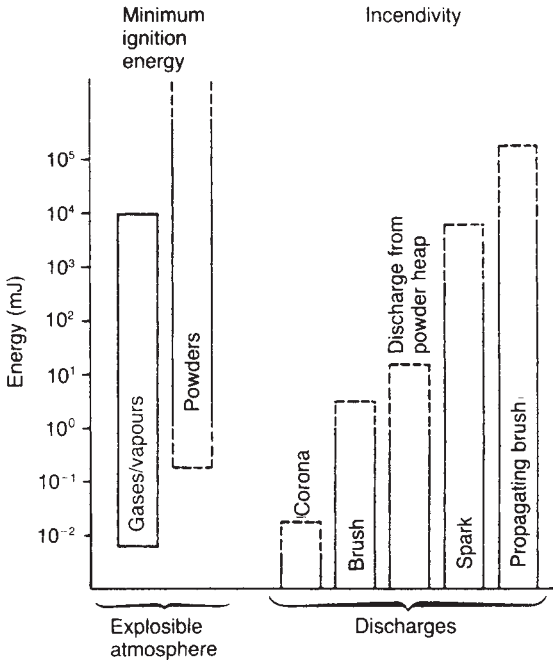

Figure 16.59 *Energy of five types of electrostatic discharge (Glor, 1988) (Courtesy of Research Studies Press)*

observed between the liquid surface and the fill pipe before its submersion, between the liquid surface and the roof even at a low liquid level, and between the liquid surface and a probe. The discharges occurred most frequently during filling when the liquid level was below one-quarter to one-third full and after it was three-quarters full. The liquid charge when discharges occurred was, with few exceptions, negative.

As found by other workers also, discharges occurred at average field strengths of the order of 400–500 kV/m, although the local field strength at some point must have reached 3000 kV/m. The author quotes, however, the view of Heidelberg and Schb'n that hazardous discharges might occur at an average field strength as low as 100 kV/m.

Typical results were for a liquid with a conductivity of 3–4 pS/m, a discharge gap of 0.2 m, a charging current of 12–18 μA and a liquid surface potential of 100 kV a discharge energy of 160–500 mJ with more than half being transferred within 0.2–0.3 μs. It was estimated that the charge in the tank was typically 12–18 μC and that in the discharge 1–5 μC. The ignition of a flammable gas mixture was demonstrated.

Leonard and Carhart (1967) carried out work on discharges between the liquid surface of JP4 and JP5 fuels and electrodes of different configurations. These were a needle, a 60° point and $^1/_4$, $^1/_2$ and 1 in. sphere electrodes. The characteristics of the discharges between these electrodes and a metal plate were also studied.

The needle and 60° point electrodes gave mainly corona discharges, but the latter also gave spark discharges. The 60° point and small spherical electrodes gave spark discharges at small gaps, but otherwise gave corona discharges. The large spherical electrodes gave pre-breakdown streamers, which never made the transition to filamentary sparks. These streamers occurred at a frequency of about 100/min and had a duration some 7 times longer than that of filamentary sparks of the same energy.

It was found that for comparable conditions with the lin. spherical electrode the discharges between the electrode and the metal plate had 30–40 times as much energy as those between the electrode and the liquid surface. For the latter case the highest energies, up to 2.3 mJ, were obtained with the lin. electrode. The discharges studied were not incendive to JP4.

Summarizing the work on incendive discharges in liquid storage tanks and in road and rail tankers, the principal conditions for which there have been proposed limiting values below which discharges are not incendive are the liquid surface charge and the maximum vapour space potential. For these conditions the value quoted may be either the technical limit at which the discharge is just incendive, or a safety limit that is intended to incorporate a safety margin. Bulkley and Ginsburgh (1968) proposed for the technical limit 20 kV and for the safety limit 10 kV. A much lower figure of IkV was suggested for the latter limit by Mahley and Warren (1968). Subsequent workers have regarded this as too low. The technical limit has been proposed as 45 kV by Strawson and Lyle (1975b) and as 25 kV by W.D. Rees (1981). H. Kramer and Schön (1975) have proposed 35 kV as the technical limit on the maximum vapour space potential.

As far as concerns tanker water washing, a technical limit for the maximum vapor space potential of below 37 kV emerges from the work of van de Weerd (1971), while one of 70 kV has been given by J.S. Mills and Oldham (1983). The safety limit on the maximum vapour space potential is taken as 10 kV by H.R. Edwards (1983) and by M.R.O. Jones and Bond (1984, 1985).

16.7.39 Powders and dusts

The problem of ignition by static electricity in powder handling has some similarities with that in handling liquids, but there are also some important differences.

The powder may be handled as a dust suspension or a settled powder, and often as both.

The charging tendency of a powder is difficult to predict, but it tends to be high. It is also difficult to modify. Options that can be used with liquids may not be available. There is limited scope for reducing the velocity in pneumatic conveying. There is also limited scope for dosing with an additive to increase conductivity.

In the settled state particularly, a powder has a high bulk density and its volume charge density tends to be correspondingly high.

Prediction of the charging tendency is made difficult by a number of factors, including the particle diameter and size distribution, impurities, the water content, and the speed of separation.

The extent of charging of a powder depends on its volume resistivity. Charging is to be expected at a resistivity of $10^8 \Omega$ m and above. The resistivity of most organic powders exceeds this value.

Some data on the electrical volume resistivity of powders are given in Table 16.37. Figure 16.60 (N. Gibson, 1971) show the distribution of the resistivities of organic powder products.

Table 16.37 *Electrical volume and surface resistivity of selected solid materials*

A Volume and surface resistivity[a]

	Volume resistivity[b] (Ω m)	*Surface resistivity*[c] (Ω)
Plastics, overall range	10^{6}–10^{15}	10^{8}–10^{17}
PVC, unplasticized	10^{12}–10^{13}	10^{13}–10^{14}
PVC, plasticized	10^{9}–10^{12}	10^{10}–10^{13}
Polyethylene, high density	10^{14}	10^{14}–10^{15}
Polyethylene, low density	10^{15}	10^{14}–10^{15}
Polypropylene	10^{15}	10^{14}–10^{15}

B Surface resistivity of glass: effect of relative humidity[d]

Relative humidity (%)	*Relative surface resistivity*
100	1
80	4
70	30
60	800
50	30,000
40	6,000,000

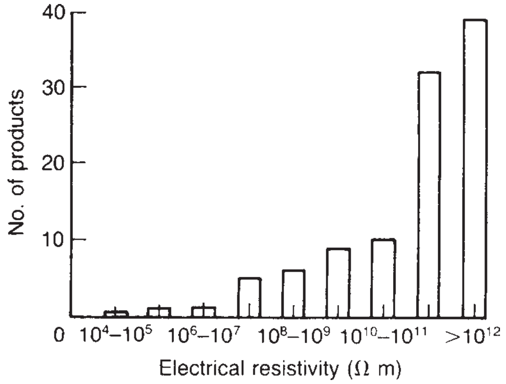

Figure 16.60 *Electrical volume resistivity of powders (N. Gibson, 1979) (Courtesy of Filtration and Separation)*

Given that the resistivity of the powder is sufficiently high for it to exhibit charging, the charging tendency depends more on the operations to which the powder is subjected than on the powder properties. Operations in which charging occurs include micronizing, grinding, sieving, gas filtration, pneumatic conveying and mechanical transfer.

The electrostatic charges generated in powders by these operations are typically as follows (N. Gibson, 1969):

	Charge (C/lb)
Micronizing	10^{-7}–10^{-3}
Grinding	10^{-7}–10^{-6}
Scroll feed transfer	10^{-8}–10^{-6}
Pouring	10^{-9}–10^{-7}
Sieving	10^{-11}–10^{-9}

The charge per particle increases, but less than proportionately, with increasing particle diameter. Thus the charge per unit mass must decrease. This is in line with the data just given.

The charge density on a powder is commonly expressed either as the volume charge density or the mass charge density. The relation between the two is

$$\frac{q}{m} = \frac{s}{\rho_e} \qquad [16.7.226]$$

where q is the charge on a particle (C), m is the mass of the particle (kg), s is the volume charge density (C/m^3) and ρ_e is the effective density (kg/m^3 air). The ratio q/m is also the mass charge density of the powder (C/kg). The effective density is that of the dust cloud or settled powder, as the case may be, and in the latter case it is the bulk density. The charge on a particle is then

$$q = \pi d^2 \sigma \qquad [16.7.227]$$

and the mass is

$$m = \frac{\pi}{6} d_d^3 \rho_s \qquad [16.7.228]$$

where d_d is the particle diameter (m) and ρ_s is the density of the particle (kg/m^3). Hence from Equations 16.7.227 and 16.7.228

$$\frac{q}{m} = \frac{6\sigma}{d_p \rho_s} \qquad [16.7.229]$$

The maximum charge on the particle in free space is determined by the maximum surface charge density.

As an illustration, consider a powder with a material density of 1000 kg/m^3 and a limiting surface charge density in free space of 2.7×10^{-5} C/m^2. Then for particle diameters of 10^{-2} and 10^{-6} m Equation 16.7.229 gives mass charge densities of 1.6×10^{-5} and 2×10^{-1} C/kg, respectively.

Dust may be in suspension or deposited. There is very little information on the occurrence of discharge between particles in suspension, but it cannot be ruled out. With a deposited dust there is a relaxation of the charge similar to that in a liquid. If the dust has a high resistivity, the relaxation time may be hours or even days. Discharges from deposited dusts are often coronas.

In much equipment handling dusts a flammable atmosphere does not exist during normal operation, because the dust suspension is above its upper flammability limit. But a flammable suspension is more likely to occur during transient conditions such as start-up and shut-down.

The principal hazard in dust-handling equipment is that presented by a container or other object made of conducting material but insulated from ground. There are certain factors that tend to reduce the probability of electrostatic ignition in equipment handling dust suspensions. One is that the dust suspensions tend to have high MIEs. A second is that discharge is frequently by a corona. The hazard of static electricity in dusts is discussed by K.N. Palmer (1973a).

16.7.40 Powder flow in pipes

The charging current for the flow of particles in a pipe, in other words in pneumatic conveying, has not been studied as extensively as that for liquids. The most common approach appears to be to estimate the maximum theoretical charge on the particles and to express the experimental results in terms of the fraction of this maximum charge attained.

The maximum charge on a particle in flow in a pipe differs from the maximum charge in free space. The maximum space charge density is obtained from Equation 16.7.61 and is inserted in Equation 16.7.229 to give the maximum charge on a particle q/m, or mass charge density.

As an illustration, consider the example given by J.F. Hughes and Bright (1979) for which the pipe radius is 0.05 m and the particle density is 0.95×10^3 kg/m^3. Then, utilizing the usual values for the permittivity of air and the breakdown field strength, Equation 16.7.61 gives a space charge density of about 1.06 C/m^3 and Equation 16.7.229 gives a mass charge density of about 1.12×10^{-6} C/kg. Furthermore, by equating the mass charge density q/m in Equations 16.7.226 and 16.7.229, and utilizing Equations 16.7.22 and 16.7.61, the condition for the equality of the maximum mass charge densities in free space and in a pipe is obtained:

$$\frac{d_d \rho_s}{3 r_p \rho_e} = 1 \qquad [16.7.230]$$

Several workers have obtained experimentally determined values of mass charge densities, and hence charging currents, which are close to the theoretical maximum. For example, J.F. Hughes and Bright (1979) report mass charge densities of $0.8\text{–}3.4 \times 10^{-6}$ C/kg for the case described above, for which the theoretical value was 1.12 C/kg. On the other hand, Boschung and Glor (1980) obtained the results shown in Figure 16.61, where the experimental mass charge densities are about one-tenth of the theoretical values.

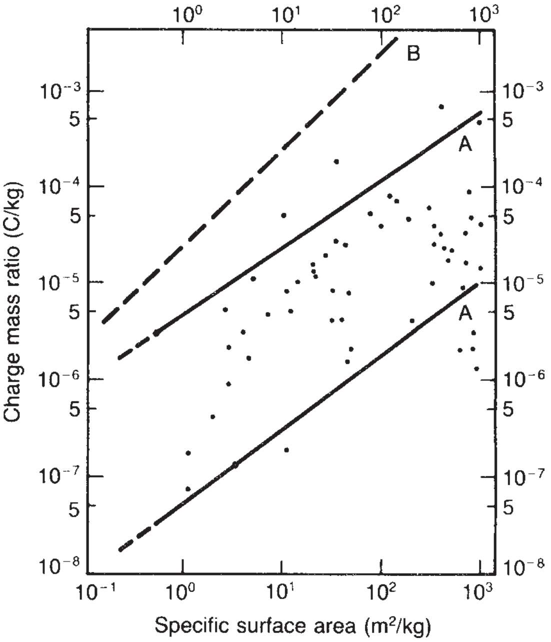

Figure 16.61 *Mass charge densities in powder flow in a pipe (Boschung and Glor, 1980): A, general trend of experimental data; and B, maximum values from a theoretical model (Courtesy of the Journal of Electrostatics)*

16.7.41 Powder storage silos

As with liquid storage tanks, so with powder silos there is a problem of charge accumulation and relaxation. The heap of powder in a silo tends to have a high volume resistivity and a high mass charge density. Such a powder will therefore retain a large charge over a long period. Relaxation of the charge may take days or even weeks.

The main hazard in such a situation is a discharge. The envelope of conditions that can give a discharge is determined by two limiting factors. The field must be strong enough to give field breakdown but not so strong that it prevents a charged particle from settling under gravity. Glor (1984) has utilized these two limitations to derive a simple model, which gives the envelope for discharges shown in Figure 16.62. This model leads to the conclusion that discharges are to be expected only for rather coarse powders, having particle diameters in the range 1–10 mm.

16.7.42 Discharges incendive in powder and dust systems

The incendivity of discharges for flammable gases was described in Section 16.7.10. The incendivity of a discharge for dusts may be determined by comparing the effective energy of the discharge with the MIE of the dust. The MIEs of dusts are given in Chapter 17 but, broadly, dusts typically have an MIE in the range 1–10 mJ.

A spark discharge may be incendive to dusts, depending on its energy.

A brush discharge is not regarded as incendive to dusts. According to Glor, there is no known case of ignition of a dust by a brush discharge. In practice it is difficult in handling powders to avoid brush discharges.

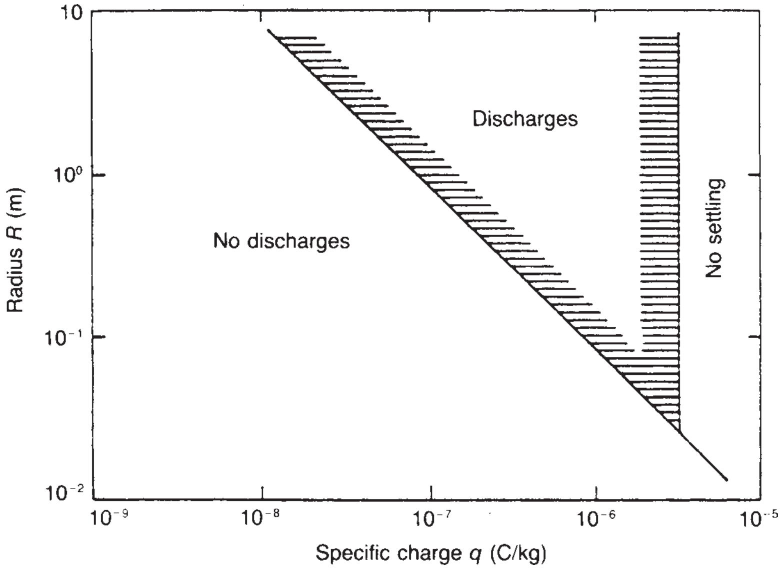

Figure 16.62 *Region for brush discharges on a settled powder in a silo: spherical heap of radius R (Glor, 1984) (Courtesy of the Journal of Electrostatics)*

A propagating brush discharge has very high energy and is incendive to most dusts.

With powders it is also necessary to consider another type of discharge, that is a bulking brush discharge in a silo. A discussion of the conditions under which such a discharge is most likely to occur has been given by Glor (1988). The conditions are a high bulk resistivity ($>10^{10}$ Ωm) and relatively large particle size (diameter >1 mm). The energy release in a bulking brush discharge is estimated to be of the order of 10 mJ and this is sufficiently high to be incendive to many dusts.

16.7.43 Drums and small containers

As mentioned earlier, explosions due to static ignition also occur in the filling of drums. Treatments of this problem include those by Pesetsky and Fisher (1975), Britton and Smith (1988) and Rosenthal (1988).

An incident is described by Pesetsky and Fisher involving an explosion during the filling with toluene of a 55 US gal steel drum that was not grounded. The drum was lined with a 5 mil (1 mil = 0.001 in.) non-conductive epoxy coating. Tests showed that when an ungrounded steel drum was filled with toluene, discharges between the steel drum and a grounded probe regularly caused ignition. It was also found that insertion of a 3 ft section of plastic pipe into the filling line increased the charging current by a factor of 23. It was estimated that under the test conditions the capacitance of the drum was about 100 pF, while the potential was measured as 8700 V, giving an energy of 3.6 mJ. In other tests in which a plastic drum and a plastic filling pipe were substituted, both the drum and the liquid reached a potential of 87,000 V, that is a value 10 times as high, but incendive discharges were not obtained between an grounded probe and the liquid surface. The authors refer, however, to work by Bruinzeel (1963) on tank filling, using a liquid with conductivity some 20 times less than toluene, in which incendive discharges were obtained from the liquid surface.

Britton and Smith (1988) describe an extensive investigation of drum explosions, following an incident in which an explosion occurred in a lined drum that was grounded. A review of all available incidents showed that in all cases low conductivity liquids (<50 pS/m) were involved. The authors conclude, however, that in certain situations a conductive liquid may give an incendive discharge. While it is true that for a grounded drum, unlined or with a lining of negligible resistance, an incendive discharge requires a low conductivity liquid, with a lined drum it may occur with either a conductive or a low conductivity liquid.

In at least one case reviewed the drum was grounded and the ignition occurred due to brush discharge between the liquid surface and the filling lance tip. It is this type of incendive discharge in particular that the authors address.

Such a discharge has a relatively low energy and ignition occurs only over a limited range of concentration. This cuts both ways. On the one hand it greatly reduces the risk of an explosion, but on the other it means that the fact that an explosion has not occurred to date is no guarantee that it will not do so.

The risk of static ignition depends on a number of factors, including the grounding, the drum, the liquid conductivity, the filling arrangements and the fill pipe. With regard to grounding, the authors state that to obtain an incendive discharge a potential of 1000 V is required. Allowing a safety factor of 10, the potential should be limited to 100 V. The charging current rarely exceeds 10^{-4} A. Thus it is sufficient that the resistance to ground does not exceed 1 MΩ.

One measure is to reduce the resistance of the lining. Some drum linings have a significant electrical resistance, while others do not. Polyethylene, for example, is essentially a perfect insulator. On the other hand, drum coatings of the epoxy or phenolic types have very low resistance.

Another approach is to address the charge generation and relaxation. Some features are prolific charge generators. The authors state that a high charging current can be generated not only by a filter but also by a hose with an internal grounding spiral. In their work, such a hose gave a charging current much greater than that of a smooth bore hose and within an order of magnitude of that produced by a microfilter.

Britton and Smith refer to recommendations on relaxation of the charge. It is normally advised that three time constants be provided for the liquid between a filter and the drum. Of the then current guides, API RP 2003 gives a relaxation time of 30 seconds for liquids with a conductivity less than 50 pS/m, and BS 5958: 1991 gives a relaxation time of 3 time constants for liquids with conductivities down to 2 pS/m combined with a global relaxation time of 100 s for liquids with lower conductivity.

The design of the fill pipe is also important. The dip pipe should have the largest practicable diameter and should have a pointed end; a rounded end is to be avoided.

The authors present electrostatic models for drums in support of the assessment of the risk of incendive discharge.

Dahn, Kashani and Reyes (1994) describe the problem of control of the static electricity hazard in the use of flexible intermediate bulk containers (FIBCs) for powders. They point out the hazard of attempting to solve the problem by utilizing grounded exterior bag surfaces. This tends to increase the likelihood of a propagating brush discharge. Further, if the grounding is lost and the static charge is high, there is potential for an incendive discharge.

They describe their preferred approach, the elements of which are to estimate the static charging rate, the charge dissipation rate, the field strength and the discharge strength. The charging rate is determined by a test in which the powder is passed down an inclined chute into a metal bucket container where the charge is measured. Tests are also done using an ASTM method to determine the surface and volume resistivities so that the charge dissipation may be estimated.

For the field strength in the container they use Equation 16.7.58a. As an illustration, they give a calculation of the field strength for the case of a container of radius 0.807 m, with a charge density of 38.53×10^{-6} C/m^3 and utilizing the permittivity of air of 8.83×10^{-12} C/V m. The resultant field strength is 1171 kV/m.

They also give calculations of the energy in a propagating brush discharge.

16.7.44 Moving machinery

Static electricity is generated by the relative movement of surfaces in machinery. In particular, conveyor belts and reeled material tend to accumulate a large electrostatic charge.

The voltages generated by a conveyor belt are often compared with those generated by a van de Graaff generator. Typically such a generator might have a potential of 100 kV with a current of several microamps, but values of up to 50 kV and several milliamps have been quoted.

Cross (1981) has described experiments on two conveyor belts, one an insulating belt and one an antistatic belt, in which the effect of humidity was measured. At zero absolute humidity the potential on the insulating belt reached 110 kV, while that on the antistatic belt was about 6 kV. Bucket elevators also can build up an appreciable charge.

16.7.45 Human body

The human body can become electrostatically charged and can be the source of an incendive spark. The human body has a low volume resistivity and thus acts as a conductor. Charging can occur by contact charging, by induction or by charge sharing. Some activities which can cause charging are walking, rubbing, removing clothing, pouring liquids and powders, and touching charged objects. The maximum potential of the body is of the order of 50 kV, the limitation being leakage and sparking. It is not uncommon for the body to be at some 10 kV. The capacitance of the body is in the range 100–300 pF, say 200 pF. Then at a potential of 10 kV, from Equation 16.7.19 the energy of a discharge from the body is some 10 mJ.

Discharge from the body is therefore capable of giving a spark incendive to a flammable gas mixture. Removal of clothing can also give an incendive spark. BS 5958 : 1991 recommends precautions against incendive discharge for the body for flammable mixtures with MIEs < 100 mJ. Discharge from clothing is reckoned to be incendive only to sensitive mixtures.

The main precaution against sparks from the human body is grounding. The charging current which occurs as a result of manual activities generally does not exceed 10^{-6} A. Then, applying the $100/I$ criterion gives a required resistance to ground of not more than 10^8 Ω. There are also two other relevant criteria. For avoidance of uncomfortable shocks the resistance to ground should not exceed 10^9 Ω. For protection against mains voltage it should not exceed 5×10^4 Ω. In BS 5958 Part 1: 1991 a resistance to ground for personnel of 10 represents good practice in most applications, but the standard allows one of up to 10^6 Ω in certain cases.

In order to achieve this degree of grounding it is necessary to consider both footwear and flooring. BS 5958: 1991 gives requirements for the two main types of footwear used: antistatic footwear and conducting footwear. It also states that leather footwear usually has a sufficiently low resistance, except when very dry.

BS 2050: 1978 gives requirements for flooring materials and BS 3187: 1991 gives requirements for laid floors, but only of the conductive type. A conductive type floor is not suitable if protection is required against mains voltage. It is sometimes permissible to provide a limited area of low resistance flooring such as a metal plate.

16.7.46 Containments

The effect of the containment has been referred to a number of times in the preceding sections. It is now considered in more detail. Containment materials are classed as conductive or non-conductive. BS 5958: 1991 defines a non-conductive, or high resistivity, material as one with volume and surface resistivities of 10^{12} Ωm and 10^{12} Ω, respectively. In process containments the principal conductive materials are metals and the principal non-conductive materials are plastics. Some data on the electrical volume and surface resistivities of solid materials are given in Table 16.37. In addition, use is also made of non-metallic conductive materials, essentially plastics modified to increase their conductivity.

Some principal containments and containment materials are given in Table 16.38, based broadly on the distinctions made in BS 5958. Most are self-explanatory, but several require further comment. Where the container is non-conducting, there may be the possibility of a discharge

Table 16.38 Some containments and containment materials

Metal container for liquids
Non-conducting container for liquids
Metal container for liquids with fixed non-metallic coating
Metal container for liquids with outer non-metallic coating/ jacket
Metal pipes for gases and liquids
Metal container for powders
Non-conducting container for powders
Container for powders with liner:
Metal container with conductive liner
Metal container with non-conductive liner
Non-conductive container with non-conductive liner

from its external surface. Some metal containers have an internal non-conductive coating. This creates the possibility that charge from repeated filling or rubbing is retained on the coating. Metal containers may also have an external non-conductive coating or jacket. There is then the possibility of a discharge from the external surface of the container. Another possible effect where there is a non-conductive outer surface, whether that of the main container or of a coating, is that metallic objects on this surface may constitute isolated conductors. Any situation where there may be a discharge from the container is relevant if the container is in a classified hazardous area.

Some containers for dry powders have removable liners. Broadly, BS 5958: 1991 treats a metal container with a conductive liner as an unlined metal container and a non-conductive container with a non-conductive liner as an unlined non-conductive container. It recommends against the use of a non-conductive liner with a metal container or of a conductive liner with a non-conductive container, and recommends additional precautions where such mixed systems have to be used.

16.7.47 Precautions against static electricity

Static electricity can act as a source of ignition giving rise to a fire or explosion only under the following conditions:

(1) a flammable atmosphere exists;
(2) an electrostatic charge is generated, accumulates and produces an electric field strength which exceeds the critical value for breakdown;
(3) the resultant incendive discharge has an energy greater than the minimum ignition energy of the flammable atmosphere.

Thus precautions against static electricity aim to eliminate one or more of the above factors. These precautions tend to be based, therefore, on the following approaches:

(1) elimination of a flammable atmosphere;
(2) control of charge generation;
(3) control of charge accumulation;
(4) minimization of incendive discharge.

It is a general principle in handling flammable materials to make avoidance of a flammable atmosphere the first line of defence where this is practical. It is necessary also to try to eliminate sources of ignition, but it is much more difficult to do this reliably.

Since electrostatic charge builds up both on process materials and on process plant, it is not sufficient simply to ensure that charge is drained away from plant by measures such as grounding. It is essential to deal also with the charge on the material being handled.

In the handling of liquids the precautions used may include the following:

(1) elimination of flammable mixtures;
(2) bonding and grounding;
(3) modification of liquid conductivity;
(4) limitation of flow velocity;
(5) minimization of charge generation by –
    (a) immiscible liquids,
    (b) filters, valves;
(6) avoidance of splashing and settling;
(7) avoidance of grounded probes;
(8) grounding of personnel;
(9) measures associated with low conductivity containers;
(10) provision of relaxation time.

The elimination of a flammable mixture is used particularly for liquid storage tanks and for tank cleaning on tankers.

Bonding and grounding are discussed in Section 16.7.48.

The modification of liquid conductivity was developed particularly by Shell, and the Shell additive ASA 3 is widely used for conductivity modification. Modification of liquid conductivity has been discussed by Klinkenberg and van der Minne (1958). The liquid conductivities recommended in order to keep charge separation below a safe level are 50 and 500 pS/m for pipeline velocities below and above 7 m/s, respectively.

Thus some products, such as crude oil, have a sufficiently high conductivity to render them safe, while others, such as light distillates, do not. It is possible, however, to modify the conductivity of the latter by the use of a very small amount of a suitable additive. Additives are usually a combination of divalent or polyvalent metal salt of an acid such as carboxylic or sulphonic acid and a suitable electrolyte that imparts a conductivity of about 10,000 pS/m in a 0.1% solution in benzene. Thus concentrations of 0.6 and 6 ppm of additive Shell ASA 3 raise the conductivity of such products to about 200–300 and 1000 pS/m, respectively.

The charging current in the pipeline flow of liquids is of the order of 10^{-10}–10^{-7}A. This current is approximately proportional to the square of the velocity. Keeping the velocity down can, therefore, reduce charge generation. A limit on pipeline velocities of 7 and 1 m/s, respectively, for liquids without and with an immiscible component has been recommended by Klinkenberg and van der Minne (1958). The much lower limit for liquids with an immiscible component, such as free water, is due to the fact that in such liquids the rate of charge generation can be up to 50 times greater.

Filters generally require special precautions. Since the streaming current generated in a filter is proportional to the flow rate rather than the square of the flow rate, as with a pipe, the limitation of liquid velocity is rather less effective for filters. The usual approach is to allow a relaxation time by providing an adequate length of pipe between the filter and the tank. This is more difficult to do, however, for high purity products with long relaxation times.

For liquid storage in a tank of non-conductive material or in a tank of non-conductive material with an embedded metal grid not in contact with the liquid, BS 5958:1991 recommends the use of an grounding plate of area

$$A_{\mathrm{ep}} = 0.04\,V_{\mathrm{t}} \qquad [16.7.231]$$

where A_{ep} is the area of the grounding plate (m^2) and V_{t} is the volume of the tank (m^3).

Although they are generally less prolific generators than filters, valves and other constrictions can also give substantial increases in charging.

Tank filling arrangements should avoid free fall and splash filling of liquids. Inlets should reach to the bottom of the tank or, preferably, should enter at the bottom of the tank and be submerged.

Grounded probes in tanks should be avoided as far as is practicable, as should isolated conductors.

There should be suitable arrangements for level gauging. The hazard is reduced if antistatic additives are used and if an adequate relaxation time is allowed. Level measuring equipment, which is used where there is an electrostatic hazard, includes non-conducting ullage tapes and permanently fixed and grounded sounding pipes extending to within a few centimeters of the tank bottom. Detailed discussions of the precautions associated with level gauging are given by J.R. Hughes (1970) and Page and Gardner (1971).

Settling of immiscible liquids, such as water droplets in oil, should be avoided as far as possible.

A liquid storage tank made of a non-conductive material may be provided with a grounded metal grid on or just below the surface throughout the material. If this conducting grid covers the inner surface of the tank and is thus in contact with the liquid, this provides a ground for the liquid.

Precautions against the charging of the human body take the form of special footwear and flooring. There are two types of product available: antistatic and conductive. Both prevent accumulation of electrostatic charge, but whereas the former gives protection against electrical mains failure, the latter does not and should only be used where there is other protection against such failure. There are a number of British Standards on antistatic and conductive footwear and flooring. Since the resistance of these products can change, it is important that it be monitored regularly; instruments are available to do this.

The hazard involved in using non-conducting containers may be dealt with by limiting the container size. Some maximum sizes for non-conducting plastic containers have been suggested by Heidelberg and Schön (1960) as follows:

	Maximum container size (l)
Liquids with low ignition energy	1
Liquids with flashpoint <21°C	2–5
Liquids with flashpoint >21°C	60

As already indicated, both conducting and non-conducting containers present static electricity hazards and applications need to be considered individually.

The precautions required in the handling of dusts and powders are somewhat similar to those for liquid handling. Principal measures again include elimination of flammable suspensions, bonding and grounding of plant, and grounding of personnel. Antistatic additives, which modify dust resistivity, are not well developed. Measures such as humidification and ionization are used, but have limitations. Non-metallic containers for sensitive dusts should have low resistance. Detailed information on the precautions for dust handling is given by K.N. Palmer (1973a).

The electrostatic hazard from steam leaks is that a nearby conductor insulated from ground becomes charged. An example of such a conductor is wire netting around lagging. Insulated conductors should be avoided in situations where they could become a hazard.

Steam used for purging or cleaning can cause charge generation. Again it is necessary to consider both the plant and the fluid. The risk of ungrounded pipelines and charge accumulation on these is reduced if the lines used are fixed rather than portable apparatus. Keeping the flow velocity down should minimize charge generation in the steam. Grounded probes should be avoided so that the probability of a discharge is reduced.

Carbon dioxide should not be used for the rapid inerting of flammable atmospheres, since it can generate static electricity and so act as an ignition source.

The accumulation of electrostatic charge on moving machinery can be prevented in some cases by grounding the machinery. Objects such as conveyor belts and transmission belts, however, may also accumulate charge and this is not prevented by normal grounding arrangements. The usual solution is to modify the conductivity of the belt material by the incorporation of additives during manufacturing or by the use of a dressing in operation.

The reduction of the resistance of materials is a widely used approach and there are British Standard specifications for low resistance polymeric materials not only for flooring, footwear and belts, as already mentioned, but also for sheeting, hose, tires and wheels.

Electrostatic eliminators based on ionization are used to prevent charge accumulation in applications such as reeling operations. The charge is either drained to ground through the ionized air or is directly neutralized by ions from the air. Air can be ionized by heat, high voltage, ultraviolet light or radioactivity. Not all types of electrostatic eliminator are suitable for flammable atmospheres. Flames are sometimes used, for example, as ionizers on printing presses.

Devices that have pointed surfaces and are electrically energized are another type of ionizer. If flammable mixtures can be present, however, it is necessary to ensure that the electrical equipment is not itself a source of ignition.

Another method of ionization uses a radioactive source. This type of equipment is of limited applicability, because it is only suitable where charging rates are low. It is used, however, in the paper and textile industries. It is necessary with such devices to take the usual precautions for a radioactive hazard.

Since a pointed object will ionize air near a charged object, it is also possible to use devices rather like wire brushes as induction collectors. There is in this case no electrical energization.

The relative humidity in the atmosphere has a considerable influence on the incidence of electrostatic hazards. In general, most fires attributed to static electricity occur indoors in winter when the relative humidity is below about 30%. If the relative humidity is kept above 60–70%, the electrostatic charge tends to drain away. This is largely a surface electrical conductivity effect. The change in surface conductivity with relative humidity can be dramatic. For plate glass there is a 1000-fold increase in surface conductivity between 20% and 50% relative humidity.

16.7.48 Precautions against static electricity: grounding and bonding

Grounding and bonding comprise one of the principal methods of providing protection against static electricity. Bonding involves making an electrical connection between two conducting objects and ground. The effect of bonding is to maintain the two objects connected at the same potential and that of grounding is to drain away to ground the charge on the object connected. Grounding and bonding systems are also required to give protection against electrical systems and against lightning, but the systems considered here relate only to static electricity.

The purpose of grounding and bonding is to prevent an incendive discharge. The conditions for an incendive discharge to occur are that the field strength reaches the breakdown value and that the energy in the discharge equals the relevant ignition energy.

A potential of at least 300 V is normally considered necessary for an incendive discharge, but since a potential of 100 V has been considered hazardous in explosives manufacture, the latter figure is generally taken as the limit value. Applying Equation 16.7.1 (Ohm's law) gives the criterion that the resistance should not exceed $100/I$. Charging currents vary in the range 10^{-11} – 10^{-4} A. Taking the worst case of a charging current of 10^{-4} A yields the criterion resistance to ground of $10^6\ \Omega$. Taking a more realistic value of 10^{-6} A for the charging current yields a resistance to ground of $10^8\ \Omega$.

As a practical matter it is usually recommended that for conducting equipment, such as a metal, the resistance to ground should not exceed $10\ \Omega$. The reason for this is that the equipment might contain certain high resistance features such as paint, grease and oil, corrosion and rust, which could increase in resistance and negate the required grounding if the resistance were set at, say, $10^6\ \Omega$. The value recommended in BS 5958: 1991 is $10\ \Omega$; this has the advantage of being the same as the value prescribed for lightning protection.

Different requirements for grounding are given in BS 5958 for equipment made of non-conducting material and of conductive or antistatic materials. For plant built in non-conducting material, isolated conductors are of particular concern. It is frequently recommended that all isolated conductors be grounded. BS 5958 questions this philosophy and proposes instead an approach based essentially on hazard assessment, taking into account the probability that the item will be charged, that it will give an incendive spark and that a flammable mixture will be present. For equipment made of conductive or antistatic material, BS 5958 recommends a resistance to ground not greater than $100/I$. This will tend give a resistance in the range 10^4–$10^8\ \Omega$. The general recommendation is for $10^6\ \Omega$, but a higher resistance, which still meets the $100/I$ criterion, is acceptable.

General grounding requirements are discussed in BS 5958: Part 1: 1991. These include a table summarizing the requirements. Further guidance on detailed requirements for particular situations is given in BS 5958: Part 2: 1991.

Grounding is usually achieved by means of copper strips or wire attached to a special point on the object to be grounded. Bonding across flanged joints to ensure better electrical continuity than that through the bolts has been widely practiced, but many companies have satisfied themselves by tests that this is not necessary and have discontinued the practice.

A good grounding system also requires that it be recognizable as such and that it be checked periodically and after maintenance operations.

Grounding of the human body and the use of appropriate footwear and floors are described in Section 16.7.45.

16.7.49 Precautions against static electricity: BS 5958

BS 5958: Parts 1 and 2: 1991 gives very detailed recommendations for precautions against static electricity, with those for particular situations being given in Part 2. Table 16.39 lists the principal contents of Part 2.

Some of the precautions for handling liquids recommended in BS 5958: Part 2: 1991 are summarized in Table 16.40. For liquid storage tanks made of metal, a flammable atmosphere may be eliminated by reduction of the vapour space by using a floating roof, or by some form of atmosphere control such as inerting. The tank should be grounded. Splash filling should be avoided. Filling may be by a top or bottom fill pipe. A top fill pipe should extend close to the bottom of the tank. There should be a limitation of the liquid velocity during filling. Measures should be taken to avoid excessive charge in the liquid entering the tank. An adequate relaxation time should be allowed before operations such as gauging and sampling are carried out. Measures should be taken to avoid discharge between the liquid in the tank and the tank itself during such operations.

The standard discourages the use of non-conductive liquid storage tanks and recommends that specialist advice be taken before installing one. The precautions recommended for metal storage tanks apply, but in addition it is preferable that the liquid itself should be grounded and, for a classified hazardous area, the effect of an external discharge should be considered.

The recommendations for metal road and rail tanks are broadly similar, but additional measures are specified concerning filling hoses.

For barge and ship loading BS 5958: 1991 gives recommendations on atmosphere control, grounding, fill pipes and liquid filling velocity.

Some of the limitations on liquid velocity for operations involving filling with liquids, as given in BS 5958: 1991, are summarized in Table 16.41. For small liquid containers the Standard recommends for metal containers grounding of the container and a limitation of the liquid velocity during filling. For non-conductive containers consideration needs to be given to the hazardous area classification. The container itself can be considered a Zone 1 area if either a flammable liquid is being handled or if a flammable atmosphere may be present in normal operation. A non-conductive container should be used only if the risk of ignition is acceptably low, which may be a matter for expert guidance. With non-conductive containers in classified hazardous areas consideration needs to be given also to external discharge. This applies whether or not the liquid is flammable.

Table 16.39 *Principal contents of BS 5958: Part 2: 1991*

Larger containers
3. Fixed metal tanks for the storage of liquids
4. Fixed non-metallic tanks for the storage of liquids sited partially or wholly above ground
5. Fixed non-metallic tanks for the storage of liquids sited completely below ground
7. Metal road/rail tanks for liquids
8. Non-metallic road/rail tanks for liquids
13. Ships (tankers) and barges
17. Metal containers and tanks for the storage and transport of liquids, with a fixed internal non-metallic coating
18. Metal containers for liquids with outer non-metallic coatings or jackets

Smaller containers
11. Small metal containers for liquids
12. Small non-metallic containers for liquids
21. Containers for powders
22. Flexible intermediate bulk containers
23. Removable non-metallic liners in containers for solvent wet materials or powders

Equipment and processes
9. Installation for the transfer of liquids to and from road and rail vehicles
10. Liquid/liquid and solid/liquid blending and mixing
16. Fine particle filters and water separators
19. Pipelines for liquids and gases
20. Pneumatic conveying systems
33. Vacuum filters
34. Centrifuges
35. Flaker
36. Dust collectors

Operations
6. Gauging and sampling of tanks
14. Tank cleaning with high-pressure water jets or steam
24. Manual addition of powders to flammable liquids
25. Release of gases and vapours

The standard also gives precautions for filling containers with high resistivity powders. These may be summarized as follows. A distinction is made between metal containers of volume $\leq 65\ \text{m}^3$ or non-metallic containers of $5\ \text{m}^3$ and larger ones, and between powders which give rise to flammable mixtures with a minimum ignition energy MIE of ≤ 25 mJ and those with an MIE of >25 mJ. It may be noted that for metal containers the volume delimitation just quoted is an increase from one of $5\ \text{m}^3$ in the 1983 edition, reflecting a growth in knowledge. For metal containers, if the container volume is $\leq 65\ \text{m}^3$ and the MIE is >25 mJ, the measures recommended are to ground the container and any filling pipe. However, if there is a possibility that a flammable atmosphere such as a dust cloud with an MIE of ≤ 100 mJ could occur, personnel should also be grounded. For the same size container, if the MIE is ≤ 25 mJ, there should be grounding of equipment and personnel and, in addition, consideration should be given to charge rate limitation and explosion prevention and protection; these comprise a set of measures which in this context it is convenient to refer to as 'explosion protection'. If the metal container is $>65\ \text{m}^3$, there should be grounding of equipment and personnel and, unless incendive discharges can be ruled out, consideration should be given to explosion protection. Moving on to non-metallic containers to be filled with dry powders, if the container volume is $\leq 5\ \text{m}^3$ and the MIE is >25 mJ, the measures recommended are to ground the container and any filling pipe. It should also be established that the rate of charge input is insufficient to promote propagating brush discharges. However, if there is a possibility that a dust cloud with an MIE of ≤ 100 mJ could occur, personnel should also be grounded. For the same size container, if the MIE is ≤ 25 mJ, there should be grounding of equipment and personnel and, unless incendive discharges can be ruled out, consideration should be given to explosion protection. For the same size container, if the MIE is <25 mJ and there is a possibility of propagating brush discharges, there should be grounding of equipment and personnel and, unless incendive discharges can be ruled out, consideration should be given to explosion protection; in addition, grounded rods should be inserted into the container to assist relaxation of charge from the powder. If the non-metallic container is >5 m, for which the probability of incendive discharge from a dust cloud is as yet unknown, there should be grounding of equipment and personnel and, unless it can be shown that incendive discharges will occur neither from the bulk powder nor the dust cloud, consideration should be given to explosion protection; if there is a possibility of propagating brush discharges, consideration should be given to the use of grounded rods.

The Standard deals with the use of removable non-metallic liners in containers for solvent wet materials or dry powders. The effect of such a liner depends on whether it is used in a metal or in a non-conductive container. If the liner is used in a metal container, it may insulate the material being handled from ground via the metal and it may itself become charged, with the possibility of a propagating brush discharge. The standard strongly recommends that the liner be conductive with a surface resistivity not exceeding $10^{11}\ \Omega$. The precautions applicable to the equivalent unlined container should be taken. A liner with a higher resistivity should be used in a metal container only where this is essential, in which case expert advice is required. The precautions recommended by the standard for the case of a non-metallic liner in a non-conductive container are the same as those for a non-conductive container alone. The use of conductive liners in non-conductive containers is not recommended but, if practiced, such liners should be grounded. In almost all cases an essential precaution is that removal of the liner from the container, with the attendant risk of sparking, should be avoided in the presence of a flammable mixture.

Another type of container is the FIBC used for powders. Typically, such containers are made of polypropylene fabric or some similar heavy-duty material. Some have conducting thread woven into them. The variety of FIBCs, and the lack of data on their performance, is such that the standard gives only very general advice and recommends expert consultation. It does, however, state the basic principle that if an FIBC is made of a conducting material it should be grounded.

Table 16.40 *Some precautions against static electricity given in BS 5958: Part 2: 1991 – precautions for selected containments and equipment and operations involving liquids*

Configuration/operation	*Containment material*	*Precautions*
1. Liquid storage tank	Metal	Vapour space reduction/atmosphere control Liquid conductivity Grounding of tank Avoidance of splash filling, fill pipe arrangements Liquid velocity Charge generators Relaxation time Gauging and sampling
2. Liquid storage tank	Non-conductor	As (1) plus: limitation on use, grounding of liquid, hazardous areas
3. Road/rail tanker	Metal	As (1) plus: hoses
	Non-conductor	As (2) plus: hoses
4. Liquid/liquid and liquid/solid-blending		Atmosphere control Grounding Agitator power
5. Small containers for liquids	Metal	Grounding Liquid velocity
6. Small containers for liquids	Non-conductor	As (5) plus: hazardous areas
7. Ships and barges: loading		Atmosphere control Grounding Fill pipe Liquid velocity
8. Ships and barges: tank cleaning		Atmosphere control Grounding

For liquid–liquid and liquid–solid blending, measures recommended in the Standard include atmosphere control, grounding of the container and limitation of agitator power.

The Standard also deals with a number of operations. One of these is gauging and sampling. Such operations are commonly carried out on storage tanks. The gauging and sampling equipment should be made of a conducting material such as a metal or of wood or natural fibre. The resistivity of wood and natural fibre is such that they do not become highly charged or give incendive sparks. Use should not be made of metal chains or of synthetic polymers, which have high resistivity. All metallic parts on gauging and sampling equipment should be grounded, by connection to the grounded tank if it is a metal one or direct to ground if the tank is a non-conductive one. For liquids with conductivities of ≤ 50 pS/m, gauging and sampling operations should not be carried out during any charge generating operation, including filling, and after filling not until the lapse of a prescribed relaxation time. The relaxation times recommended are at least 30 min if the filling liquid has a separate water phase and a period of, say, 10 min if it does not. After any mixing operation the gauging and sampling should be deferred until the components have settled. After a cleaning operation that has generated a charged mist, gauging and sampling should be delayed until the mist has settled, which may take some hours. If the liquid conductivity is >50 pS/m, gauging and sampling may be done at any time. Also, the foregoing restrictions on when gauging can be performed do not apply if it is done using fixed gauging equipment or through a fixed, grounded pipe extending to the bottom of the tank. Gauging and sampling should not be undertaken during adverse weather conditions such as thunderstorms or snow or hail storms.

Another operation considered is the manual addition of powders to flammable liquids. The flammable vapour should be contained within the receiving vessel, and dust cloud formation should be strictly controlled. The container being emptied should preferably be of metal or other conductive material and should be grounded. A paper sack can be grounded by contact with the grounded plant. Emptying from non-conductive containers is not generally recommended. The standard also gives precautions to be taken if there is a liner in the container being emptied, these precautions being similar to those described above in relation to the filling of lined containers. The receiving vessel and chutes should preferably be of metal or other conductive material and should be grounded. The Standard recommends against the use of non-conductive materials for such equipment. The risk of incendive discharge by the powder as it enters the receiver is assessed as generally low unless the chute is longer than 3 m or the powder has high resistivity, in which case expert advice is in order. For a liquid in the receiving vessel with a conductivity of >50 pS/m, it is sufficient to ensure that the liquid is grounded, either by contact with the grounded metal vessel or, if the vessel has a non-conductive lining, by a special ground point at the base of the receiver. If the liquid conductivity is ≤ 50 pS/m, and it cannot be reduced below this by a conductivity

Table 16.41 *Some precautions against static electricity given in BS 5958: Part 2: 1991 – some limitations on liquid velocity for operations involving filling with liquids*

Configuration/operation	*Liquid conductivity* (pS/m)	*Liquid velocity*[a] (m/s)
1. Liquid storage tank filling	≤ 50	≤ 7 General limit ≤ 1 Until fill pipe submerged ≤ 1 If immiscible phase present
	>50	No limitation
2. Road or rail tanker loading	≤ 50	Lower of (a) $u \leq 7$ (b) $ud \leq N$[b] ≤ 1 If immiscible phase present
3. Small container filling	≤ 50	≤ 1 If immiscible phase present
	>50	No limitation
4. Ship or barge loading	≤ 50	≤ 1 Until fill pipe submerged ≤ 1 If immiscible phase present
	>50	No limitation

[a] These are the liquid velocity limits given for metal containers.

[b] N is a constant with a value of 0.5 m^2/s for liquid conductivities of >5 pS/m. The Standard states that the value to be applied for liquid conductivities of ≤ 5 pS/m is a matter for debate and quotes values of 0.38 and 0.5 m^2/s as having been accepted, but it also states that in the United Kingdom the value used is 0.5 m^2/s.

modifier, expert advice should be sought. An alternative basis of safety can be the elimination of a flammable atmosphere, but in this case it should be appreciated that air can enter with the powder. It may be necessary to monitor the oxygen content.

The Standard emphasizes that in operations generally, it should be ensured that the human body does not present an ignition risk.

The foregoing summary is no more than a sample from the detailed recommendations made in the Standard on a wide range of situations.

16.7.50 Precautions against static electricity: NFPA 77

In the United States the relevant standard is NFPA 77: 2000 *Static Electricity.* Its recommendations agree in broad outline with, but differ in some details from, those just described.

The precautions given for the handling of liquids include avoidance of entrained water and gas, avoidance of splash filling and gas bubbling, limitation of flow velocity, location of the fill pipe near the bottom of the container and provision of relaxation time.

The code gives detailed arrangements for a number of specific situations, including filling of storage tanks, road tankers, rail tank cars, small containers and drums.

Where bottom loading of road tankers is used, the code recommends limitation of the flow velocity or use of splash deflectors to prevent upward spraying.

It draws attention to the particular hazard of hydrogen containing small particles of oxide from the inside of containments. In this contaminated state the gas will generate charge. Its MIE is very low.

16.7.51 Precautions against static electricity: Expert Commission

Another set of recommendations on static electricity are those of the Expert Commission for Safety in the Swiss Chemical Industry (1988). The following account summarizes some of the principal points.

The report gives guidance on a number of specific situations. For the handling of liquids, these include (1) liquid transfer through pipes and hoses, (2) liquid filling or emptying of small containers and drums under gravity, (3) liquid transfer by drum pumps, (4) liquid filling of agitated vessels, (5) operations at the open access port of an agitated vessel, (6) liquid filling of large glass vessels, (7) loading and unloading of road and rail tankers and (8) transfer and filtration of suspensions on filters and centrifuges close to the flashpoint.

Guidance is also given on the handling of powders. Separate consideration is given to the handling of powders without and with flammable vapours. Specific situations considered include (1) 'open' charging of powder into flammable liquids, (2) discharging of solids containing flammable liquids from filtration apparatus, (3) charging and emptying of containers, (4) pneumatic conveying, (5) charging of powders into silos, (6) spray and fluidized bed drying and (7) ventilation, extraction and dust aspiration systems. For each situation the report rehearses the hazards and describes precautions. It gives a large number of diagrams showing in detail the configurations recommended.

For liquid transfer through pipes and hoses, the hazards are those already described. Precautions include exclusion of impurities such as water or dust, operation with the pipe full, limitation of the flow velocity and care with charge generators such as filters. Guidance is given on velocity limits for partially full pipes and for pipes conveying slurries of crystals, and on hose selection.

For liquid filling or emptying of small containers and drums under gravity, the hazards depend on whether the container is conductive or non-conductive, as described above. Precautions include taking the fill pipe close to the bottom of the container, and grounding of the container and fill pipe and of personnel. Liquids containing an immiscible component should be charged only into conducting containers. For liquids at a temperature less than 5°C below the flashpoint a table is given for the selection of a suitable type of container.

For liquid transfer by drum pumps, the hazards are charging of the liquid and sparking between the drum pump and the container. Precautions are to connect the drum pump both to the container being emptied and to that being charged and to ground it. The connectors should be permanently fixed to the drum pump so that it is clear that the connections need to be made. The connecting points should not be the openings of the drum or the container, as these are the very points where a flammable mixture is most likely to be present.

For liquid filling of agitated vessels, the situation particularly envisaged is the charging of a liquid using compressed air or inert gas, where the hazards are charging by turbulence and the creation of brush discharges between the liquid surface and internal fittings. Precautions include bottom filling or taking a top fill pipe close to the bottom, limitation of charging velocity, avoidance of discharging by 'blowing off with air, and use of nitrogen blanketing. Guidance is also given on the alternative procedure of charging under vacuum and on special precautions for enameled vessels.

For operations at the open access port of an agitated vessel, the hazard is sparking between the liquid surface of the reaction mass and an approaching metal object, or between the port flange and a conducting object in contact with the liquid. Precautions include avoidance of sampling through open ports or, if this cannot be avoided, the use of non-conductive sampling devices and the observance of a relaxation time.

For liquid filling of large glass vessels, the hazards are charging of the liquid and the vessel by turbulence and sparking between conductive items. Precautions include grounding of metal parts, limitation of flow velocity and inerting. Guidance is given on the alternative procedure of charging under vacuum.

For loading and unloading of road and rail tankers, the hazards are charging of the liquid, the vehicle and even the driver when leaving the cab, and sparking between conductive items. Precautions include a connection between the vehicle and the fixed tank at the terminal and the use of conductive hoses and footwear.

For the transfer and filtration of suspensions on filters and centrifuges at temperatures less than 5°C below the flashpoint, the hazard is charge generation during the filtration or centrifugation so that the filter cake or isolated conductors become charged, and sparking between these and conductive items. Precautions include grounding and inerting.

For powders, the report distinguishes between powders without and with flammable vapours. It takes the dividing line as 1% flammable solvent; powders with less than this can be considered as essentially solvent free. For solvent-free powders the hazard is charging of large metal parts and sparking from these. Precautions include the grounding of such parts. Provided the solvent-free status of the powder is assured, the construction material of containments such as drums or pipes is not restricted. Containers with plastic liners are acceptable.

For powders that are handled in the presence of a flammable vapour, are wet with flammable solvent or are charged into flammable solvent, the report gives the following guidance. The hazards include charging not only of metal parts but also of the powder and of sparking from metal parts. There is a particular hazard of brush discharges. A large proportion of incidents due to static electricity occur with such systems. Precautions include grounding and inerting. For powders containing flammable solvents only grounded containers should be used.

Powders containing flammable solvents should not be poured from non-conductive containers or bags or through non-conductive ducts into a charging vessel. Nor should powders be poured into a vessel containing a flammable solvent from non-conductive containers or non-conductive ducts.

For the open charging of powder into flammable liquids, three cases are distinguished: Case A, non-combustible or high MIE powders; Case B1, open charging of powders into precharged solvent; and Case B2, open charging of solvent-wet solids into an empty container. Guidance is given for each of these cases.

For discharging of solids containing flammable liquids from filtration apparatus, including centrifuges, the hazard is charging of the filter cake, filter cloth and metal parts and sparking to conductive items. In some cases dust formation has been observed with solvent contents up to 10%. Precautions include conductive filters, discharging using grounded chutes and containers, non-conductive shovels, local exhaust ventilation and inerting. Non-conductive filters should be withdrawn slowly.

For charging and emptying of containers with powders containing flammable liquids, the hazard is charging and sparking to a conductive item or brush discharges. Precautions include the use of grounded, metal containers and the avoidance of non-conductive containers or non-conductive linings.

For pneumatic conveying, the hazards are charging of the pipe and of the powder, charge accumulation in silos and sparking between metal parts. Precautions include the use of grounded, metal pipes. If plastic piping is used, the flanges should be plastic also or, if metal, grounded. Before discharge into a silo, the charge on powder can be reduced by first passing the powder through a grounded, metal cyclone.

For the charging of powders into silos, the hazard is as described above. In principle, a large, charged dust cloud could be created and could discharge, though the report states that no such cases are known. Precautions include the avoidance of internal insulating coatings, the use of conducting paints and the exclusion of tramp metal.

For spray and fluidized bed drying, the hazard is charging of metal parts and of the powder, and sparking. The high-speed movement and the very dry atmosphere are conducive to high charge generation. Precautions include grounding and inerting.

For ventilation, extraction and dust aspiration systems, the hazard is charging of dust deposits and sparking. Precautions are the use of grounded metal rather than plastic ducting, the avoidance of sections of plastic duct or, if this is unavoidable, the use of bridging connections across such sections.

16.8 Electrical Equipment

Electrical equipment is widely used in process plant and may be a source of ignition unless close control is exercised.

In the United Kingdom the relevant legislation is as follows. For the premises to which it applies, the Factories Act 1961, Section 31, deals with hazard from flammable and explosive materials, but the main statutory requirements governing electrical apparatus are those given in the Electricity at Work Regulations 1989, which apply to all places of work. Regulation 6, on adverse or hazardous environments, states that:

> Electrical equipment which may reasonably/foreseeably be exposed to – (a) mechanical damage; (b) the effects of weather, natural hazards, temperature or pressure; (c) the effects of wet, dirty, dusty or corrosive conditions; or (d) any flammable or explosive substance, including dusts, vapors or gases, shall be of such construction or as necessary protected as to prevent, so far as is reasonably practicable, danger arising from such exposure.

In addition, the Highly Flammable Liquids and Liquefied Petroleum Gases Regulations 1972 state in Regulation 9.1: 'No means likely to ignite vapor from highly flammable liquids shall be present when a dangerous concentration of vapors from highly flammable liquids may be reasonably expected to be present.' In general, these regulations apply to premises where the Factories Act applies. A highly flammable liquid is one that has a flashpoint below 32°C and supports combustion under specified test conditions.

The Petroleum (Consolidation) Act 1928 is also relevant in cases where petroleum spirit and certain other materials are kept.

The use of electrical apparatus in flammable atmospheres is a topic in which there is active development of standards and codes of practice. In consequence, there is a continuously changing situation and a rather large number of codes, which may contain contradictory provisions.

Some important British Standards on electrical protection are given in Table 16.42.

The relations between these standards are as follows. BS 5345: 1977– gives the overall philosophy of the use of electrical apparatus in flammable atmospheres. It supersedes the older code BS CP 1003: 1964–, which is obsolescent and is retained only for use with existing plants. BS 5345: Part 1 covers general recommendations and Part 2 covers hazardous area classification.

The principles and specific methods of safeguarding are dealt with in BS 4683: 1971–BS 5501: 1977– and BS 5345: Parts 3–8.

There are several other relevant UK codes. Of particular importance are the Institute of Petroleum (IP) *Area Classification Code for Petroleum Installations* (the IP *Area Classification Code*) (1990 MCSP Pt 15) and the *Electrical Safety Code* (1991 MCSP Pt 1). Another, older code is the ICI *Electrical Installations in Flammable Atmospheres Code* (the ICI *Electrical Installations Code*) (ICI/RoSPA 1972 IS/91).

US codes include NFPA 70: 2002 *National Electrical Code* and API RP 540: 1991 *Recommended Practice for Electrical Installations in Petroleum Processing Plants*.

The international standard in this field is the International Electrotechnical Commission (IEC) *Publication 79, Electrical Apparatus for Explosive Gas Atmospheres*.

Codes and standards for HAC, as distinct from safeguarding, are given in the next section.

Organizations in the UK, which are engaged in work in this field, include the Electrical Research Association (ERA) and the Electrical Equipment Certification Service (EECS).

16.8.1 Hazardous area classification

The basis for the control of electrical equipment to prevent its acting as a source of ignition is the classification of plant according to the degree of hazard. Originally this procedure was commonly termed the 'electrical area classification', but it is now known by the more comprehensive term HAC, or classification of hazardous locations (CHL).

The definitions originally used in the United Kingdom for area classification and given in BS CP 1003: 1964– are based on divisions:

Division 0	An area or enclosed space within which any flammable or explosive substance, whether gas, vapour or volatile liquid, is continuously present in a concentration within the lower and upper limits of flammability.
Division 1	An area within which any flammable or explosive substance, whether gas, vapour or volatile liquid, is processed, handled or stored, and where during normal operations an explosive or ignitable concentration is likely to occur in sufficient quantity to produce a hazard.
Division 2	An area within which any flammable or explosive substance, whether gas, vapour or volatile liquid, although processed or stored, is so well under control that the production (or release) of an explosive or ignitable concentration in sufficient quantity to constitute a hazard is only likely to occur under abnormal conditions.

These definitions have been replaced in BS 5501: Part 1: 1977 and BS 5345: Part 1: 1989 with the international definitions of the IEC which are in terms of zones:

Zone 0	A zone in which an explosive gas air mixture is continuously present or present for long periods.
Zone 1	A zone in which an explosive gas–air mixture is likely to occur in normal operation.
Zone 2	A zone in which an explosive gas–air mixture is not likely to occur in normal operation and if it occurs will only exist for a short time.
Non-hazardous	An area in which an explosive gas–air mixture is not expected to be present in quantities such as to require special precautions for the construction and use of electrical apparatus.

The IP *Area Classification Code* also makes use of the following fluid categories:

Fluid Category A	A flammable liquid that, on release, would vaporize rapidly and substantially.
Fluid Category B	A flammable liquid, not in Category A, but at a temperature sufficient for boiling to occur on release.
Fluid Category C	A flammable liquid, not in Categories A and B, but which can, on release, be at a temperature above its flashpoint, or form a flammable mist.
Fluid Category G	A flammable gas or vaopur.

The code gives further guidance on assignment to Category A.

Table 16.42 *Selected British Standards on electrical protection*

Standard	Part	Title
BS CP 1003: 1964–		Electrical apparatus and associated equipment for use in explosive atmospheres of gas or vapour other than mining applications (obsolescent)[a]
	Part 1: 1964	Choice, installation and maintenance of flameproof equipment and intrinsically-safe equipment
	Part 2: 1966	Methods of meeting the explosion hazard other than by use of flameproof or intrinsically-safe equipment
	Part 3: 1967	Division 2 areas
BS 5345: 1977–		Code of practice for the selection, installation and maintenance of electrical apparatus for use in potentially explosive atmospheres (other than mining applications or explosive processing and manufacture)
	Part 1: 1989	General recommendations
	Part 2: 1983	Classification of hazardous areas
	Part 3: 1979	Installation and maintenance requirements for electrical apparatus with type of protection 'd'. Flameproof enclosure
	Part 4: 1977	Installation and maintenance requirements for electrical apparatus with type of protection 'i'. Intrinsically safe electrical apparatus and systems
	Part 5: 1983	Installation and maintenance requirements for electrical apparatus protected by pressurization 'p' and by continuous dilution, and for pressurized rooms
	Part 6: 1978	Recommendations for type of protection 'e'. Increased safety
	Part 7: 1979	Installation and maintenance requirements for electrical apparatus with type of protection N
	Part 8: 1979	Installation and maintenance requirements for electrical apparatus with type of protection 's'. Special protection
BS 229: 1957		Specification. Flameproof enclosure of electrical apparatus (obsolescent)
BS 4137: 1967		Guide to the selection of electrical equipment for use in Division 2 areas (obsolescent)
BS 1259: 1958		Intrinsically safe electrical apparatus and circuits for use in explosive atmospheres (obsolescent)
BS CP 1013: 1965		Grounding
BS 4683: 1971–		Specification for electrical apparatus for explosive atmospheres
	Part 1: 1971	Classification of maximum surface temperatures
	Part 2: 1971	The construction and testing of flameproof enclosures of electrical apparatus
	Part 3: 1972	Type of protection N (withdrawn)
	Part 4: 1973	Type of protection 'e' (obsolescent)
BS 5501: 1977		Electrical apparatus for potentially explosive atmospheres
	Part 1: 1977	General requirements
	Part 2: 1977	Oil immersion 'o'
	Part 3: 1977	Pressurized apparatus 'p'
	Part 4: 1977	Powder filling 'q'
	Part 5: 1977	Flameproof enclosure 'd'
	Part 6: 1977	Increased safety 'e'
	Part 7: 1977	Intrinsic safety 'i'
	Part 8: 1988	Encapsulation 'm'
	Part 9: 1982	Specification for intrinsically safe electrical systems 'i'
BS 6941: 1988		Specification for electrical apparatus for explosive atmospheres with type of protection N

[a] Obsolescent. Replaced by BS 5345:1977–, but retained temporarily as a reference guide for existing plants.
[b] Obsolescent.

In the USA, NFPA 70: 2002 gives in Article 500 the following classification of hazardous locations:

Class I	in which the combustible material is a gas or vapour.
Class II	in which the combustible material is a dust.
Class III	in which the combustible material is a fibre or flying material.

Each class is divided into Division 1 and Division 2, the distinction between the two being based on the frequency with which the substance may be present in the atmosphere.

The CHLs given in API RP 500: 1991 is essentially the same as that in NFPA 70, but with some change of wording:

Class I	A location in which flammable gases or vapours are, or may be, present in the air in quantities sufficient to produce explosive or ignitable mixtures.
Division 1	A location is a location (1) in which ignitable concentration of flammable gases or vapours exist under normal operating conditions; (2) in which ignitable concentrations of such gases or vapours may exist frequently because of repair or maintenance operations or leakage; or (3) in which breakdown or faulty operation of equipment or processes might release ignitable concentrations of flammable gases or vapours, *and* might also cause simultaneous failure of

electrical equipment that could become a source of ignition. Division 2 location is a location (1) in which volatile flammable liquids or flammable gases are handled, processed or used, but in which the liquids, vapours or gases normally will be confined within closed containers or closed systems from which they escape only in case of accidental rupture or breakdown of such containers or systems, or in case of abnormal operation of equipment; (2) in which ignitable concentrations of gases and vapours normally are prevented by positive ventilation, and that might become ignitable through failure or abnormal operation of the ventilating equipment; or (3) that are adjacent to a Class I, Division 1 location (and not separated by a tight–tight barrier), and to which ignitable concentrations of gases or vapours might occasionally be communicated unless such communication is prevented by adequate positive-pressure ventilation from a source of clean air, and effective safeguards against ventilation failure are provided.

NFPA 497 M: 1997 gives a grouping of atmospheric mixtures. API RP 500 gives the following partial listing:

Group A	Atmospheres containing acetylene.
Group B	Atmospheres such as butadiene, EO, propylene oxide, acrolein, or hydrogen (or gases or vapours equivalent in hazard to hydrogen, such as certain manufactured gases).
Group C	Atmospheres such as cyclopropane, ethyl ether, ethylene, hydrogen sulfide or gases or vapours of equivalent hazard.
Group D	Atmospheres such as acetone, alcohol, ammonia, benzene, butane, gasoline, hexane, lacquer solvent vapours, methane, naphtha, natural gas, propane or gases or vapours of equivalent hazard.

16.8.2 Safeguarding of equipment

There are a number of methods available for the safeguarding of electrical equipment so that it is suitable for use in a hazardous area, but it is a fundamental principle that electrical equipment should not be located in a hazardous area if it is practical to site it elsewhere. The methods of safeguarding traditionally used in the United Kingdom are listed in the ICI *Electrical Installations Code* as:

(1) segregation;
(2) flameproof enclosures;
(3) intrinsically safe systems;
(4) approved apparatus and apparatus with type of protection 's';
(5) pressurizing and purging;
(6) apparatus with type of protection 'N';
(7) Division 2 approved apparatus;
(8) apparatus with type of protection 'e';
(9) non-sparking apparatus and totally enclosed apparatus;
(10) apparatus for use in dust risks.

The *Code* discusses these methods and their application.

Reference is made to normally sparking, non-sparking and totally enclosed apparatus. The ICI *Code* describes these as follows. Normally sparking apparatus is that which in normal operation produces sparks, arcs or surface temperatures capable of igniting the flammable atmosphere. Non-sparking apparatus is that which in normal operation does not produce such sources of ignition, although it may do so as a result of electrical or mechanical failure. It includes Division 2 approved apparatus and apparatus with type of protection N. Examples of non-sparking apparatus include cage motors and solenoid valves.

Totally enclosed apparatus is that contained in an enclosure, which renders the risk of entry of a flammable atmosphere small. Total enclosure is applied to lamp fittings. It may also be applied to non-sparking apparatus as an additional safeguard. An example of the latter is a totally enclosed cage motor.

The principle of segregation is the use of a fire-resistant impermeable barrier to create a lower risk zone or non-hazardous area where electrical equipment suitable for a lower classification can be used. An example is the use of a non-sparking motor in a Zone 2 area to drive a pump in a Zone 1 area, the two machines being connected by a shaft that passes through a gas-tight gland in a wall separating the two zones.

The methods of protection given above are now supplemented by a number of newer methods.

The British Standards governing safeguarding of electrical apparatus are principally BS 4683: 1971–, BS 5501: 1977– and BS 5345: Part 1: 1989. BS 229: 1957 also applies, but is obsolescent.

The certification of equipment is performed by the EECS. This body is the successor to the former British Approvals Service for Electrical Equipment in Flammable Atmospheres (BASEEFA). Guidance on the system operated by the EECS is given in EECG2 *Electrical Equipment Certification Guide* (1992). The EECS inherited from BASEEFA a system of SFA standards. As far as concerns the 'types of protection' described below, this system is now essentially obsolete, although some limited use is made of SFA 3009 for special protection 's' and of SFA 3102 for intrinsic safety 'i'.

The overall procedure for selecting electrical apparatus for flammable atmospheres is described in BS 5345: Part 1: 1989. The selection is made by establishing the zone type in which the apparatus is to be used and then selecting the appropriate apparatus on the basis of:

(1) temperature classification;
(2) apparatus group;
(3) environmental conditions.

There is a maximum surface temperature of the equipment, which should not be exceeded. This corresponds to the ignition temperature of the gases or vapours involved. The relation between the apparatus Class T and the maximum surface temperature are given in BS 5345: Part 1: 1989 as follows:

Class	*Maximum surface temperature* (°C)
T1	450
T2	300
T3	200
T4	135
T5	100
T6	85

Apparatus is grouped according to the properties of the gases or vapours involved. BS 5345: Part 1: 1989 divides apparatus into: Group I, apparatus for mines susceptible to firedamp; and Group II, apparatus for places with potentially explosive atmosphere, other than mines susceptible to firedamp. In the present context it is only Group II that is of interest. This is itself is divided into subgroups.

BS 5345: Part 1: 1989 lists the following relationships between representative gases and the group and subgroup classifications:

Representative gas	BS 55 01[a]	BS 4683	BS 229	BS 1259
Methane	I[b]	I[b]	I	1
Propane	IIA	IIA	II	2c
Ethylene	IIB	IIB	II	2d
Hydrogen	IIC	IIC	IV	2e
Acetylene	IIC	Not allocated	IV	2f
Carbon disulfide	IIC	Not allocated	IV	2f

[a] Reference is to the then current edition of these standards.

[b] For underground mining applications.

For BS 229 the entries refer to the former gas groups and for BS 1259 to the former apparatus class.

BS 5345: Part 1: 1989 gives data on the flammability characteristics of the common industrial gases. Most gases and vapours are classified in BS 5345: Part 1 as Group IIA.

The allocation to apparatus subgroup in BS 5345: Part 1: 1989 is on the basis of the MESG and/or minimum igniting current (MIC).

These apparatus groups and subgroups and the method of allocation follow broadly that given in BS 5501: Part 1: 1977. For flameproof enclosures the criterion is the MESG, which is related to the subdivision as follows:

	MESG (mm)
Subdivision A	>0.9
Subdivision B	0.5–0.9
Subdivision C	<0.5

The MESG was described in Section 16.2. For intrinsically safe apparatus the criterion is the MIC ratio, which is related to the subdivision as follows:

	MIC
Subdivision A	>0.8
Subdivision B	0.45–0.8
Subdivision C	<0.45

The MIC is the ratio of the MIC for the gas or vapour to that for laboratory methane. A gas or vapour is assigned to a subdivision on the basis either of its MESG, of its MIC ratio, or both.

The methods of safeguarding recognized in BS 5345: Part 1: 1989 are shown in Table 16.43, which gives the definitions for each type of protection and cross-references to other standards. Similar, but in some cases not identical definitions, are given in BS 4683: 1971– and BS 5501: 1977.

Type of protection 'd' is a flameproof enclosure. The principle of a flameproof enclosure is that an explosion may occur in the enclosure, but a flame does not then travel back through any opening. There are maximum permissible dimensions for an opening in a flameproof enclosure. The opening needs to be of sufficient length and construction to prevent the passage of flame. MESGs were discussed in Section 16.2. The equipment should be sufficiently robust to withstand an occasional explosion without distorting, otherwise the dimensions of the gap may increase above the safe level. Alteration of the internals of a flameproof enclosure is not allowed because of the possible hazard of pressure piling.

Where a flameproof enclosure is exposed to wet weather it should be weatherproof. Weatherproofing is normally effected by the use of gasketed joints additional to and separate from the flame paths. For other apparatus suitable grease or tape is usually used. Protection against corrosion is also necessary in some applications.

Flameproof enclosures are classified by T Class and by apparatus subgroup. The main example of flameproof enclosures is the casing of flameproof electric motors.

Type of protection 'i' is intrinsically safe apparatus or system. The principle of intrinsic safety is that there is insufficient energy in the system to given incendive sparking or heating effects.

Two categories of intrinsically safe system are recognized in BS 5345: Part 4: 1977– ia, suitable for use in hazardous areas including Zone 0; and ib, suitable for use in hazardous areas excluding Zone 0.

In an intrinsically safe system it is necessary to take precautions to ensure that the power source of the system cannot release unsafe amounts of energy in the hazardous area and also that power from other sources cannot invade the system. There are thus requirements for insulation, grounding, screening, etc.

There are two main types of intrinsically safe system. One has some parts in the hazardous area, but the power supply is in the non-hazardous area. With this method it is necessary not only that the equipments in both areas be intrinsically safe but also that they be matched so that the system also is intrinsically safe. The power supply should be such as not to overload the current-limiting devices. Where the power supply is from the mains, it is usually necessary to use an inviolate transformer. Current limitation is then effected by inviolate resistors. Alternatively, barrier units may be used to limit both voltage and current.

The other system has all parts in the hazardous area and has its own power supply such as a battery. This type of system may be a fixed installation or a portable apparatus. In the former case it should again be intrinsically safe as a system.

It is particularly important with an intrinsically safe system that the system is not used outside the scope of the certification. Intrinsically safe systems are classified by T Class and by apparatus subgroup.

Since the minimum ignition energy of flammable mixtures is very small, this method of safeguarding is applicable only to low power systems, in particular instrumentation. Examples of intrinsically safe systems include instrument systems and portable gas detectors. Further information is given in *Intrinsic Safety* by Redding (1971a).

Table 16.43 *Types of electrical protection in BS 5345: 1989 (Reproduced by permission of the British Standards Institution)*

Type of protection	*Title*	*Description*
d	Flameproof enclosure	A method of protection where the enclosure for electrical apparatus will withstand an internal explosion of the flammable gas or vapour (for which it is designed) that may enter it, without suffering damage and without communicating the internal flame to the explosive atmosphere for which it is designed, through any joints or structural openings in the enclosure
i	Intrinsically safe apparatus or system	A protection technique based upon the restriction of electrical energy within apparatus and in the interconnecting wiring, exposed to a potentially explosive atmosphere, to a level below that which can cause ignition by either sparking or heating effects. Because of the method by which intrinsic safety is achieved it is necessary that not only the electrical apparatus exposed to the potentially explosive atmosphere, but also other (associated) electrical apparatus with which it is interconnected, is suitably constructed.
p	Pressurization, continuous dilution and pressurized rooms	A method of protection using the pressure of a protective gas to prevent the ingress of an explosive atmosphere to a space that may contain a source of ignition and, where necessary, using continuous dilution of an atmosphere within a space that contains a source of emission of gas, which may form an explosive atmosphere
e	Increased safety	A method of protection by which additional measures are applied to an electrical apparatus to give increased security against the possibility of excessive temperatures and of the occurrence of arcs and sparks during the service life of the apparatus. It applies only to an electrical apparatus, no parts of which produce sparks or arcs or exceed the limiting temperature[a] in normal service
N	Type of protection N	A type of protection applied to an electrical apparatus such that, in normal operation, it is not capable of igniting a surrounding explosive atmosphere, and a fault capable of causing ignition is not likely to occur
s	Special protection	A concept for those types of electrical apparatus that, by their nature, do not comply with the constructional or other requirements specified for apparatus with established types of protection, but that nevertheless can be shown, where necessary by test, to be suitable for use in hazardous areas in prescribed zones
o	Oil immersion	A method of protection where electrical apparatus is made safe by oil immersion in the sense that an explosive atmosphere above the oil or outside the enclosure will not be ignited
q	Powder/sand filling	A method of protection where the enclosure of electrical apparatus is filled with a mass of granular material such that, if an arc occurs, the arc will not be liable to ignite the outer flammable atmosphere
m	Encapsulation	A type of protection in which parts that could ignite an explosive atmosphere by either sparking or heating are enclosed in a compound in such a way that this explosive atmosphere cannot be ignited

[a] Limiting temperature is defined in BS 5345: Part 6: 1976.

Type of protection ‘p’ is pressurization, continuous dilution and purging. Pressurizing and purging are used to control the atmosphere in a room or apparatus. Such control allows the safe use of electrical apparatus which otherwise would be hazardous.

In pressurizing, a positive pressure of air or inert gas is maintained in the enclosure so that the flammable material cannot enter. In purging, a flow of air or inert gas is maintained through the enclosure so that a flammable atmosphere does not form. Sometimes a combination of pressurization and purging may be employed.

Mechanical ventilation may be used for pressurization and purging. In the latter case the ventilation may be a forced or induced draught. Alternatively, an air or gas supply may be used.

Air is a suitable pressurizing medium and is generally preferable to inert gas, because it does not constitute an asphyxiation hazard. For purging, inert gas provides a higher degree of protection against flammability hazard and is suitable for small enclosures, but air is preferable for large enclosures and rooms on account of the asphyxiation hazard. The source of air or inert gas should be free of flammables and should be reliable. It may be necessary to clean and/or dry the air or inert gas.

It is recommended in BS 5501: Part 3: 1977 that the minimum overpressure in a pressurized enclosure should be 0.5 m bar.

The ICI *Code* states that pressurizing is not suitable for Zone 0. For Zone 1 with normally sparking apparatus there should be a pressure failure interlock and alarm. The interlock should disconnect the electrical supply on failure of pressure, except where this could create a hazardous condition, in which case other precautions are necessary. For Zone 1 with non-sparking apparatus and for Zone 2 with normally sparking apparatus there should be a pressure alarm. The action to be taken on failure of purging requires consideration of the particular circumstances.

Further details of pressurizing and purging, including monitoring systems, room and enclosure design, piping and ducting design and auxiliary apparatus are given in BS 5345: Part 5: 1983 and in the ICI *Code*.

> Examples of enclosures, which may be pressurized with air or inert gas, are a totally enclosed motor and an instrument cubicle. Also a control room is often fitted with double doors, forming an air lock, and pressurized with air. Examples of enclosures that may be purged or pressurized/purged are rooms or instrument cubicles containing instruments analyzing flammable gas.

Type of protection N is defined in terms of the degree of protection achieved rather than of the particular means by which this is done. The general characteristics of such apparatus are that under normal operation it does not produce an arc or spark except where the latter occurs in an enclosed break device, has insufficient energy to cause ignition of a flammable atmosphere or occurs in a hermetically sealed device and does not develop a surface temperature capable of igniting a flammable atmosphere.

Apparatus with type of protection N complies with another British Standard that specifies this type of protection, e.g. BS 5000: Part 16: 1985 for motors.

Guidance on the construction and testing for type of protection N is given in BS 6981: 1988.

Before the introduction of type of protection N, apparatus could be submitted to HM Factories Inspectorate (HMFI) for approval for use in Division 2 applications, the basis of examination being BS 4137: 1967 *Guide to the Selection of Electrical Equipment for Use in Division 2 Areas*. If an apparatus was considered suitable for use in a Division 2 area, HMFI issued a letter to this effect and the apparatus was then commonly referred to as 'Division 2 approved'.

Type of protection 'e' is again defined in terms of the degree of protection achieved. It has features in common with type of protection N, but is more stringent. Apparatus with type of protection 'e' complies with BS 5501: Part 6: 1977.

Special protection 's' deals with 'approved' apparatus. This is equipment for which there is no specific British Standard. It is covered instead by the approval system.

'Approved' apparatus is that which has been approved for use in flammable atmospheres by HMFI. This approval system operated up to 1969, the list of approved equipment being given in HMSO *Form F931 Intrinsically Safe and 'Approved' Electrical Apparatus*. This was subsequently superseded by certification as special protection 's' in accordance first with BASEEFA *Certification Standard SFA 3009* and then with the EECS certification system. Apparatus with type of protection 's' is classified by T Class and by apparatus subgroup. Examples of approved equipment include compressed air-driven generator and lamp sets, and battery handlamps.

Before the introduction of 'Division 2 approved' apparatus and apparatus with type of protection N, use was made in Division 2 areas of non-sparking apparatus and of totally enclosed apparatus.

There are three other types of protection recognized in BS 5345: Part 1: 1989. These are oil immersion V, powder/sand filling 'q' and encapsulation 'm'. Compounds used for encapsulation include thermosetting, thermoplastic and elastomeric compounds.

There is much less guidance on dust risks, but some is given in the ICI *Code*. For dusts the most widely used method of safeguarding is a combination of (1) enclosure of apparatus and (2) elimination of hot surfaces.

The apparatus is enclosed so as to limit the amount of dust that can come in contact with sources of ignition and it is designed so that in normal operation its surface temperature does not exceed the ignition temperature of the dust in cloud or layer form. Other methods that may be used with dust risks include segregation, intrinsically safe systems and pressurizing or purging.

There are certain general precautions that should be taken with all the methods of safeguarding described. Apparatus should be used only for the purpose for which it has been designed and certified. It should not be altered by modification. It should not be allowed to deteriorate due to weather or corrosion. It should be properly maintained.

BS 5345: Part 1: 1989 gives a scheme for the selection of apparatus and systems, as shown in Table 16.44. Intrinsic safety is applied in all zones, but the type used should be suitable for the zone. The same applies to special protection 's'. The principal application of flameproof enclosures is in Zone 1. Pressurization and purging is applicable in Zones 1 and 2. Of the methods involving enhanced safety, type of protection 'e' is suitable for Zones 1 and 2, while type of protection N is suitable for Zone 2.

Other aspects of electrical systems in flammable atmospheres include: the installation of electrical equipment, particularly cabling; the inspection and maintenance of equipment; and electronic instrumentation. These are treated in detail in BS 4683: 1971–, BS 5501: 1977 and the ICI *Code*.

16.8.3 Electrical surface heating

The methods of safeguarding described above have been developed primarily for equipment such as electric motors and electronic instruments in which heating is undesirable. Their application to apparatus the prime purpose of which is heating requires separate treatment.

Electrical surface heating (ESH) is widely used in process plants and constitutes another potential source of ignition.

Types of heater used include (1) flexible heaters (fabric, braid, mesh), (2) heating cable, (3) panel heaters and (4) parallel circuitry heaters. The latter are often purpose made and may be in panel, mantle or jacket form.

An account of the design of electrical surface heaters for use in hazardous areas has been given by Dobie, Cunningham and Reid (1976). Their approach to safeguarding is to design the apparatus so that for a given workpiece surface temperature (e.g. pipe temperature) the maximum linear

***Table 16.44** Selection of methods of safeguarding electric apparatus in hazardous areas in BS 5345: 1989 (Reproduced by permission of the British Standards Institution)*

Zone	*Type of protection*		*Part of BS 5345*
0	'ia'	Intrinsically safe apparatus or system	4
	's'	Special protection (specifically certified for use in Zone 0)	8
1	Any explosion protection suitable for Zone 0 and:		
	'd'	Flammable enclosure	3
	'ib'	Intrinsically safe apparatus or system	4
	'p'	Pressurization, continuous dilution and pressurized rooms	5
	'e'	Increased safety	6
	's'	Special protection	8
2	Any explosion protection suitable for Zones 0 or 1 and:		
	N[a]	Type of protection N[b]	7
	'o'	Oil-immersion	9[c]
	'q'	Sandfilling[d]	9[c]

[a] Alternatively, apparatus that in normal operation is not capable of producing ignition capable arcs, sparks or surface temperatures may also be acceptable for use in Zone 2 where it has been assessed by persons who should:

(a) be familiar with the requirements of any relevant standards and codes of practice and their current interpretations;
(b) have access to all information necessary to carry out the assessment;
(c) where necessary, utilize similar test apparatus and test procedures to those used by recognized testing stations.

[b] Whereas in BS 6941 the type of protection is known as type N, in IEC publication 79 15 it is designated type 'n';

[c] In preparation.

[d] The use of apparatus with type of protection 'q' in Zone 1 is under consideration.

power loading (W/m) cannot give an element surface temperature in excess of the ignition temperature of the flammable atmospheres as given in BS 4683: Part 1: 1971. The equipment is also designed so as not to give rise to hazards from arcs and sparks.

Guidance on EHS devices, including their use in hazardous areas, is given in BS 6351 *Electrical Surface Heating*, of which Part 1: 1983 deals with specification, Part 2: 1983 deals with design and Part 3: 1983 deals with installation, testing and maintenance. Part 1 requires that an ESH device for use in a hazardous area should *inter alia:* (1) comply with type of protection 'e', N, 'd', 's', 'm' or 'p'; (2) be assigned a temperature classification; (3) be given a type test to establish the maximum surface temperature; and (4) comply with respect to the terminations and markings with specified in British Standards. Procedures are given for type testing, a distinction being made between ESH devices that have self-limiting characteristics and those that do not.

BS 6351: Part 2: 1983 sets certain minimum safety requirements for all ESH devices. It gives a system of service categories with a two-digit code, the first digit indicating the probability of the presence of water and the second the risk of mechanical damage. 0 denotes no risk, 1 low risk and 2 high risk: thus, for example, a coding of 00 denotes no risk in both categories and one of 22 high risk in both categories. The principal requirements referred to are (1) overcurrent protection, (2) residual current protection with trip indication, (3) means of isolation and (4) overtemperature limitation. Overcurrent protection and means of isolation are required for all ESH devices. For types of protection N and 'e' all four requirements apply.

Part 3 states isolation and permit-to-work requirements.

Further recommendations for ESH are given in the ICI *Electrical Installations Code*.

16.9 Hazardous Area Classification

The exclusion of sources of ignition is effected on process plant by a system of HAC. The principles of HAC have been outlined in Chapter 10 in relation to plant layout. In this section consideration is given to the application of these principles.

Hazardous area classification is the subject of a number of codes and standards. These include BS 5345 *Code of Practice for the Selection, Installation and Maintenance of Apparatus for Use in Potentially Explosive Atmospheres (Other than Mining Applications or Explosive Processing and Manufacture)*, including Part 1: 1989 *General Recommendations* and, in particular, Part 2: 1983 (1990) *Classification of Hazardous Areas*. Other relevant British Standards have been given in Section 16.8. Influential codes have been those of the successive IP codes and the ICI *Electrical Installations in Flammable Atmospheres Code* (the ICI *Electrical Installations Code*) (ICI/RoSPA 1972 IS/91). The current IP code is *Area Classification Code for Petroleum Installations* (the IP *Area Classification Code*) (1990 MCSP 15).

In the USA, NFPA codes include NFPA 70: 2002 *National Electrical Code*, NFPA 497: 1997 *Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas*. API RP 500: 1991 *Recommended Practice for Classification of Locations for Electrical Installations at Petroleum Facilities* consolidates previous separate codes (RP 500A, 500B and 500C).

Other accounts of HAC include *Classification of Hazardous Locations* (A.W. Cox, Lees and Ang, 1990) and those by Swann (1957, 1959), Levine (1965a,b, 1968a,b, 1972a, 1983), Magison (1966, 1975, 1978), Burgoyne (1967b, 1969, 1971), Bartels (1971a, 1975a,c, 1977−), O'Shea (1982), Palles-Clark (1982), Peck and Palles-Clark (1982), Fordham Cooper (1986) and Mecklenburgh (1986).

Electrical safety and HAC has been the subject of a series of symposia by the IEE (1971, 1975, 1982, 1988 Conf. Publs 74, 134, 218 and 296, respectively; 1982 Coll. Dig 82/26).

Traditionally, HAC has centred around electrical equipment and has been the province of electrical engineers. Electric motors, instruments and other electrical equipment have to be present on plant, but may constitute potential sources of ignition. It is necessary, therefore, to assess the ignition risk and to match the equipment to it. This has been done by a system of area classification.

As already described, however, there are many other potential ignition sources on plant and a more balanced approach is called for. The modern approach to HAC involves the control of all sources of ignition and deals not only with design but also with activities such as operation and maintenance. There is a tendency for chemical engineers to be much more involved.

16.9.1 Hazardous area classification systems

The HAC system currently applicable in the United Kingdom is that of the IEC and is outlined in Chapter 10 and in Section 16.8 where accounts are given of the system of zones used (Zone 0, Zone 1 and Zone 2) together with definitions of these zones.

In the United States, two principal systems are those of the NFPA and the API, which are also described in Section 16.8.

16.9.2 ICI Electrical Installations Code

The ICI *Electrical Installations in Flammable Atmospheres Code* (the ICI *Electrical Installations Code*) (ICI/RoSPA 1972 IS/91) describes the two basic methods of HAC: (1) the generalized method and (2) the source of hazard method. It remains a principal guide for the latter. Classification of electrical areas is not an exact science and inevitably involves a degree of judgment. There are, however, a number of guidelines available.

The terms 'normal' and 'abnormal' require some interpretation. Normal conditions should be taken to be not ideal but real conditions as they actually exist, taking into account the precautions that are taken on a well-run plant. Abnormal conditions should be read to refer not to catastrophic accidents such as a major equipment rupture but to events that are generally non-catastrophic such as a pump gland or pipe gasket failure.

The stages of the classification process are (1) identification of the hazard, (2) assessment of the hazard, and (3) delineation of the zone. The classification should be comprehensive. An area where flammable materials are not to be handled is non-hazardous, but this status should be formally established.

A basic distinction is between (1) well-ventilated locations and (2) poorly ventilated locations. Ventilation is here interpreted in a broad sense and covers the whole question of the dispersion of vapours and liquids from leaks and spillages. Thus it is necessary to consider how much flammable material may escape, whether an escape is continuous or not, whether it is lighter or heavier than air, whether there may be jet effects, whether the liquid may travel outside the area on the surface of water on the ground or in drains or pipe trenches, and what the influence of the plant topography is.

There are two basic approaches to area classification. These are (1) the generalized method and (2) the source of hazard method. The generalized method is the older and involves making a judgment on the appropriate classification for a fairly large area of plant.

The ICI *Code* gives guidance for both the generalized and source of hazard methods. For the former a Zone 0 classification is necessary for locations such as vapour spaces in closed storage tanks or closed process vessels in which a flammable atmosphere may exist continuously or for long periods and immediately above an open tank or vessel containing a flammable liquid. Locations where in normal operation there may be release of flammable materials sufficient to cause a hazard either from relief valves or vents designed to make such release or from other sources such as vessels, pumps or pipes, should be classified as Zone 1. Classification as Zone 2 is acceptable provided that there are no releases in normal operation of flammable materials sufficient to cause a hazard, that relief valves and vents release flammable materials only under abnormal conditions and that the area is well drained and ventilated so that any abnormal occurrence of a flammable atmosphere is rapidly dispersed.

The *Code* states that it is characteristic of the generalized method that it gives a large Zone 1. The typical pattern is as follows. An area somewhat larger than that occupied by the process equipment is classified as either Zone 1 or Zone 2. If it is Zone 1, it may or may not be surrounded by a Zone 2. There may be isolated Zones 0 within a Zone 1 or a Zone 2.

While this blanket application of a Zone 1 classification is in itself conservative, it is also expensive, and there may be a tendency, which should be guarded against, to ignore a few high hazard points and classify as Zone 2 an area that should be Zone 1.

The source of hazard method is the newer approach and involves identifying, assessing and delineating affected areas for individual sources of hazard. The latter are classified according to the expected frequency and period of release of flammable materials. The classification together with the suggested quantitative guidelines is as tabulated below:

Source of hazard	*Period of release*	*Frequency* (hazards/year)
0 (Continuous)	Long periods	>1000
1 (Primary)	Frequent or if infrequent persistent	10–1000
2 (Secondary)	Infrequent and of short duration	<10

The characteristic area classification yielded by the source of hazard method is predominantly Zone 2 with small isolated Zones 1. Zones 0 may also occur in either Zones 1 or Zones 2.

In a well-ventilated situation the extent of the zone is determined essentially in both methods by the distance at which it is judged that the flammable atmosphere will fall below its LFL.

In a poorly ventilated situation it is necessary to pay particular attention to the following aspects:

(1) sources of hazard which are continuous should be avoided or provided with special ventilation;
(2) each room in a building should be given separate consideration for possible sources of hazard;
(3) mobile sources of hazard should be taken into account;
(4) spillage hazards associated with portable or transportable vessels or open handling of liquids should be taken into account.

For a room which does not contain a source of hazard the classification depends on the probability of flammable materials entering the room and on the ventilation and may be Zone 1, Zone 2 or non-hazardous. In general, mechanical ventilation may be used as a means of modifying the classification for an enclosed space.

The extent of a zone in a poorly ventilated situation is again determined for both methods essentially by the dilution of the flammable atmosphere below its flammability limit. In confined situations, however, even the source of hazard method tends frequently to lead to Zone 1 classifications, so that there is less difference between the two methods in this case.

Some area classifications are illustrated in Figures 16.63 and 16.64. Figure 16.63(a) shows a classification for a reciprocating or centrifugal compressor handling a gas lighter than air (e.g. hydrogen or fuel gas) in a building with open sides and ventilation. There is a Zone 1 around the compressor. For a reciprocating compressor this Zone 1 is a sphere of 0.5 m radius all round the gland, cylinder, and frequently operated drain points or vents, and for a centrifugal compressor it is a sphere of 0.5 m radius all round the seal and a sphere of 1 m radius around the seal-oil tank cover and vent and around seal-oil traps. Figure 16.63(b) shows a classification for a reciprocating or centrifugal compressor handling a gas that is heavier than air (e.g. ethylene or propylene refrigerants). The Zones 1 are the same as for the previous case. Figures 16.64(a) and (b) show, respectively, classifications for a fixed roof and a floating roof storage tank for a flammable liquid with a flashpoint below 32°C.

The ICI *Code* also deals with area classification for flammable dusts. The basic principles of classification are similar to those for flammable gases and liquids, but it is recognized that the behaviour of dusts is generally rather less predictable.

The definition of the zones in the ICI *Code* includes dusts and has already been given. In this case the source of hazard method is less useful and the generalized method is usually more appropriate.

Since dust presents a hazard in layer as well as in cloud form, it is necessary, irrespective of the area classification, to ensure that any surface on which dust can settle is below the ignition temperature of the dust in layer form. In exceptional cases where a surface temperature higher than the ignition temperature of the dust is required for process reasons, the equipment should be designed and operated so as to prevent the accumulation of dust on its surface and the formation of dust clouds.

16.9.3 IP Area Classification Code

The IP *Area Classification Code for Petroleum Installations* (the IP *Area Classification Code*) (1990 MCSP Pt 15) is written for petroleum installations, but the principles are of wider applicability. The code utilizes the IP classification of fluids given in Chapter 10 and the British Standard classification of hazardous locations and IP grouping of atmospheric mixtures given in Section 16.8. The principal contents of the code are listed in Table 16.45 and its application is shown in Figure 16.65.

The code emphasizes that HAC is not intended to deal with catastrophic events, but with more commonly occurring releases. In the design of new plant, or in plant modification, HAC should be carried out before the design and layout are finalized, and reviewed again on completion of the design.

The code describes two methods of HAC: (1) the method of direct example and (2) the point source method.

Information required

The information required for the conduct of HAC includes (1) the classification of the fluid(s), (2) the flow diagram, (3) the piping and instrument diagram, (4) the plant layout, (5) the equipment features, including operation and (6) the ventilation.

Classification of petroleum fluids

Petroleum fluids are classified by flashpoint. The code gives in Appendix A details of the IP classification by flashpoint. This classification system is described in Chapter 10. Fluids are classed as Class 0 (LPG); Class I; Class 11(1) or 11(2); Class III(l) or 111(2); and Unclassified.

A further, supplementary classification by fluid category, utilized in the point source method, is given in the code in Appendix B. This categorization has been described in Section 16.8.

General approach

The general approach, described in the Chapters 1 and 2 of the IP *Code*, is to identify the sources and grades of release, and then to assign the appropriate zones. The grades of release are defined as:

Continuous grade release	A release that is continuous or nearly so, or that occurs for short periods that occur frequently
Primary grade release	A release that is likely to occur periodically or occasionally in normal operation
Secondary grade release	A release that is unlikely to occur in normal operation and, in any event, will do so only infrequently and for short periods

The grade of release reflects the frequency and duration of the release.

The *Code* gives the following rule of thumb to assist in the assignment of the grade of release. A release should be treated as continuous if it is likely to be present for more than 1000 h/year, as primary if present for more than 10 but less than 1000 h/year and as secondary if present for less than 10 h/year.

For open-air conditions, there is a direct relation between the grade of release and the type of zone to which it gives rise, the continuous grade corresponding to Zone 0, the primary grade to Zone 1 and the secondary grade to Zone 2. However, this relationship applies only where the ventilation corresponds to unrestricted open locations with good natural ventilation. Poor ventilation may require the use of a more stringent zone, while very good ventilation may allow a relaxation to a less stringent one. There are certain guiding principles that govern HAC.

Where a number of fluids are handled, as in storage and loading/unloading facilities, the classification should be based on the most volatile.

The identification of sources of continuous and primary grade releases, and the delineation of Zones 0 and 1, should be as complete as possible. Many plant areas are designated as Zone 2. Particular attention should be given to sources of secondary grade releases at the edge of the plant, since these will tend to define the extent of the Zone 2. In some cases it is not practical to determine a blanket Zone 2 and the secondary grade sources, or groups of sources, must then be addressed individually. A Zone 1 area will often be surrounded in practice by a Zone 2 area, but there is no general requirement for this. Within a hazardous area,

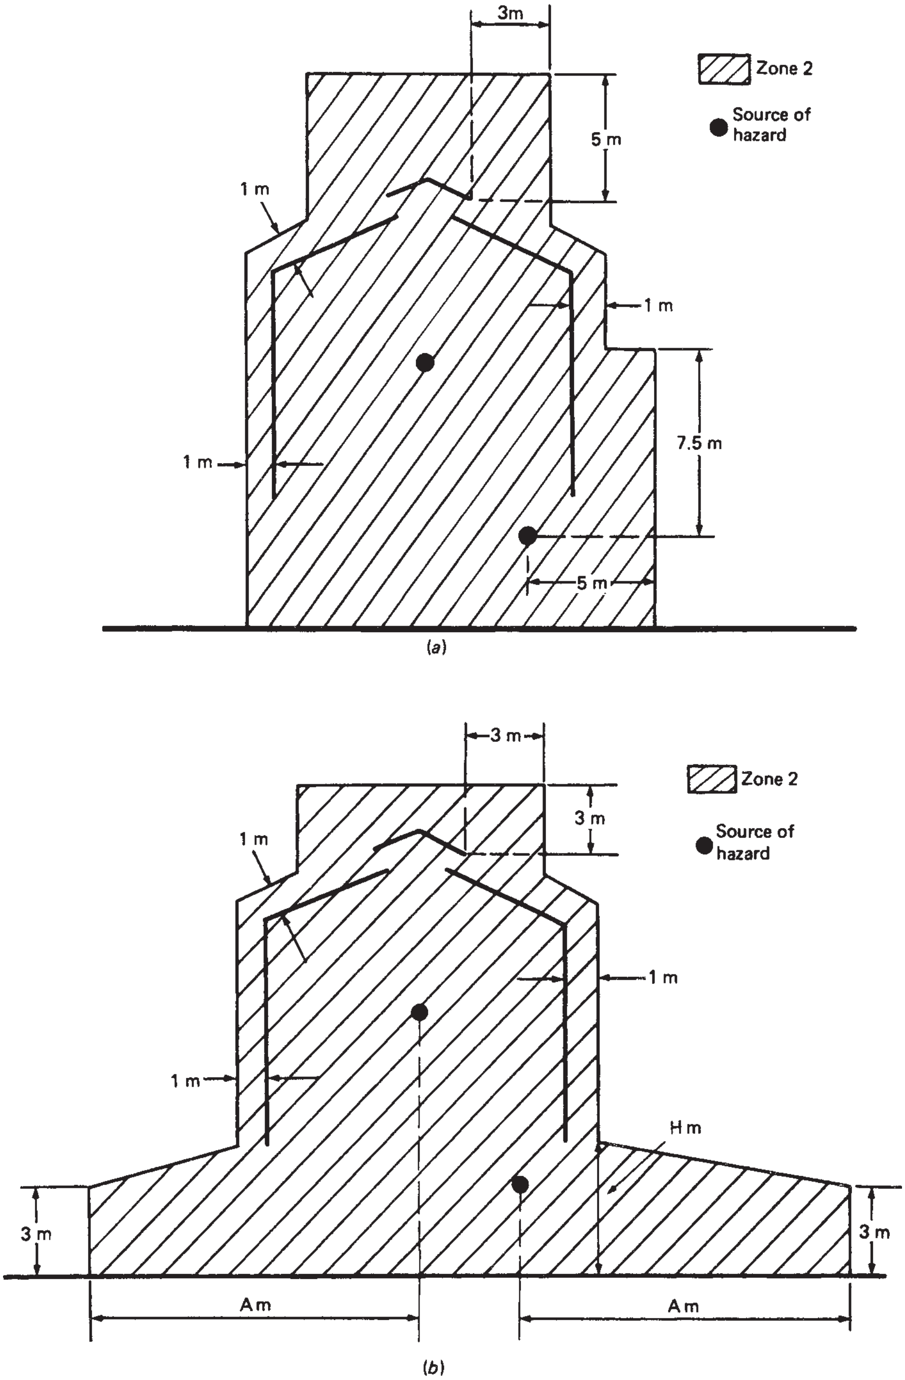

Figure 16.63 *Hazardous area classification – ICI Electrical Installations Code (Imperial Chemical Industries Ltd, ICI/RoSPA 1972 IS/91; reproduced with permission): zoning for a reciprocating or centrifugal compressor handling flammable gas in building with open sides and roof ventilation: (a) compressor handling a lighter than air gas; (b) compressor handling a heavier than air gas. Extent of Zone 2: for gases heavier than air, up to 30* bar*, up to 100*°C *(e.g. ethylene and propylene refrigerants), A is 15* m*; for supercritical ethylene, up to 100* bar*, A is 30* m*; dimension H is 3* m *or height of the wall opening, whichever is the greater*

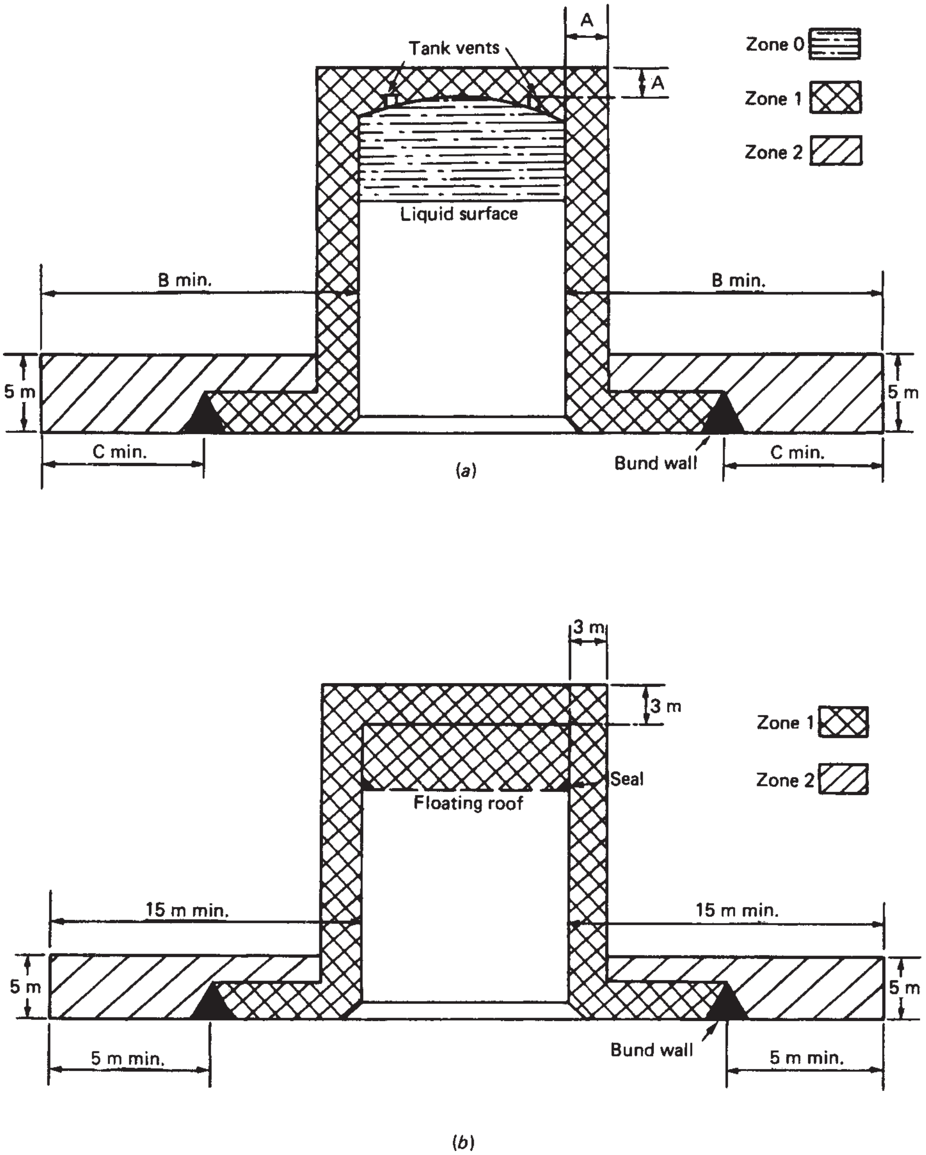

Figure 16.64 *Hazardous area classification – ICI Electrical Installations Code (Imperial Chemical Industries Ltd, ICI/RoSPA 1972 IS/91; reproduced with permission): zoning for a storage tank holding a flammable liquid with flash point below 32°C: (a) fixed roof tank; (b) floating roof tank. Extent of Zones 1 and 2: for a tank with capacity greater than 50* m^3*, A is 3 m and for a tank with smaller capacity A is 1.5* m*; Zone 2 extends Bm minimum from the tank side and C m minimum from the bund. For a tank with capacity greater than 100* m^3 *B and C are 15 and 5* m *respectively; for a tank with a capacity between 50* m^3 *smaller distances may be appropriate*

the designation of small areas as non-hazardous should be avoided. HAC is not sufficiently precise to warrant this.

Classification by method of direct example

The basic method of classification, the method of direct example, is described in Chapter 3 of the IP *Code*.

There are on petroleum installations some arrangements of equipment, which are so common that it is possible to give exemplars of the zonings to be used. The zoning of the relevant exemplar is applicable to an installation that does not differ significantly from it. Differences that may be significant may be associated with the fluid, the type of equipment, the operating conditions, the plant layout

***Table 16.45** Principal contents of the IP Area Classification Code (IP, 1990 MCSP Pt 15)*

1. Introduction
2. The technique of HAC
3. The classification of storage tankage, bulk loading and unloading by road and rail, petroleum jetties, and bulk distribution and marketing facilities by the method of direct example
4. The classification of drilling rigs and other equipment systems used in well operations and production wellhead areas
5. Alternative procedure for classification of an upstream or downstream petroleum sector facility by consideration of the individual point source
6. Variation in ventilation conditions
7. Application to the selection and location of electrical facilities
8. Application to the control and location of ignition sources other than electrical

and/or the ventilation. If a significant difference exists, use should be made of the point source method.

For this method examples are given for Classes I, II(2) and III(2) for: (1) storage tanks, both fixed and floating roof, in the open, (2) road tanker loading, (3) road tanker discharge, (4) rail car loading, (5) marine facilities and jetties, (6) drum filling in the open, (7) filling and service stations and (8) certain bulk pressurized liquefied petroleum gas (LPG) installations.

Figure 16.66 shows the zoning recommended in the code for four storage tank configurations. Figure 16.66(a) is a cone or dome roof tank; Figure 16.66(b) a floating roof tank; Figure 16.66(c) a cone roof tank with an outer protective wall; and Figure 16.66(d) a floating roof tank with an outer protective wall.

Chapter 4 of the code extends the method of direct example by giving exemplars for drilling rigs and other petroleum production systems.

Classification by point source method

The alternative method of classification, the point source method, is described in Chapter 5 of the IP *Code*.

The process plant will generally consist of a Zone 2 area with Zone 1, and occasionally Zone 0, areas within this. The point source method is applied to potential sources of release to determine for each whether it should be assigned a Zone 1 or Zone 0 envelope and whether it affects the boundary of the Zone 2 area.

The method involves identifying for each point source (1) the grade of release and (2) the extent of the hazard zone, or hazard radius.

The grade of release determines the zone to be assigned: Zone 0 for continuous grade, Zone 1 for primary and Zone 0 for secondary for open air conditions, with adjustment of the severity of the zone for poor or very good ventilation.

The extent of the hazard zone is determined by the mass released and the fraction forming a gas or vapour cloud and by the conditions, which affect the dispersal of the cloud that is its buoyancy and the ventilation at that location. The hazard zone is characterized in terms of the hazard radius. The hazard radius of a source is defined as 'the largest horizontal extent of the hazardous area which is generated by the source when situated in an open area'. The *Code* gives guidance in Appendix C on the assessment of buoyancy and in Appendix D on the derivation of the hazard radius.

The *Code* treats a number of common types of point source, including the following: (1) pumps, (2) compressors, (3) piping systems, (4) drains and liquid sample points, (5) process and instrument vents, (6) liquid pools due to spillage, (7) sumps, interceptors and separators, (8) pig receivers and launchers and (9) surface water drainage systems.

The general approach taken is illustrated by the following examples. For pumps, for the case where the pump can be treated as a single point source, the hazard radius (m) is given as:

Fluid category	*Standard pump*	*High integrity pump*
A	30	7.5
B	15	3
C	7.5[a]	3

[a] For clean fluids, e.g. finished products which are pumped from atmospheric storage at rates not exceeding 100 m^3/h, the hazard radius may be reduced to 3 m.

For drains and liquid sample points the hazard radius (m) is:

Fluid category	*Diameter*[a] (mm)			
	3	6	12	25
A	7.5	15	30	–[b]
B	3	7.5	15	30
C	0.3	1.5	1.5	3

[a] Diameter of smallest item on drain or sample line, i.e. line, valve or restrictor.

[b] The size of release is greater than is normally considered in HAC, the hazard radius being greater than 30 m.

Elimination or modification of sources

As far as practical, features that pose problems in HAC should be eliminated or mitigated by changes in plant layout. In particular, (1) continuous or primary grades releases in less ventilated conditions should be avoided and (2) the creation of sheltered areas by obstructions should be minimized.

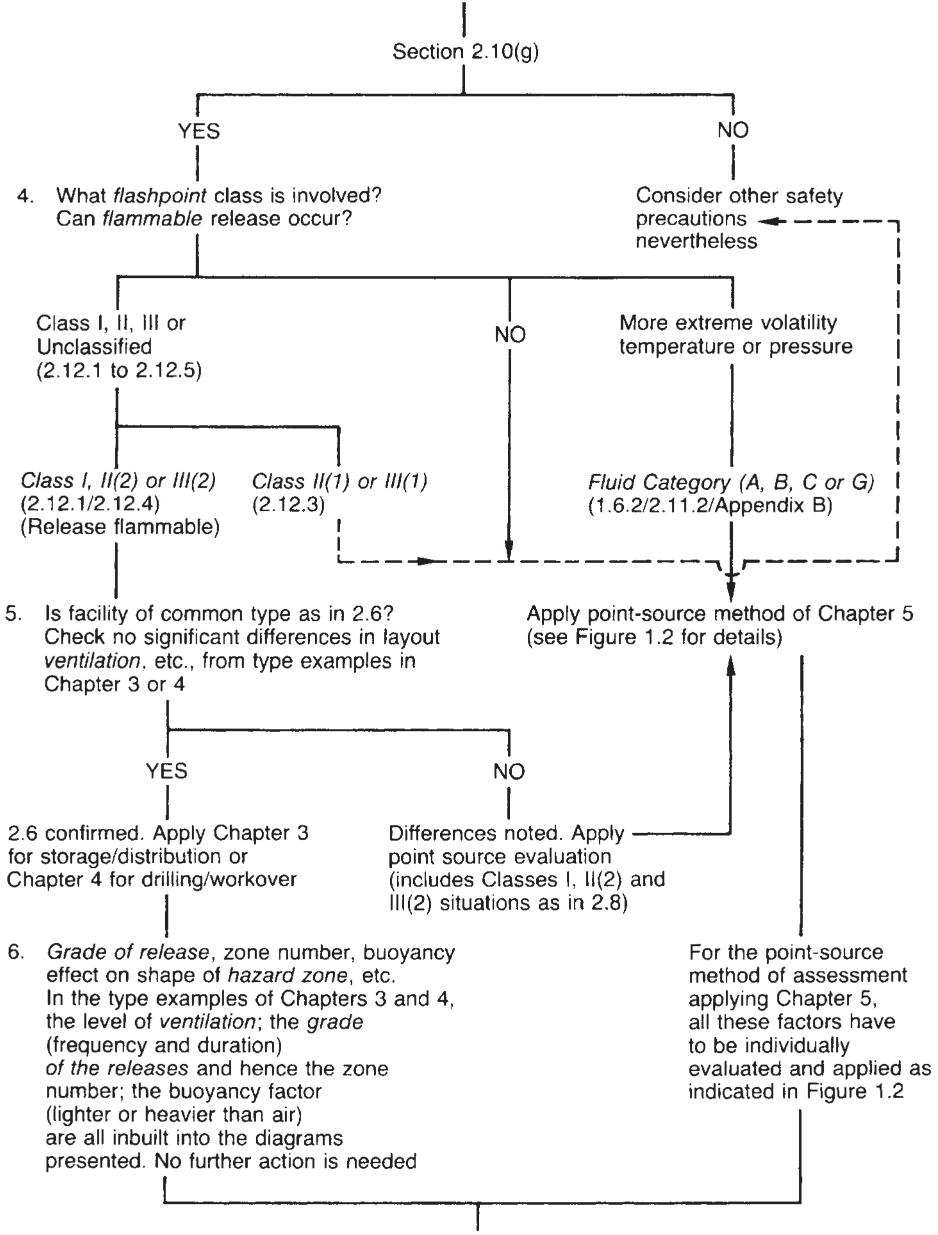
Ventilation

As the foregoing treatment indicates, ventilation affects the extent of the hazard zone. For artificial ventilation it may also affect the severity of the zone.

The IP *Code* takes as it starting point the types of ventilation given in IEC 79-10, which are (1) natural ventilation, (2) general artificial ventilation and (3) local artificial ventilation. IEC 79-10 recognizes two situations in which natural ventilation occurs. These are (1) open locations typical of process plant located outside and (2) open buildings in which the size and positioning of the openings is such as to give an equivalent degree of ventilation.

The IP *Code* treats ventilation in terms of the following situations: (1) 'open areas', (2) less ventilated conditions, which include (2a) sheltered areas and (2b) enclosed areas. The *Code* gives detailed guidance on what can be considered an open area. Essentially this is an open situation, which for

1. Familiarize concepts/definitions of *area classification* in Chapter 1 (1.1 to 1.9).
2. Define installation/plant/process sections (2.2/2.3).
3. Is quantity of *flammable* material that may be released sufficient to require classification?



Consider other safety precautions nevertheless

4. What *flashpoint* class is involved? Can *flammable* release occur?

Class I, II, III or Unclassified (2.12.1 to 2.12.5)

More extreme volatility temperature or pressure

Class I, II(2) or III(2) (2.12.1/2.12.4) (Release flammable)

Class II(1) or III(1) (2.12.3)

Fluid Category (A, B, C or G) (1.6.2/2.11.2/Appendix B)

5. Is facility of common type as in 2.6? Check no significant differences in layout *ventilation*, etc., from type examples in Chapter 3 or 4

Apply point-source method of Chapter 5 (see Figure 1.2 for details)

2.6 confirmed. Apply Chapter 3 for storage/distribution or Chapter 4 for drilling/workover

Differences noted. Apply point source evaluation (includes Classes I, II(2) and III(2) situations as in 2.8)

6. *Grade of release*, zone number, buoyancy effect on shape of *hazard zone*, etc. In the type examples of Chapters 3 and 4, the level of *ventilation*; the *grade* (frequency and duration) *of the releases* and hence the zone number; the buoyancy factor (lighter or heavier than air) are all inbuilt into the diagrams presented. No further action is needed

For the point-source method of assessment applying Chapter 5, all these factors have to be individually evaluated and applied as indicated in Figure 1.2

7. Final stages for completion of the area classification. In all cases, having evaluated the extent of the *hazard zone* and its zone number, Chapter 7 must be used to select the appropriate *type of protection* for electrical equipment, and also its *apparatus subgroup* and *temperature class* (2.13). These should be incorporated in the final *area classification* records or drawings.
   In making this selection, the question of whether there is an *internal release* should be assessed in accordance with Appendix F, 7.5(b) and 7.6(c) to determine whether it is the *internal release* or the external zone assessment that will govern the ultimate *type of protection* requirement.
8. For non-electrical *sources of ignition* see Chapter 8.

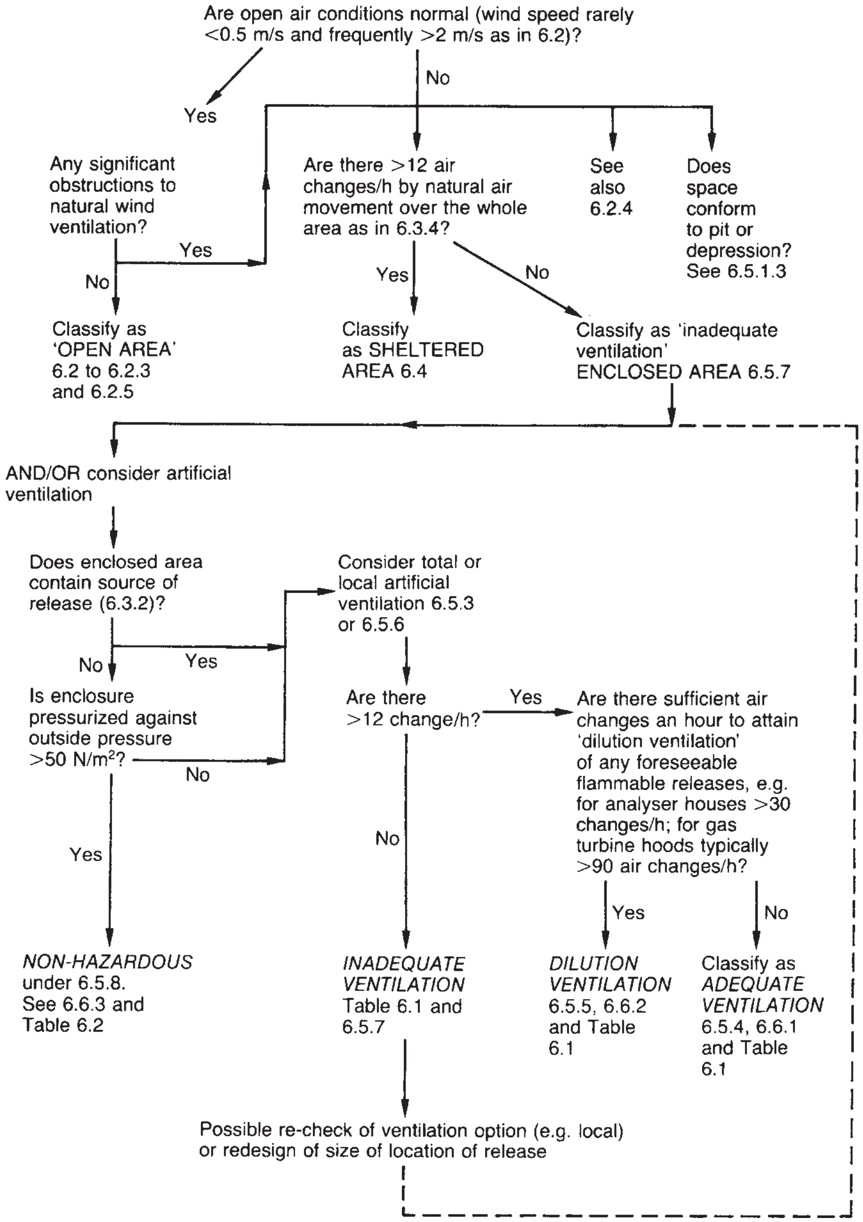

Figure 16.67 *Hazardous area classification – IP Area Classification Code (IP, 1990 MCSP Pt 15): decision tree for ventilation. This figure applies to facilities not covered in Chapters 3 and 4 of the code (Courtesy of the Institute of Petroleum; reproduced with permission)*

land-based locations means that the wind velocity is rarely less than 0.5 m/s and is frequently greater than 2 m/s.

With regard to less ventilated conditions, it distinguishes between locations where the sheltered or enclosed area itself contains a source of release and those where it merely abuts an area containing, or lies within the hazard zone of, such a source. In both cases the severity of the zoning depends on the degree of ventilation. For less ventilated conditions, the *Code* utilizes the concept of 'adequate ventilation', defined as: 'the achievement of a uniform ventilation rate of at least twelve air changes an hour with no stagnant areas'.

If a less ventilated location has adequate ventilation through natural ventilation, it may be treated as a sheltered area. Otherwise, it must be treated as an enclosed area. Guidance on the classification of sheltered areas, with natural ventilation, is given in the *Code, which* also describes a number of examples.

An enclosed area is one that in the absence of artificial ventilation has inadequate ventilation. The *Code* gives guidance on the classification of enclosed areas, utilizing the distinction between those with and those without an internal source of release.

An enclosed area requires artificial ventilation, which the *Code* treats in terms of the following three categories: (1) 'adequate' ventilation, (2) dilution ventilation and (3) overpressure ventilation.

The *Code* distinguishes between adequate ventilation and dilution ventilation. As already stated, adequate ventilation exists if there is an assurance of at least 12 air changes per hour. It is not related to the size of any potential release that may occur. If there is a release, adequate ventilation may not be sufficient to prevent the build-up of a flammable atmosphere, but on termination of the release it will be sufficient to prevent the persistence of such an atmosphere.

Dilution ventilation, by contrast, is intended to prevent a release giving rise to a flammable atmosphere and is therefore a function of the size of the potential release. It should be such that even immediately after a release the area can be considered as non-hazardous. The design criterion is that the flammable concentration should not rise above 20% of the LFL.

In some cases, particularly where there is a source of release in a large area, local artificial ventilation, typically utilizing a hood, may be used either to obtain local dilution ventilation or to restrict the extent of a Zone 1 area.

Another form of ventilation is pressurization, or overpressure ventilation. In this method an overpressure is maintained in the space so that flammable gas is excluded. The *Code* recommends an overpressure of at least 5 mm WG (50 Pa). This form of ventilation is not used where there is a source of release inside the enclosed area.

Figure 16.67 shows the decision tree given in the *Code* for the determination of ventilation.

Where artificial ventilation is provided for an enclosed area, consideration should be given to possible stagnant areas. Where these exist, possible countermeasures may include additional ventilation and gas detectors. It is necessary to consider what precautions should be taken to deal with the possibility of loss of artificial ventilation. The appropriate measures will depend on the particular situation. They may be aimed at reducing the frequency of failure, such as the installation of stand-by fans with separate power supplies and/or mitigating its consequences, such as the provision of gas detectors.

Selection and location of electrical equipment

The IP *Code* deals in Chapter 7 with the selection and location of electrical equipment, covering much the same ground as Section 16.8. The table showing the types of protection available has already been given in the previous section as Table 16.43.

The *Code* makes a distinction between electrical apparatus without and that with potential for internal release of flammable material. Certain types of instrument come into the latter category. Guidance on such apparatus is given in Appendix F of the *Code*.

Control of non-electrical ignition sources

Chapter 8 of the IP *Code* deals with the control and location of ignition sources other than electrical equipment. A hazardous area should preferably contain no fixed sources of ignition and close control should be exercised over any mobile ignition sources. In respect of mobile ignition sources, the *Code* deals mainly with permit-to-work systems and with the use of gas detectors.

Specific ignition sources the control of which is considered in the code include (1) hot surfaces, (2) furnaces and fired heaters, (3) combustion engines, (4) turbines, (5) road and rail traffic and (6) flares. Consideration is also given to pyrophoric and electrostatic hazards and air intakes.

16.9.4 API RP 500

The approach described in API RP 500 : 1991 is broadly similar to the method of direct example just described. The code utilizes the NFPA classification of fluids given in Chapter 10 and the NFPA classification of hazardous locations and grouping of atmospheric mixtures given in Section 16.8. It distinguishes between outdoor and enclosed locations.

The *Code* gives exemplars of zoning in Section A for petroleum refineries; in Section B for production facilities, on land and offshore; and in Appendix C for petroleum pipelines.

The criterion given in the *Code* for 'adequate ventilation' is 6 air changes per hour. Appendices A–C of the *Code* deal with ventilation. They treat, respectively, (1) ventilation of an enclosed area by natural means, (2) ventilation for fugitive emissions and (3) development of ventilation criteria.

16.9.5 Quantification in hazardous area classification

The methods used in the codes just described are based essentially on industry experience supplemented by estimates of the frequency and range of releases. An indication that traditional approaches have tended to yield disparate results is given in Figure 16.68 (A.W. Cox, Lees and Ang, 1990). The figure shows the zoning recommendations of selected codes for certain common items.

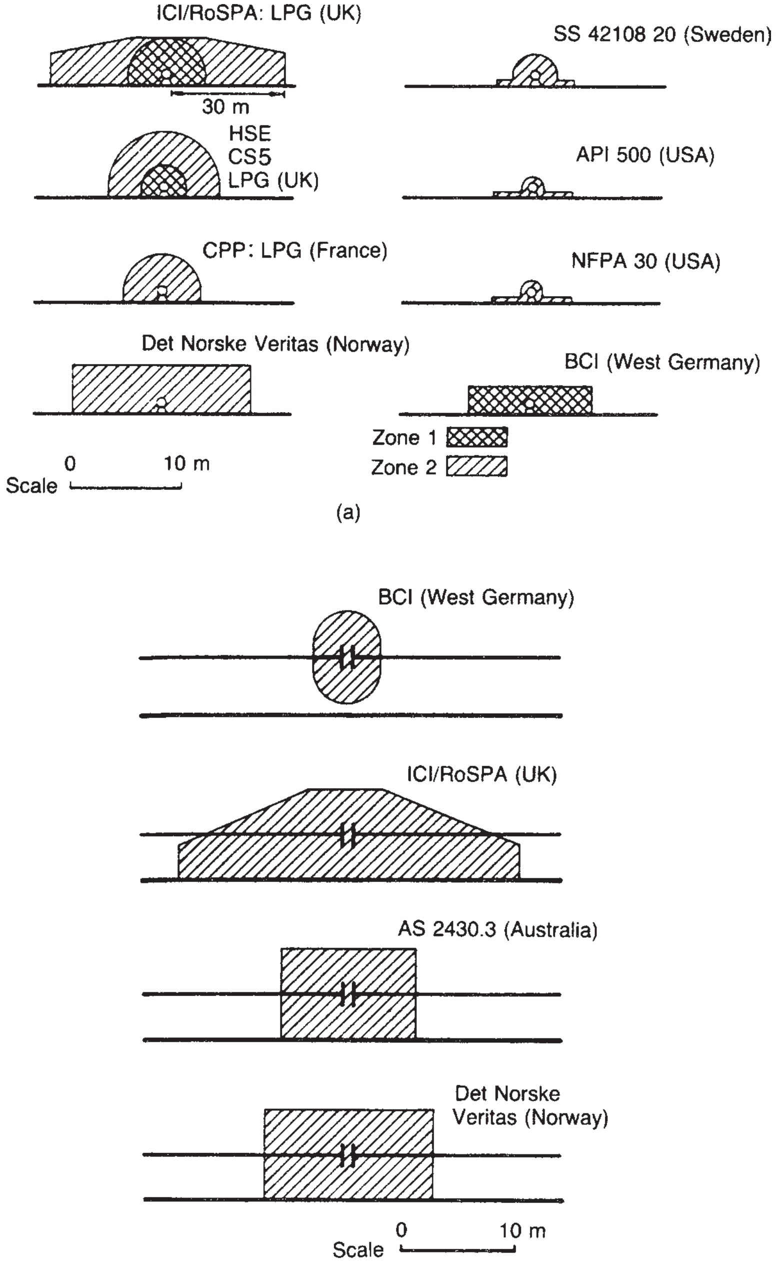
One approach to hazardous area classification is: to identify particular types of source of release; to assign to each source a typical release rate, or set of rates; to assign to each release rate a frequency; to estimate the range of the release; and to use this release range to determine, for purposes of zoning, a hazard range. The estimation of frequency and the determination of the hazard range may be a matter of judgement.

This basic approach may be applied in one of two ways. One is to perform the whole exercise afresh for each source of release on each occasion that such a source is encountered in the design. The other, and more practical, way is to do the assessment once and for all and then to produce guidelines.

Approaches on these lines evidently inform some of the methods used in the codes just described, such as the source of hazard method of the ICI *Electrical Installations Code* and the point source method of the IP *Area Classification Code*.

A method based on the examination of individual leak sources has the advantage that it forces the engineer to identify these sources and to examine them more closely. It takes full account of the properties of the fluids and the operating conditions. It allows for engineering features designed to reduce the risk. It should give greater reassurance that the zone distances are right. On the other hand, there is a view that this approach can lead to much effort for little return, the end result often being little different from that obtained using a more general approach.

Hazardous area classification has not to date been based on any formal quantitative risk assessment. There have been different views on whether or not this is necessary. In any event, in this particular field quantification has proved difficult. Foremost among the problems is the lack of data on the basic frequency and size distribution of leaks for different potential sources. Uncertainties in modelling have been another significant factor.



(a)

(b)

Figure 16.68 *Hazardous area classification: zone distances given by selected codes (A.W. Cox, Lees and Ang, 1990): (a) zone distances for pumps for LPG; (b) zone distances for flanges of pipework handling LPG; and (c) zone distances for storage tanks (Courtesy of the Institution of Chemical Engineers)*

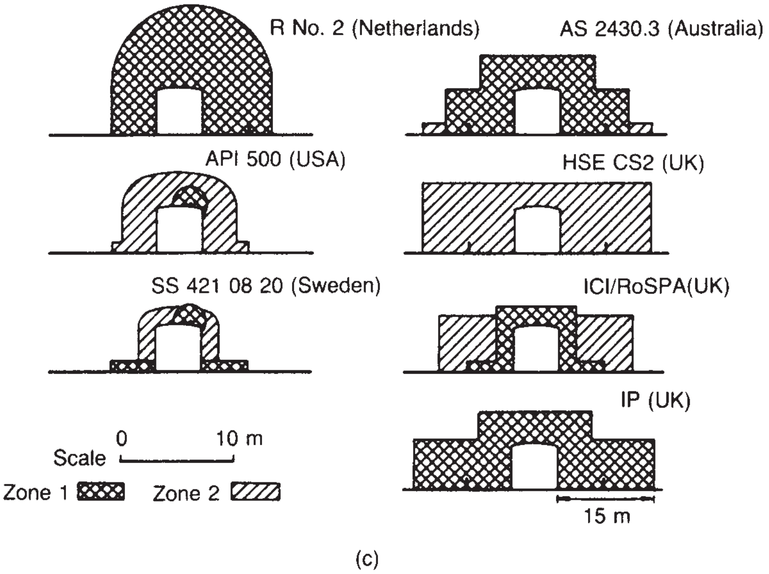


Figure 16.68 *continued*

Several parties have addressed the modeling aspect. In the mid-1980s, a draft appendix to BS 5345 was produced which contained a collection of models for use in hazardous area classification, but this did not see the light of day. A discussion of such models has been given light of day. A discussion of such models has been given by O'Shea (1982). Another set of models area those given for plan layout by Mecklenburgh (1985), as described in Chapter 10. A set of models for natural gas is given in the British Gas in-house code BGC/PS/SHA1.

Research in support of a more quantitative approach has been described in *Classification of Hazardous Areas* A.W. Cox, Lees and Ang (1990). This work involved the development and refinement of estimates of (1) the frequency and size distribution of leak s from typical leak sources, (2) the probability of ignition of the release and (3) the probability of explosion given ignition. An account of this ignition model is given in the next section. The authors state that the provision of these data provides the basis for the development of guidance based on quantitative risk assessment. They suggest that quantitative guidance might be formulated by exploring representative scenarios of release on plant layouts incorporating typical equipment, and sources of release, using a three-dimensional computer-aided design (CAD) plant layout code, utilizing the data on release frequency and size and ignition on which the ignition model is based, together with other data such as the probability of exposure of personnel.

16.10 Ignition Models

It is frequently necessary in hazard assessment to estimate the probability of ignition and of explosion if a leak occurs. There is therefore a requirement both for ignition models and for data from which to determine the parameters in such models. This is, however, an area where there is relatively little guidance available.

Information relevant to the modelling of ignition sources has been given in *Classification of Hazardous Areas*, the study by A.W. Cox, Lees and Ang (1990) already mentioned. This work includes a model for leaks of flammable fluids and for their ignition and explosion.

16.10.1 Modes of ignition

Ignition of a leak may occur either at the point of leak or at some distance from it. The cause of ignition may be the leak event itself or an ignition source. These distinctions may be illustrated by the following examples. A leak may occur at a pump seal which has failed due to a bearing failure and the hot bearing may ignite the leak. A leak may occur due to equipment rupture and the rupture may give a spark which ignites the leak. A leak may generate static electricity which then gives an incendive spark and ignites the leak. All these cases are treated here as ignitions by the leak event itself, regardless of how close to point of leak ignition occurs.

It is usually convenient to consider a limited number of specific sources and to treat the large number of other potential ignition sources as background sources. A specific ignition source may be present continuously or only intermittently.

From the foregoing, the modes of ignition may be classified as follows:

(1) event ignition;
(2) specific ignition source
  (a) continous,
  (b) intermittent;
(3) background ignition.

It may also be helpful to distinguish between those ignition sources on which action is practical when a gas alarm occurs and those for which it is not.

16.10.2 Distribution of ignition sources

Some data on the distribution of ignition sources onshore are given in Table 16.46 These data are from a survey by Cox, Lees and Ang of incidents reported to the Health and Safety Executive (HSE).

Information on ignition sources offshore has been given by Sofyanos (1981) and by Forsth (1981a,b,1983). Table 16.47 shows data given by Forsth (1983) for the Gulf of Mexico (GoM) and for the Norwegian North Sea (NNS). The number of accidents considered was 326 in the GoM over the period 1956–82 and 133 in NNS over an unspecified period.

16.10.3 Probability of ignition

The information available on the probability of ignition is mostly in the form of expert estimates. In the context of vapour cloud explosions, Kletz (1977j) states that on polyethylene plants the leaks are mostly very small and that about one leak in 10,000 ignities, due probably to good jet mixing with air. He also states that on a series of plants handling a hot mixture of hydrogen and hydrocarbons about one leak in 30 ignites. He argues that the probability of ignition increases with the size of leak and suggest that for large leaks (>10 ton) the probability of ignition is greater than 1 in 10 and perhaps as high as 1 in 2.

R.L. Browning (1969c) has given a set of estimates of the relative probabilities of ignition. For ignition under conditions of no obvioius source of ignition and with explosion-proof electrical equipment he gives the following probabilities of ignition:

	Relative probability of ignition
Massive LPG release	10^{-1}
Flammable liquid with flashpoint below 110°F or with temperature above flashpoint	10^{-2}
Flammable liquid with flashpoint 110–200°F	10^{-3}

Elsewhere R.L. Browning (1980) gives a table of probabilities which are evidently absolute probabilities. The table includes an estimate of the probability of ignition of flammable gas–liquid spills of 10^{-2}–10^{-1}.

The First *Canvey Report* (HSE, 1978b) gives for LNG vapour clouds:

	Probability of ignition
Limited releases	10^{-1}
Large releases	1

Table 16.46 *Ignition sources in fire and explosion survey of national case histories (A.W. Cox, Less and Ang, 1990) (Courtesy of the Institution of Chemical Engineers)*

	No. of incidents	*Proportion of incidents* (%)	
		Unadjusted	*Adjusted*[a]
Flame:			
General	8	9.3	16.7
LPG fired equipment	2	2.3	4.1

Self-ignition	1	1.5	1.5	5.4
Cigarette, lighter, match	1	1.5	1.5	5.5
Other	11	16.4	5	17.9
Unknown, not reported	17	–	12	–
Total		100		100

GoM, Gulf of Mexico; NNS, Norwegian North Sea.

[a] Adjusted figures are based on eliminating the hot work and unknown categories and redistributing the known ignition sources in their original relative proportions.

[b] Other than engines and exhausts.

The Second *Canvey Report* (HSE, 1981a) gives the following 'judgment' values for ignition on site:

Ignition sources	*Probability of ignition*
None	0.1
Very few	0.2
Few	0.5
Many	0.9

For offshore locations, Dahl *et al.* (1983) have analysed ignition data for gas and oil blowouts, which may be regarded as massive releases. The data are shown in Table 16.48, Section A. They cover both drilling rigs and production platforms. The overall probability of ignition of blowouts is similar for the two cases.

Cox, Lees and Ang draw on the foregoing to make estimates of the probability of ignition, They define a minor leak as one <1 kg/s and take for this an average leak flow of 0.5 kg/s. They define a massive leak as one >50 kg/s and take for this an average leak flow of 100 kg/s. They estimate the probability of ignition of a minor leak of either gas or liquid as 0.01, that of a massive leak of gas as 0.03 and that of a massive leak of liquid as 0.08. From these estimates they derive those given in Table 16.49 and Figure 16.69.

16.10.4 Probability of explosion

The information available on the probability of explosion is also mostly in the form of expert estimates. In his account of vapour cloud exlosions, Kletz (1977j) has also given estimates of the probability of explosion. He quotes the following figures:

Frequency of serious vapour cloud fires = 5/year
Frequency of serious vapour cloud explosions = 0.5/year

and derives from these for a large vapour cloud

Probability of explosion given ignition = 0.1

He also gives estimates which are evidently for the probability of explosion given leak. These are a probability >0.1 for a large vapour cloud (>10 ton) and 0.0001–0.01 for a medium vapour cloud (1 ton or less).

The First *Canvey Report* gives for a refinery

Probability fo explosion, given major fire = 0.5

and for large LNG vapour clouds

	Probability of explosion given ignition
Large vapour clouds	1
Smaller clouds of gases other than methane	0.1
Smaller clouds of methane	0.01

For offshore locations, Dahl *et al.* (1983) have analysed blowouts as shown in Table 16.48, Section B.

Sofyanos (1981) has given for fires and explosion s in the Gulf of Mexico the data shown in Table 16.50.

For the estimation of the probability of explosion, Cox, Lees and Ang use for massive leaks the value of 0.3 given by Dahl *et al.* for blowouts and for minor leaks the value of 0.04 given by Sofyanos for Category V leaks. From these estimates they derive those given in Table 16.51 and Figure 16.70.

16.10.5 Distribution of leaks

In order to model the occurrence of fire and explosion on a plant it is also necessary to have information on the frequency of leaks. Table 16.52 gives the estimates of leak frequency used by Cox, Lees and Ang.

16.10.6 Cox, Lees and Ang model

The approach taken by Cox, Lees and Ang is to define an equivalent standard plant and to make for this plant estimates of the frequency of leaks of flammable gas and liquid and of ignitions and explosions. The inventory of equipment in the equivalent standard plant (ESP) is list in Table 16.53.

These various data sets are then combined to give a model, described by the authors as a fire and explosion model, but referred to here as an ignition model. From the inventory of equipment on the ESP and the generic estimates of leak frequency the frequency of leaks on the plant is obtained. The frequency of fire and explosions is then obtained from the ignition and explosion probabilities shown in Figures 16.69 and 16.70.

The data in Tables 16.52 and 16.53 and Figures 16.69 and 16.70 used in the model were initially obtained as independent estimates, but were then adjusted to give a better fit to the historical data such as the frequency of plant fires and

Table 16.48 *Probability of ignition and of explosion for offshore blowouts (A.W. Cox, Lees and Ang, 1990; after Dahl et al., 1983) (Courtesy of the Institution of Chemical Engineers)*

A Probability of ignition

Blowout fluid	*No. of blowouts*	*No. of ignitions*	*Probability of ignition*
Gas	123	35	0.3
Oil	12	1	0.08

B Probability of explosion, given ignition

Blowout fluid	*No. of blowouts*	*No. of ignitions*	*No. of explosions*	*Probability of explosion given ignition*
Gas	123	35	12	0.34
Oil	12	1	0	0

Table 16.49 *Estimates of probability of ignition for leaks of flammable fluids (A.W. Cox, Lees and Ang, 1990) (Courtesy of the Institution of Chemical Engineers)*

Leak (kg/s)	*Probability of ignition*	
	Gas	*Liquid*
Minor (<1)	0.01	0.01
Major (1–50)	0.07	0.03
Massive (>50)	0.3	0.08

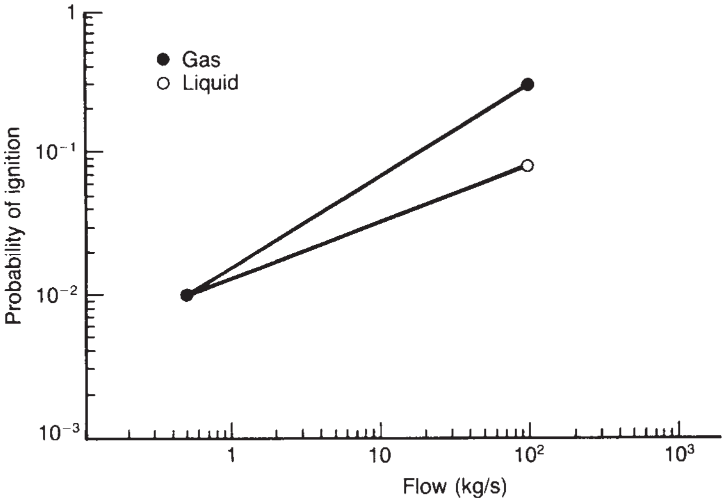

Figure 16.69 *Estimated probability of ignition for leaks of gas or liquid (A.W. Cox, Lees and Ang, 1990). (–) Initial estimates, which were used unaltered in the ignition model – see text (Courtesy of the Institution of Chemical Engineers)*

Table 16.50 *Probability of explosion given ignition for blowouts in the Gulf of Mexico (A.W. Cox, Lees and Ang, 1990; after Sofyanis, 1981) (Reproduced by permission of the Institution of Chemcial Engineers)*

Damage category[a]	*No. of incidents with fire and explosion*	*No. of incidents with explosion only*	*Probability of explosion given ignition*
I	9	5	0.55
II	13	3	0.23
III	33	6	0.18
IV	128	22	0.18
V	143	6	0.042
Total	326	42	0.13[b]

[a] The damage categories are in decreasing order of severity, Category I being loss of platform and Category V being an incident of no consequence.
[b] Weighted average.

vapour cloud explosions. For the leak frequency the original estimates are shown in Table 16.52 in brackets. No adjustment was made to the ignition probabilities given in Table 16.49 and Figure 16.69, but the explosion probabilities given in Table 16.51 and Figure 16.70 were adjusted to:

Leak (kg/s)	*Probability of explosion given ignition*
Minor (<1)	0.025
Massive (>50)	0.25

If, therefore, the estimate of the probability of explosion is based on the outcome from the model the model rather than on those derived in Subsection 16.10.4, the values given by the dotted line in Figure 16.70 apply.

Table 16.51 *Estimates of probability of explosion given ignition for leaks of flammable gas (A.W. Cox, Lees and Ang, 1990) (Courtesy of the Institution of Chemical Engineers)*

Leak (kg/s)	*Probability of given ignition*
Minor (<1)	0.04
Major (1–50)	0.12
Massive (>50)	0.3

Some results obtained by running the model for the equivalent standard plant are given Table 16.54. Leak, fire and explosion frequencies are given in Section A of the table by leak source and in Section B by fluid phase. The authors give comparisons of these results with historical data on fires and vapour cloud explosions, both overall and by leak source and fluid phase.

The purpose of the model as developed by the authors is to provide a check on the estimates of leak frequency. The conventional approach in hazard assessment is to make estimate of frequency and to derive confidence limits on these estimates. For leaks, however, the data appeared to be too sparse to permit this approach. The problem was therefore tackled in a different way. The estimates of leak size distribution and frequency were used to make, for a typical plant, estimates not only of the overall frequency of

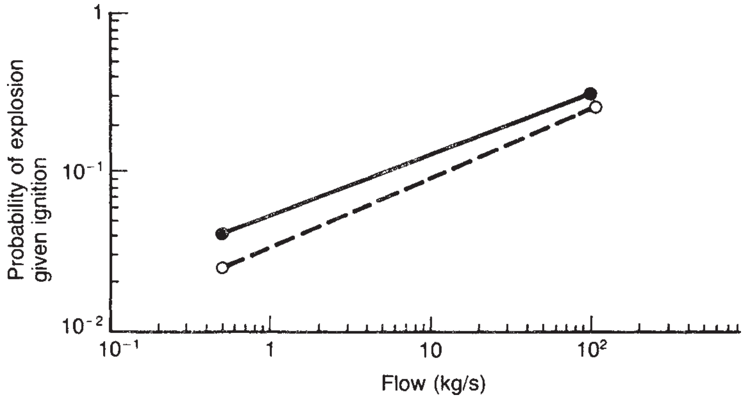

Figure 16.70 *Estimated probability of explosion given ignition for leaks of gas (A.W. Cox, Less and Ang, 1990): (–) Initial estimate; and (- -) estimate used in the ignition model – see text (Courtesy of the Institution of Chemical Engineers)*

fire and explosion but also of leaks by leak size, by fluid phase and by leak source, and hence of the distribution of leaks by size, fluid phase and leak source. Thus the model may be tested in terms not only of the final results but also of a numbers of intermediate results. For example, not only should the overall frequency of explosions accord with historical values, but so should the distribution of explosions by leak source. The totality of such comparisons

constitutes a relatively robust cross-check. It is this conceptual approach which is the main value of the model.

16.10.7 Models utilizing dispersion relations

The model just described utilizes the overall probability of ignition expressed as a function of the leak flow. The characterization of ignition probability may be extended by modeling the physical basis for the relation between it and the leak flow.

Some features which such a model should possess are given by Cox, Lees and Ang as follows:

(1) the effect of the fluid phase, gas or liquid, should be taken into account;
(2) the probability of ignition for an unprotected location should increase as the leak flow increases;
(3) there should be a finite probability of event ignition which allows for the failure to achieve perfect protection even within the designated zones, and this probability also should increase as the leak flow increases;
(4) there should be a finite probability of event ignition;
(5) the estimated probability of ignition should be the sum of (3) and (4) over the range covered by zoning and of (2) and (4) over the range not so covered.

The overall probability of ignition and the probability of event ignition estimated from the model should both be in broad agreement with that observed.

The leak flow determines the distance, and hence the area covered or volume encompassed by the leak. This area or volume may be obtained using suitable emission and dispersion relations. A model for the probability of ignition may then be constructed in which the probability is a function of the area or volume, depending on the situation considered.

One outcome of such an approach is the speculative model shown in Figure 16.71. Lone A gives the estimated probability of ignition given a normal, partial degree of protection against ignition and corresponds to the line given in Figure 16.69. Lines B and C represent the component parts of line A, line C being the part due to event ignition and line B that due to ignition sources, both specific and background. Line D gives the estimated probability of ignition assuming no protection. Line E illustrates a possible actual curve for ignition probability.

Critical features of such a model are the probabilities of event ignition and the slope of the lines derived on the one hand from estimates of overall probability of ignition and on the other from the dispersion models.

16.10.8 Models with specific ignition sources

The matter can be taken further by expressing the overall probability of ignition as a function of the contributions of the various ignition sources. For this purpose it is convenient to utilize the classification given in Section 16.10.1 and to write the overall probability of ignition P as a function of the probability P_a of ignition by the event itself, or event ignition, of the probability P_b of ignition by a specific ignition source, and of the probability P_c of ignition by one of the background ignition sources, or background ignition:

$$P = f(P_a, P_b, P_c) \qquad [16.10.1]$$

The overall probability of ignition is then

$$P = P_a + P_b + P_c - P_aP_b - P_aP_c - P_bP_c + P_aP_bP_c \qquad [16.10.2a]$$

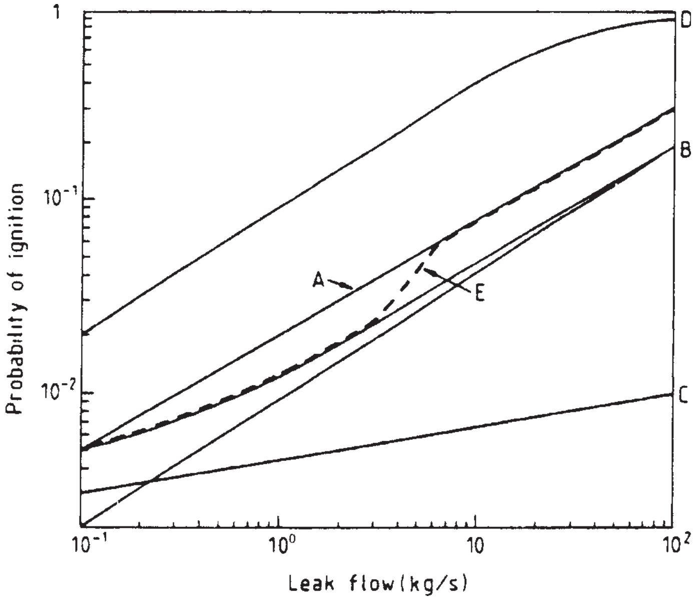
$$= P_a + P_b + P_c \quad P_a, P_b, P_c \ll 1 \qquad [16.10.2b]$$

The probability P_b of ignition by specific ignition sources is

$$P_b = 1 - \prod_{i=1}^{n} (1 - P_{b;i}) \qquad [16.10.3a]$$

$$P_b = \sum_{i=1}^{n} P_{b;i} \qquad P_{b;i} \ll 1 \qquad [16.10.3b]$$

where $P_{b;i}$ is the probability of ignition by ignition source i.



Fiqure 16.71 *Speculative model for the probability of ignition of leaks of flammable gas (after A.W. Cox, Lees and Ang, 1990) (Courtesy of the Institution of Chemical Engineers)*

For a specific ignition source the probability of ignition is

$$P_{b;i} = P_{b;i;1}P_{b;i;2}P_{b;i;3}P_{b;i;4} \qquad [16.10.4]$$

where $P_{b;i;1}$ is the probability that the source is present, $P_{b;i;2}$ is the probability that the flammable region of the gas cloud reaches the source, $P_{b;i;3}$ is the probability that the source, if active, is able to ignite the gas, and $P_{b;i;4}$ is the probability that the source is active.

The probability $P_{b;i;1}$ depends on the plant configuration and zoning practices under consideration. Probability $P_{b;i;2}$ may be estimated using dispersion relations. Probability $P_{b;i;3}$ allows for the strength of the ignition source in relation to the strength required to ignite the cloud. Probability $P_{b;i;4}$ allows for the fact that the ignition source may be intermittent. The last two depend on the type of ignition source.

The model can accommodate different sets of specific ignition sources. From Tables 16.46 and 16.47 and from general considerations a suitable set might be

(1) flames;
(2) hot work;
(3) hot surfaces;
(4) electrical;
(5) engines, motors;
(6) human activity.

In making this selection, allowance has been made for the possibility of action when a gas alarm occurs. An engine may be shut-down, but a hot exhaust will remain hot for a period. Broadly speaking, the items in this set on which action may be taken are hot work, engines and motors and human activity.

For the probability P_a of event ignition the offshore data given in Table 16.47 suggest an overall value of about 1–5%, say 3%. It may be expected that this probability will be higher for a large leak than for a small one.

Insofar as a model of this kind gives more detailed information about the specific ignition sources and their characteristics, it provides a basis not only for hazard assessment but also for taking action to reduce the probability of ignition.

16.10.9 Models in hazard assessment systems

Hazard assessment systems often include an ignition model. Other ignition models have been given in specific hazard assessments. Most of these models relate to ignition sources which might ignite a vapour cloud drifting beyond the plant boundary.

In the Vulnerability model described by Eisenberg, Lynch and Breeding (1975), the occurrence of ignition is determined as follows. It is assumed that an ignition source is located at the centre of each population cell and that ignition occurs if a flammable mixture reaches such an ignition source. The type of ignition source is specified for each cell by the user, the two types giving fire or explosion, respectively.

The handling of ignition sources in the SAFETI package has been described by Ale and Whitehouse (1986) and Pitblado and Nalpanis (1989). As for population, a 100 m × 100 m grid is used, and ignition sources are located inside each grid. Point, line or areas sources may be specified. Each source has two attributes: the probability that it is active and the probability that it is effective. Day and night are treated as separate cases.

A somewhat different approach is used in the short-cut classical method (SCM) described by R.A. Cox and Comer (1982). There the probability P of ignition is assigned specified values at regular intervals of distance dr and is thus specified as a function of the direction θ and the distance r ($= i\mathrm{d}r$)

$$P = f(\theta, r) \qquad [16.10.5]$$

Another approach, described by English and Waite (1989), is to assume a constant density μ of ignition sources. The probability increment δP of ignition for a sector of semi-angle θ_s at distance r is then

$$\delta P = \mu r \tan \theta_s \mathrm{d}r \qquad [16.10.6]$$

and the probability P of ignition by the time a distance r has been reached is

$$P = 1 - \exp(-\theta_s \mu r^2) \qquad [16.10.7]$$

The treatment of ignition sources in the *Rijnmond Report* is described in Appendix 8.

16.11 Fire in Process Plant

Fires in process plant are a serious hazard to both life and property. It is essential, therefore, to understand the ways in which fire can occur and develop.

Normally, fire occurs as a result of a leakage or spillage of fluid from the plant. Larger leaks may occur due to the failure of a vessel, pipe or pump, and smaller ones from flanges, sample and drain points and other small bore connections.

Combustion of material which has leaked from a plant may take a number of forms. A leak of gas or liquid may be ignited at the point of issue so that it behaves like a flame on a burner. In some circumstances this flame may be directed like a blow torch at another part of the plant.

If the leak gives rise to a gas or vapour cloud which grows for a period before it is ignited, the resultant effect may be either a vapour cloud, a flash fire, or a vapour cloud explosion. Vapour cloud explosions are considered in Chapter 17.

In a flash fire the gas cloud burns, but does not explode. A typical flash fire may cause quite extensive damage, particularly to vulnerable items such as electric cabling, but may leave the main plant equipment relatively unharmed. However, a flash fire does cause a sudden depletion of oxygen, and this effect can be lethal to personnel.

If the leak forms a liquid pool on the ground, this may ignite and burn. The flame may be substantial and may do damage by direct impingement or by radiation.

If the release results from fire engulfment of a vessel, a fireball may be formed.

Prevention of fire in process plant is primarily a matter of preventing leaks and avoiding sources of ignition.

In addition to fires arising from leakage in general, there are certain characteristic types of fire on process plant. These include (1) pump fires, (2) flange fires, (3) lagging fires, (4) duct fires, (5) cable tray fires, and (6) storage tank fires. These various types of fire are now discussed.

16.11.1 Pump fires

Pumps tend to leak at the gland or the seal and the leakage frequently ignites causing a fire. Pump fires have been discussed by Kletz (1975b), who describes a number of incidents involving leakage and/or fire from seals on cold duty pumps on olefin separation plants. He quotes three cases of leaks from cold ethylene pumps. In one there was a leakage over 20 min of some 3 ton of vapour which formed a cloud, but blew away without igniting. In the other two there was ignition at the pump. The cause of ignition may have been static electricity. In both instances there was a jet of vapour containing liquid droplets. With C3 and C4 hydrocarbons at moderate pressure and ambient temperature, however, there are far fewer pump seal leak fires.

***Table 16.55** Estimated frequency of pump fires (after Kletz, 1971) (Courtesy of the Institution of Chemical Engineers)*

Material in pump	*Estimated frequency of fires* (fires/pump-year)
LPG below ambient temperature	$>10^{-3}$
Material above autoignition temperature	$>10^{-3}$
Flammable material well above ambient temperature (e.g. petrol at 70°C, gas oil at 150°C)	$<10^{-3}$ $>10^{-4}$
LPG at ambient temperature	$<0.33 \times 10^{-3}$ $>0.33 \times 10^{-4}$
Petrol or similar materials at or near ambient temperature	$<10^{-4}$ $>10^{-5}$
Gas oil or similar materials below their flashpoints	$<10^{-5}$

Kletz (1971) has also provided estimates made by experts of the frequency of fires on pumps with different duties. These estimates are given in Table 16.55.

These accounts of pump fires are given by Kletz in the context of the use of emergency isolation valves to prevent a serious leak at the pump. The provision of such isolation arrangements is one of the principal means of mitigating pump fires. An alternative approach is to improve the mechanical reliability of the pump. The use of double mechanical seals, for example, greatly reduces the frequency of seal failure.

A fire at a pump can do considerable damage. It is important, therefore, to assess the effect of a fire on equipment above the pump. In some fires the damage has been much reduced by a concrete floor above the pump alley.

Electrical and instrument cabling is particularly liable to be damaged by a pump fire. If such cabling is put out of action, the plant may be down for a much longer period than is required to deal with the fire itself. Methods are available for giving such cabling a 15-min protection against fire, but they involve additional expense.

The provision of protection against pump fires is a good illustration of the loss prevention approach. The need for measures such as improved pump reliability, an emergency isolation valve or protected cabling, should be assessed by considering for each case the frequency and consequences of a pump fire.

16.11.2 Flange fires

Pipe flanges tend to leak and sometimes the leakage is ignited so that there is a fire.

An account of flange fires and their prevention has been given by McFarland (1969). Leakage at flanges is induced mainly by temperature transients which put elements of the flange assembly under stress and may cause them to yield.

Figure 16.72 shows this effect for a normal gasketed joint. The joint is shown in Figure 16.72(a) as new, in Figure 16.72(b) during the passage of hot fluid when the temperature of the inside of the pipe is hotter than that of the outside and causes differential expansion, and in Figure 16.72(c) after the transient has caused yielding of the flanges an/or bolts and compression in the gasket.

A lens ring joint of the type which is self-tightening under pressure is illustrated in Figure 16.73. Figure 16.73(a) shows the joint as new and Figure 16.73(b) shows it after a sudden reduction in temperature has caused the joint ring to suffer radial strain and leak. Figures 16.73(c) and (d) indicate two possible solutions, the use of an insulating pad between the joint ring and the pipe bore, and the provision of a more massive flange.

Figures 16.74(a) and (b) show two other methods of improving the leak-tightness of an existing flanged joint: using longer bolts with sleeves and with Belleville washers, respectively. In the latter case it is necessary to ensure that the washers cannot lose temper due to high temperatures.

The main alternative hypothesis advanced to explain the Flixborough disaster involved a flange fire. The elbow of an 8 in. line showed evidence of having been subjected to a directed flame. It was suggested that a gasket blew on a non-return valve inside a lagging box near to the elbow and gave rise to an annular leak and off-port flame directed at the elbow.

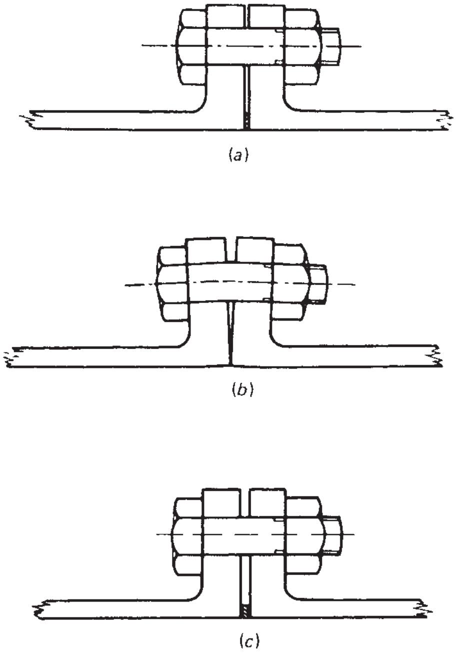


Figure 16.72 *A normal gasketed joint (after McFarland, 1969): (a) as new; (b) a hot fluid puts pipe under stress and causes bolts and flanges to yield; (c) when the fluid temperature falls, leakage can occur (Courtesy of the American Institute of Chemical Engineers)*

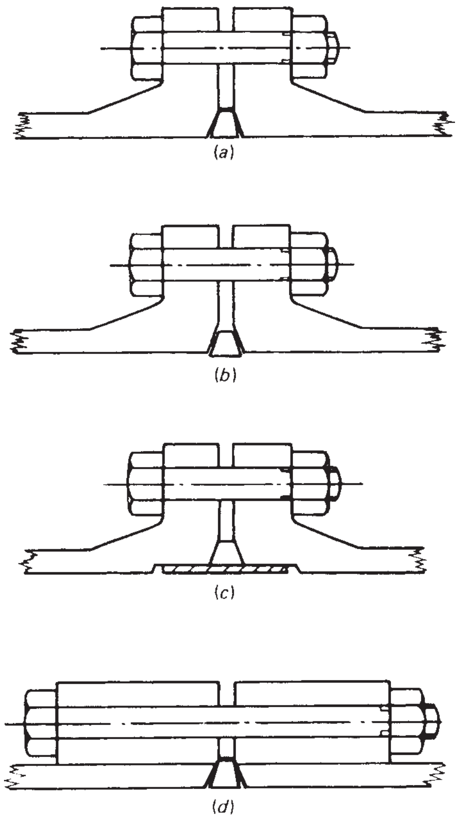

Figure 16.73 *A lens ring joint (after McFarland, 1969): (a) as new; (b) if there is a sudden temperature reduction the joint ring can suffer radial strain and leak; (c) addition of an insulating panel between the joint ring and the pipe bore reduces leakage; (d) use of more massive flanges gives better resistance to stress (Courtesy of the American Institute of Chemical Engineers)*

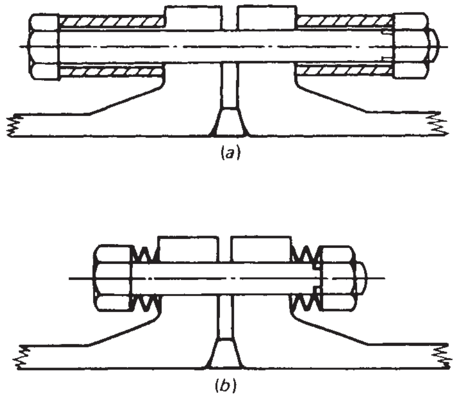

Figure 16.74 *Modification of existing joints (after McFarland, 1969): (a) use of longer bolts and sleeves; (b) use of Belleville washers (Courtesy of the American Institute of Chemical Engineers)*

16.11.3 Lagging fires

Lagging on plant equipment frequently becomes impregnated with oils and other liquids. If the lagging is hot, self-heating and ignition may occur, leading to a lagging fire.

In one small refinery the number of lagging fires in the period 1958–61 ranged from 14 to 21 per year (Petkus, 1964).

Lagging fires have been investigated by P.H. Thomas, Bowes and co-workers (e.g. P.H. Thomas, 1958; P.H. Thomas and Bowes, 1961a, 1967; Bowes and Langford, 1968; Bowes, 1974a, 1976) and by Gugan (1974a, 1976).

A lagging fire is essentially a self-heating phenomenon. Self-heating was discussed in Section 16.6. The design of insulation systems to minimize lagging fires has been considered in Chapter 12.

The conditions for a lagging fire to occur are that there should be sufficient fuel, oxygen and heat. Factors relevant to the occurrence of a fire are (1) oil, (2) leak, (3) insulation material, (4) insulation sealing, and (5) insulation geometry and temperature.

The most important factor in a lagging fire is the oil itself. For significant self-heating to occur the oil needs to be involatile (a volatile oil vaporizes too easily). An intrinsically reactive unsaturated oil is more prone to self-heating than is a saturated mineral oil, but any combustible involatile oil may self-heat.

Some liquids are described as 'fire resistant'. Of these, some, such as chlorinated paraffins and phosphate esters, are intrinsically fire resistant, but others, such as liquids dosed with antioxidant or hydraulic fluids containing water, are not, and may become combustible again if they suffer preferential loss of the antioxidant or water, respectively, in the warm lagging.

The amount of oil which gives the maximum ignition sensitivity in the more porous insulating media is estimated by Gugan (1974a) as about 6–12% v/v (equivalent to about 150 = 300% w/w).

A continuous leak is not necessarily the most favourable to self-heating. If a suitable concentration of oil can only be maintained by a continuous flow, the oil is too volatile; and if there is a continuous flow of involatile oil, it is likely to oversaturate the lagging.

Typical leakage points which may cause a lagging fire are pumps, flanged joints, and sample and drain points.

The material of insulation is another factor in determining self-heating, although it is generally less important than the nature of the oil. A good insulating material has a low thermal conductivity based on a porous structure of low density. It is precisely these features which favour self-heating. The important aspects for self-heating are the extent to which the material provides surface area on which the oil is exposed, allows air to diffuse in and prevents heat from being conducted away.

The insulation material may have some inhibiting or catalytic effect on self-heating in some systems. Bowes (1974a) quotes a difference in the minimum pipe temperature of 24°C for the ignition of oil in two different lagging materials.

Frequently the main insulating material is covered with an impervious cement finish or sealing material. This greatly reduces the extent to which oxygen can diffuse into the insulation.

The temperature which can be attained in the lagging depends on its geometry and on the pipe temperature. In some cases it is possible to estimate the lagging temperature resulting from self-heating by using theoretical methods in combination with suitable experimental tests, as described in Section 16.6.

There are a number of precautions which can be taken against lagging fires. One is to prevent the lagging becoming soaked with oil. This means primarily a high standard of operation and maintenance to avoid leaks. But, in addition, measures may be adopted such as not lagging flanged joints and protecting lagging at sample points with sheet metal collars.

As discussed earlier, the maximum temperature which is attained in self-heating depends on the thickness of the lagging. A thick lagging gives good heat insulation, but also favours self-heating. A compromise is necessary, therefore, between these two factors.

Methods of making the lagging surface impervious to air include the use of a cement finish, bituminous coating material or aluminium foil. If such sealing is used, it is necessary to ensure that the sealing is maintained, particularly at the ends of the lagging.

Another approach is to use not the usual type of insulating material but other insulation such as foam glass or crimped aluminium sheeting. Foam glass is relatively brittle and requires additional care. It is more expensive, although the price differential appears to be narrowing. Aluminium sheeting is another alternative, although it is not a particularly good insulation. It has been suggested that the use of aluminium introduces the hazard of aluminium–iron smear ignition.

On some plants with high risk and difficult self-heating problems, the approach adopted is to do without insulation altogether. In such cases expanded metal 'stand-offs' may be used to protect personnel from the hot pipework.

A lagging fire is usually detected by the evolution of smoke or other fumes. Such fumes are in fact the most satisfactory means of detection insofar as they precede incandescence as well as accompany it. It is usually a matter of chance, however, whether self-heating is detected before a fire has developed.

The use of temperature sensitive paints has been suggested as a means of detection, but this is not likely to be particularly effective since the lagging surface temperature is not a very reliable indicator of self-heating.

The hazard from a lagging fire may be that of flames issuing from the lagging. But frequently the worst hazard occurs when the lagging is opened up to remove the smouldering material. The fire may then grow, sometimes very strongly, particularly if it has been deprived of air previously.

Flames from a lagging fire should normally be extinguished with small quantities of water. Water should also be available to extinguish fire when smouldering lagging is removed. Fire extinguishing agents which do not contain water are generally less effective, because of the high risk of re-ignition. Regard should be paid, however, to any hazard which the use of water may involve, such as that associated with electrical equipment. Any lagging which might re-ignite should be removed to a safe place. Further precautions may be required if the lagging contains asbestos material or evolves toxic fumes.

Accidents involving lagging fires are described in Case Histories A115 and A122.

16.11.4 Duct and cable fires

Ducts of various kinds are common in process plants and buildings. They include ducts used for (1) the conveyance of fluids, (2) extraction and other ventilation, (3) pipes and (4) electrical cables.

Such ducts may have walls which are combustible and/or may/contain combustible materials. In ordinary ventilation systems the duct walls may be plastic. In fume extraction systems combustible deposits may build up on the duct walls. Cable and pipe coverings may be combustible. Other sources of combustible material include leaks from pipes and debris left in the duct.

In many ducts air flow occurs due to forced ventilation, which is used not only in the ventilation and extraction systems, but also to dilute leaks in ducts carrying pipes. In other cases air flow may occur in fire conditions due to the flue effect.

If combustible material in a duct is ignited, fire growth can be rapid, because the heat does not escape as readily as in an open fire and much of it serves to preheat surfaces further down the duct, making the fire much more severe and causing combustion of materials which would not normally make much contribution to a fire.

Accounts of duct fires include those by A.F. Roberts (1969/70) and Anon. (1979 LPB 30, p. 155). Investigations have been carried out by Roberts and co-workers (A.F. Roberts and Clough, 1967a,b; A.F. Roberts, 1969/70, 1971a). These have included experimental work on fires in ducts with walls of wood and of polyurethane.

Roberts has given a model of duct fires in which, as shown in Figure 16.75 important parameters are the length L of the flame zone and the velocity V of the advance of the leading edge of the flame. From these the dimensionless parameters L^* and V^* may be defined as

$$L^* = \frac{4CfLB\rho_f}{V_A\rho_A D} \qquad [16.11.1]$$

$$V^* = \frac{4CfVd\rho_f}{V_A\rho_A D} \qquad [16.11.2]$$

where B is the rate of penetration of burning into the fuel bed, C is the mass of air required for the complete combustion of unit mass of fuel, d is the depth of fuel bed consumed by the fire, D is the duct diameter, f is the fraction of surface covered by the lining, V_A is the velocity of the air, ρ_A, is the density of the air and ρ_f is the density of the fuel bed.

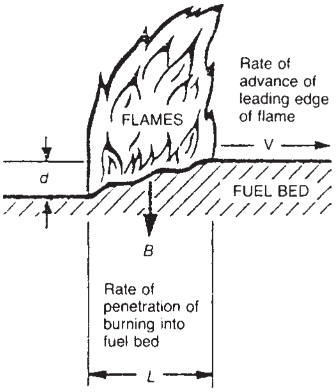

Figure 16.75 *Flame spread in a duct fire (A.F. Roberts, 1969/70) (Courtesy of HM Stationery Office.© All rights reserved)*

An important distinction is between oxygen-rich and fuel-rich fires. The parameter L^* is effectively a fuel/air ratio so that the conditions for such fires are that for $L^*<1$ the fire is oxygen rich, while for $L^*>1$ it is fuel rich.

A fuel rich fire is the more serious hazard, There is a greater rate of flame advance and heat release, the combustion gases still contain a large proportion of flammable material and they are also toxic. In a fuel rich fire the flame advances some 10 times as rapidly as in an oxygen-rich fire. Potentially combustible materials arc subject to prolonged preheating by flames and combustion products at 1000–1300°C. At a fuel/air ratio of 3, two-thirds of the material vaporized or pyrolysed is still unreacted. The combustion gases contain a large proportion of carbon monoxide. Evidence indicates that fuel-rich combustion is favoured by narrow ducts, high air velocities, high fuel loading, the presence of obstructions and large ignition sources.

In an established duct fire, the transition from oxygen-rich to fuel-rich conditions tends to increase the hazard. Reduction of the air flow may thus actually make things worse. Since the combustion gases leaving the duct may still be highly flammable, they present the hazard of further fire and explosion. These gases also contain large amounts of smoke and toxic gas, which are not only hazardous, but also tend to hamper severely attempts to fight the fire.

Work by C.K. Lee, Chaiken and Singer (1979) on duct fires with forced ventilation indicates that the fire can cause an appreciable increase in the flow resistance of the duct and can even lead to flow reversal.

Much of the interest in duct fires relates to fire in coal mine roadways, where wood is used as a lining. Work on such fires has been done by Roberts and co-workers (A.F. Roberts and Kennedy, 1965; A.F. Roberts, Clough and Blackwell, 1966; A.F. Roberts and Clough, 1967a,b) and by de Ris (de Ris, 1970; A.F. Roberts, 1971a).

These studies indicate that in modelling duct fires with infinitely thick walls there is need for care in making the assumption of a steady state. Roberts comments that a fully developed duct fire would be a highly elongated phenomenon and suggests that the full length of the fire, from the start of the burnt out zone to the end of the preheating zone, might be of the order of 370 times the duct diameter.

Another point highlighted by this work is the uncertainty surrounding the value of the heat of vaporization H_{vap} of wood, which extends not only to the magnitude but even to the sign.

There are a number of precautions which may be taken against duct fires. Good housekeeping can reduce the amount of combustible material in the duct. Fire detectors may be provided to give early warning. Fire stops may be installed to prevent fire spread. The duct may be designed to allow access for firefighting. Fire protection systems of various kinds are available. Proper working practices may be enforced by the use of a permit-to-work system.

As stated earlier, a case history of a duct fire is given by Anon. (1979 LPB 30, p. 155). Other case histories include those of cable tray fires as described below.

A type of duct fire which is of particular concern in process plants is cable tray fires. This problem has been discussed by the FPA (1974a) and by Anon. (1980 LPB 41, p. 5).

This is an important matter, because damage to cable systems often results in a long outage.

The widespread use of electric motors in process plants has led to a proliferation of motor control centres and large electric power and control cable runs. In a large proportion of cases it is not practical to use metal conduits and cables are run in open metal troughs.

A single cable may not burn very readily, but a number of cables will often burn vigorously, particularly in a vertical duct which is favourable to fire spread. Once heated up cables may not need a flame to ignite them. Rubber covered cables can be ignited by hot air or radiant heat.

PVC insulated cables present a particular problem. They burn well and readily spread fire in vertical ducts, with the plastic melting and releasing burning droplets. The PVC also decomposes to give large quantities of hydrogen chloride gas which is toxic and renders corrosive the water used in firefighting. In one power station fire about a third of the damage was attributed to this cause.

Where power and control cables are mixed, short circuits can occur from high current lines to lines which are not rated for such currents.

Cable ducts form a means by which fire may spread. This is especially serious where the cable ducts lead to a vulnerable point such as a control room.

Ignition in several cable fires has been assisted by an oil leak from machinery which has entered the cable duct through an unsealed opening.

Damage to cables may disable the emergency system, including the telephones required to summon assistance. In one incident notification of the fire brigade was delayed because the telephone circuits had failed.

There are a number of precautions which may be taken against cable fires. Cables may be segregated from other services and the different types of cable, particularly power and instrument cables, may be segregated. The criticality of all cable runs should be assessed and an appropriate degree of protection provided for each. The hazard of fire spread through cable ducts to vulnerable points should be minimized.

Fire protection for petrochemical plants and oil platforms has been discussed by Corona (1984) who states that a fire protection system for cabling should be based on a hydrocarbon pool fire at not less than 1800°F (980°C), should maintain the cable temperature within operating limits, which on ordinary PVC cables is usually below 300°F (149°C), and should do this for a time period long enough for emergency operation of equipment, which might be of the order of 20 min. Another time period often quoted for cable protection in petrochemical plants is 15 min.

Use may be made of fire resistant cabling. If reliance is placed on such fire resistance, it is important to select the right cable. This is partly a matter of specifying the degree of fire resistance required and partly one of assessing whether a given cable meets this specification. Several workers have emphasized that any tests conducted should be on a sufficiently large scale as to be realistic.

The problem of fire testing of cables and of standard fires for such tests is discussed by Schultz (1986). He describes the protection of cables using a ceramic-refractory blanket held by steel bands.

Spillage of oil into the cable duct may be minimized by sealing the cable holes. Protection against the spread of fire through the duct may be provided by fire stops. The design of such stops is discussed by Anon. (1980 LPB 41, p. 5).

Smoke detection devices may be used to give early warning. The cable duct may be designed to give access for firefighting with a maximum distance between access points. Points may be provided to receive high expansion foam from mobile generators.

Use is also made of sprinklers and other fixed fire protection systems. The application of such protection to electrical cables is a specialist matter.

Protection against cable fires is required during construction as well as during operation. There have been several serious cable fires during the construction phase.

Accounts of case histories of cable fires have been given by the FPA (1974a) and by Anon. (1980 LPB 41, p. 5).

16.11.5 Storage tank fires

Storage tank fires are not infrequent in process plant and other sites. The quantities of material involved, and consequently the losses, tend to be large. The problem is discussed in *Fire Protection Manual for HydrocarbonProcessing Plants* (Vervalin, 1964a, 1973a), in *Tank Fires* (OIA, 1974 Loss Inf. Bull. 400–1) and by a number of other authors (e.g. Burgoyne, 1950; Kletz, 1971).

Storage is discussed in Chapter 22, where the main types of storage tank are described. The larger storage tanks are atmospheric tanks of the fixed roof or floating roof types. The main materials held in atmospheric storage tanks are flammable liquids.

The scale of the fire/explosion on a storage tank installation can be very large. A single 'jumbo' storage tank in the petroleum industry may have a capacity of 500,000 barrels or more. In many tank fires more than one tank is involved.

The frequency of fires/explosions in fixed roof tanks containing volatile hydrocarbons has been estimated by Kletz (1971) as once in 833 tank-years. The estimated frequency for tanks holding non-hydrocarbons is one-tenth of this value. Comparable data for floating roof tanks are not given.

It is also apparent that, in addition to accidents involving fire/explosion, there are also near misses in which, for example, tanks are buckled but do not rupture.

In some cases there is a fire/explosion of a flammable mixture in the vapour space of the tank. In others a vapour cloud forms outside the tank and the ignites. Other cases are fire following liquid slopover or liquid spillage due to tank rupture.

One of the most frequent causes of tank fires/explosions is overfilling of the tank. This is usually due to defects in operating procedures, failure of instrumentation and/or operator error. Failure of ancillary equipment, such as pumps, and strikes of lightning are other common causes.

If there is an initial explosion which blows the tank roof off, a fire may be established in the tank and may burn there without spreading.

If there is a spillage of liquid into the bund around the tank, due to overfilling, a vapour cloud may form, find a source of ignition, and flash back. This may ignite the liquid leaving the tank and/or that in the bund.

If there is a spillage of liquid in the bund from ancillary equipment, such as a pump, and the spillage again ignites, a general fire may occur. Initially at least there may be no fire in the tank.

Once a fire is established, it frequently causes failures which feed the fire. Thus a fire on equipment such as pumps or pipework within the bund can cause a pipe failure which then results in spillage of the tank contents into the bund.

Experience shows that pipework exposed to a strong fire in a bund usually fails within about 10–15 min. and heat radiation from a tank fire may cause other nearby tanks to fail.

There are a number of measures which can be taken to reduce the risk of tank fires. Much can be done by good plant layout. There should be generous spacing between tanks to reduce the risk from radiant heat. Tanks should be provided with water spray systems which drench them in water and keep them cool. To some extent there is a trade-off which can be made between these two measures.

Frequently the fire engulfs all tanks in the bund. It is highly desirable, therefore to have a separate bund for each tank, particularly for large tanks.

Pipework inside bunds should be kept to a minimum with as few flanges, valves and other fittings as possible. Pipework can be buried, but then tends to corrode. Pumps should be installed outside bunds, both because they are sources of leakage and of ignition, and because they are often needed to fight the fire by pumping out the tank.

Measures should be taken to prevent overfilling of the tank. A high level alarm is normally a minimum requirement and often a high level trip is desirable. This instrumentation should be backed up by appropriate operating procedures.

If a fire occurs in a tank, the water sprays should be activated to protect the other nearby tanks. It is often appropriate to pump down to a suitable receiver the tank which is on fire, but it should be borne in mind that in the later stages of this operation the liquid may be very hot and may create a hazard at the receiver.

Tank fires are fought with water and/or foam. The quantities required are very large. It is essential, therefore, that the fire water mains be adequately sized, both for the fire pumps and for the drench water sprays. The tank farm should not be a backwater in this respect. Similarly, there should be a substantial storage of foam.

A tank fire can be difficult to fight for several reasons. The conditions favour the formation of vapour clouds. Metal surfaces become and remain very hot. In consequence, there is frequently flashback of fire to an area where it had appeared to have been extinguished.

Some atmospheric storage tanks contain refrigerated liquefied flammable gas. There is much less experience, however, with fires on such tanks.

Liquefied flammable gases are also stored in pressure vessels. Again, at a pressure storage vessel overfilling is one of the most frequent causes of fire. A fire which develops around a storage vessel containing a liquid under pressure can cause the pressure in the vessel to build up so that there is an explosion.

It is normal practice to provide a pressure relief valve on such vessels and it is essential for it to be properly designed and maintained, although this does not fully protect against the hazard. If the vessel is overheated, it. may rupture even though the relief valve has operated. The occurrence of boiling liquid expanding vapour explosions (BI.EVEs) on pressure storage vessels is described in Chapter 17.

Measures should be taken to minimize fire and explosion on pressure storage vessels. The ground underneath the vessel should be sloped away to prevent accumulation of flammable liquid. There should be water sprays and/or fireproof thermal insulation to give protection against fire exposure and there should be safeguards against overfilling.

16.11.6 Major fire events

In addition to the various types of process plant fire just described, there are a number of major fire events to which process plants are vulnerable. These are (1) vapour cloud fires, (2) fireballs, (3) pool fires, (4) jet flames and (5) engulfing fires. These are described in Sections 16.14, 16.15, 16.17, 16.19 and 16.20, respectively.

16.11.7 CCPS Fire and Explosion Model Guidelines

Guidance on the modelling of such major fire events is given in the CCPS *Guidelines for Evaluating the Characteristics of Vapor Cloud Explosions, Flash Fires and BLEVEs* (1994/15) (the CCPS *Fire and Explosion Model Guidelines*).

The *Guidelines* deal with (1) vapour cloud, or flash, fires, (2) vapour cloud explosions and (3) BLEVEs. They also cover (4) fireballs, which are treated as an aspect of BLEVEs. For each of the three phenomena the *Guidelines* outline basic physical concepts, experimental work and available models and correlations for the phenomena themselves and for damage and injury, and give sample problems. They also contain a set of case histories.

Vapour cloud fires and fireballs are treated here in Sections 16.14 and 16.15, respectively and vapour cloud explosions and BLEVEs are discussed in Chapter 17.

16.12 Flames

An important factor in the consideration of both the causes and the effects of fires/explosions in process plants is the behaviour of flames. The study of combustion and flames is a specialist matter and only a few selected features are mentioned here. It is emphasized, however, that this discipline makes a very large contribution to loss prevention.

Accounts of combustion and flames are given in *Flames* (Gaydon and Wolfhard, 1953–) and *Combustion, Flames and Explosion of Gases* (B. Lewis and von Elbe, 1961), in the other texts quoted in Section 16.3 and in the series *International Symposia on Combustion* (Combustion Institute, 1928–).

Certain aspects of the behaviour of flames inside plant have already been considered. These include flames in vessels, flames in pipes and cool flames, which were discussed in Section 16.3. The present section is concerned with flames in the open.

Flames outside the plant include those of:

(1) flash fires;
(2) pool fires;
(3) fireballs;
(4) flares;
(5) jet flames;
(6) fire engulfed vessels.

These are considered in the following sections.

In general, a complete model of a flame will include information on:

(1) flame shape and dimensions;
(2) heat release rate;
(3) fraction of heat radiated;
(4) flame temperature;
(5) flame emissivity;
(6) surface emissive power;
(7) view factor.

However, it is often not necessary to have full information on all of these. If the flame can be treated as a point source, it may be characterized by the heat release rate and the fraction of heat radiated and the simple point source view factor used. The other methods require the flame dimensions and may utilize a more accurate view factor. There are three approaches. One is to use the flame dimensions in combination with the heat release rate and the fraction of heat radiated, which together, in effect, give the surface emission. Another is to use the flame dimensions in combination with the flame temperature and flame emissivity, which together again give the surface emission. The third is to use the flame dimensions and the surface emissive power.

16.13 Radiant Heat Transfer

In many process plant fires the dominant mode of heat transfer is radiation. An account is given here of radiant heat transfer relevant in the present context, but it is emphasized that this is no more than an outline treatment of a rather complex topic. Standard texts on radiant heat transfer include *Radiation Heat Transfer* (Sparrow and Cess, 1966, 1978), *Thermal Radiation Heat Transfer* (Siegel and Howell, 1991) and *Radiative Heat Transfer* (Modest, 1993), and, for process plant, *Heat Transmission* (McAdams, 1954) and *Process Heat Transfer* (D.Q. Kern, 1950).

16.13.1 Thermal radiation

Radiant energy may be conceived as being transmitted either as electromagnetic waves or as photons. It travels at the speed of light and may be characterized either by its frequency v or by its wavelength λ, which are related by the equation

$$c = \lambda v \qquad [16.13.1]$$

with

$$c = c_o/n \qquad [16.13.2]$$

where c is the velocity of light, n is the refractive index and the subscript o refers to vacuum conditions.

The electromagnetic spectrum ranges from γ-rays (wavelength $\approx 10^{-12}$ m) to radio waves (wavelength $\approx 10 - 10^2$ m). The range of wavelengths for thermal radiation is approximately 0.3–50 μm. As shown in Figure 16.76, this range spans the infrared and visible ranges and part of the ultraviolet range.

16.13.2 Black body radiation

It has been shown by Planck from thermodynamic considerations that there is a maximum amount of radiant energy of a given frequency which can be emitted at a given temperature. An object which emits this quantity is termed a black body and the quantity itself the monochromatic, or spectral, emissive power for black body radiation. The fundamental form of Planck's law is

$$e_{bv} = \frac{2\pi h v^3 n^2}{c_o^2[\exp(hv/kT) - 1]} \qquad [16.13.3]$$

where e_{bv} is the monochromatic emissive power for a black body, h is Planck's constant and k is Boltzmann's constant.

On the assumption that the refractive index is independent of frequency

$$v = c_o/n\lambda \qquad [16.13.4]$$

Equation 16.13.3 may be reformulated in terms of the wavelength λ using the relation

$$e_{bv}\, dv = -e_{b\lambda}\, d\lambda \qquad [16.13.5]$$

which yields the equation

$$e_{b\lambda} = \frac{2\pi h c_o^2}{n^2\lambda^5[\exp(hc_o/n\lambda kT) - 1]} \qquad [16.13.6]$$

or

$$e_{b\lambda} = \frac{c_1}{n^2\lambda^5[\exp(c_2/n\lambda T) - 1]} \qquad [16.13.7]$$

with

$$c_1 = 2\pi h c_o^2 \qquad [16.13.8a]$$

$$c_2 = hc_o/k \qquad [16.13.8b]$$

Equation 16.13.7 may be further recast in the form

$$\frac{e_{b\lambda}}{\sigma n^3 T^5} = \frac{c_1/\sigma}{(n\lambda T)^5[\exp(c_2/n\lambda T) - 1]} \qquad [16.13.9]$$

where σ is the Stefan–Boltzmann constant. The quantity on the right-hand side of Equation 16.13.9 is a function solely of $n\lambda T$. The form of this function is shown in Figure 16.77.

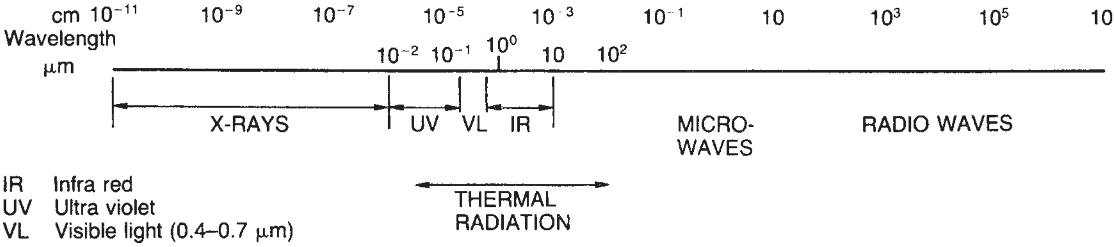

Figure 16.76 *The electromagnetic spectrum*

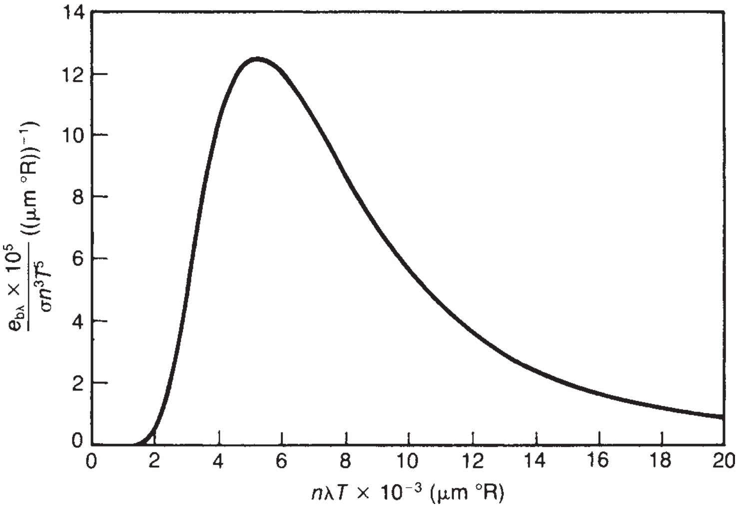

Figure 16.77 *Emissive power of a black body (Sparrow and Cess, 1978) (Courtesy of Brooks/Cole Publishers)*

The principal black body radiation constants are:

Speed of light in vacuum $c_o = 2.9979 \times 10^8$ m/s
Planck's constant $h = 6.626 \times 10^{-34}$ J s
Boltzmann's constant $k = 1.381 \times 10^{-23}$ J/K
Stefan–Boltzmann constant $\sigma = 5.6705 \times 10^{-8}$ W/m^2 K^4
First radiation constant $c_1 = 3.472 \times 10^{-16}$ W m^2
Second radiation constant $c_2 = 0.01439$ m K

The total emissive power of a black body is thus

$$e_b = \int_0^\infty e_{b\nu}\, d\nu \qquad [16.13.10]$$

Then from Equation 16.13.3

$$e_b = n^2 \frac{(2\pi k^4)T^4}{c_o^2 h^3} \int_0^\infty \frac{x^3}{e^x - 1} dx \qquad [16.13.11]$$

$$= n^2 \frac{(2\pi k^4)T^4}{c_o^2 h^3} \frac{\pi}{15} \qquad [16.13.12]$$

$$= n^2 \sigma T^4 \qquad [16.13.13]$$

Equation 16.13.13 is the Stefan–Boltzmann equation.

The refractive index n in Equation 16.13.13 is conventionally taken as unity. This is the value in most practical applications involving transmission of radiation through a gas. The equation then reduces to

$$e_b = \sigma T^4 \qquad [16.13.14]$$

16.13.3 Non-black and gray body radiation

For a non-black body the monochromatic emissive power e_λ is

$$e_\lambda = \epsilon_\lambda e_{b\lambda} \qquad [16.13.15]$$

where ϵ_λ is the monochromatic hemispherical emissivity.

It is also necessary to consider the absorption of radiation. If radiation incident on the surface is H_λ, the amount absorbed is $\alpha_\lambda H_\lambda$ and that reflected is $\rho_\lambda H_\lambda$, where α_λ is the monochromatic hemispherical absorptivity and ρ_λ the monochromatic hemispherical reflectivity. For an opaque surface

$$\alpha_\lambda + \rho_\lambda = 1 \qquad [16.13.16]$$

It has been shown that for a system in thermodynamic equilibrium that

$$\epsilon_\lambda = \alpha_\lambda \qquad [16.13.17]$$

Equation 16.13.17 is Kirchhoff's law.

For a black body ϵ_λ is unity and so therefore is α_λ. Thus a black body is also a perfect absorber as well as a perfect emitter of radiation.

The total emissive power e of a non-black body is

$$e = \int_0^\infty e_\lambda\, d\lambda \qquad [16.13.18a]$$

$$= \int_0^\infty \epsilon_\lambda e_{b\lambda}\, d\lambda \qquad [16.13.18b]$$

The overall emissivity ϵ is

$$\epsilon = e/e_b \qquad [16.13.19]$$

$$= \frac{\int_0^\infty \epsilon_\lambda e_{b\lambda}\, d\lambda}{\int_0^\infty e_{b\lambda} d\lambda} \qquad [16.13.20]$$

$$\alpha = \frac{\int_0^\infty \alpha_\lambda H_\lambda\, d_\lambda}{\int_0^\infty H_\lambda\, d\lambda} \qquad [16.13.21]$$

where H_λ is the hemispherically incident radiation per unit area per unit time.

The emissivity ϵ is a function of the surface. The absorptivity α, on the other hand, is a function not only of the surface but also of the nature of the incident radiation.

There are several cases for which a simple relation between ϵ and α applies. The most important of these is the gray body. For a gray body ϵ_λ and α_λ are independent of wavelength λ and hence

$$\epsilon_\lambda = \epsilon \qquad [16.13.22]$$

$$\alpha_\lambda = \alpha \qquad [16.13.23]$$

Then from Kirchhoff's law as given in Equation 16.13.17

$$\alpha = \epsilon \qquad [16.13.24]$$

In engineering applications the gray body assumption is frequently made.

Other cases where a simple relation holds between ϵ and α are described by Sparrow and Cess (1966, 1978).

For gray body radiation from an opaque material

$$\alpha + \rho = 1 \qquad [16.13.25]$$

From Equations 16.13.14 and 16.13.19 the emissive power of a gray body is

$$e = \epsilon\sigma T^4 \qquad [16.13.26]$$

The total radiation from a gray body is given by the radiosity B, which is the sum of the radiation emitted by the surface and that reflected from it

$$B = \epsilon\sigma T^4 + \rho H \qquad [16.13.27]$$

Radiation from a surface may be uniform in all directions or it may be directional. The two situations are termed diffuse and specular radiation, respectively. Surfaces of interest in engineering applications usually approximate to diffuse surfaces and the assumption is usually made that the radiation is diffuse.

In general, a surface tends to be diffuse at short wavelengths and specular at long wavelengths. Roughness increases the diffuseness of the surface.

16.13.4 Participating media

The radiation transmitted may be affected by the medium through which it passes. Radiation can suffer attenuation due to absorption and scattering. A medium which causes such attenuation is termed a participating medium.

Most monatomic and diatomic gases are non-participating media, except when at high temperature and/or when dissociated. Dry air is therefore also effectively a non-participating medium, but air containing water and air or gas containing water and carbon dioxide are participating media.

The attenuation of the radiation with distance x may be expressed by the relation

$$I_\lambda = I_{o\lambda}\exp(-\beta_\lambda x) \qquad [16.13.28]$$

with

$$\beta_\lambda = \kappa_\lambda + \gamma_\lambda \qquad [16.13.29]$$

where I_λ is the monochromatic radiation intensity, $I_{o\lambda}$ is the initial monochromatic radiation intensity, β_λ is the monochromatic extinction coefficient, κ_λ is the monochromatic absorption coefficient and γ_λ is the monochromatic scattering coefficient.

An overall absorption coefficient κ may be defined by the relation

$$k = \frac{\int_0^\infty \kappa_\lambda \int_{4\pi} I_\lambda \mathrm{d}\omega \mathrm{d}\lambda}{\int_{4\pi} I \mathrm{d}\omega} \qquad [16.13.30]$$

and a similar relation applies for the overall scattering coefficient γ.

16.13.5 Radiant exchange

The intensity of radiation i from a radiation source, as shown in Figure 16.78, is

$$i = \frac{\mathrm{d}\Phi}{\mathrm{d}\omega\cos\theta} \qquad [16.13.31]$$

where Φ is the radiant flux contained within the solid angle $\mathrm{d}\omega$ and θ is the angle between the direction of this flux and the normal. For uniform, or diffuse, radiation

$$i = \Phi/\pi \qquad [16.13.32]$$

A similar expression applies for radiosity

$$i = B/\pi \qquad [16.13.33]$$

For the general situation of an arbitrary configuration with radiant transfer between two differential surfaces $\mathrm{d}A_i$ and $\mathrm{d}A_j$, as shown in Figure 16.79, the treatment is as follows. Noting that r is the distance between the surfaces and that $\mathrm{d}\omega$ is the solid angle subtended by $\mathrm{d}A_j$ when viewed from $\mathrm{d}A_i$ and that it is given by

$$\mathrm{d}\omega = \mathrm{d}A_j\cos\beta_j/r^2 \qquad [16.13.34]$$

and that from Equation 16.13.33

$$i_i = B_i/\pi \qquad [16.13.35]$$

the radiation leaving $\mathrm{d}A_i$ in the direction of $\mathrm{d}A_j$ may be expressed as

$$= i_i\,\mathrm{d}A_i\cos\beta_i\,\mathrm{d}\omega \qquad [16.13.36]$$

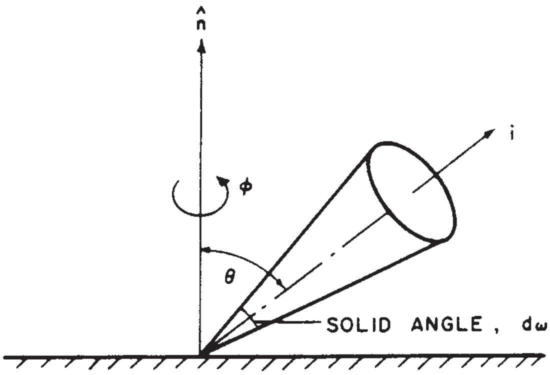

Figure 16.78 Intensity of radiation (Sparrow and Cess, 1978) (Courtesy of Brooks/Cole Publishers)

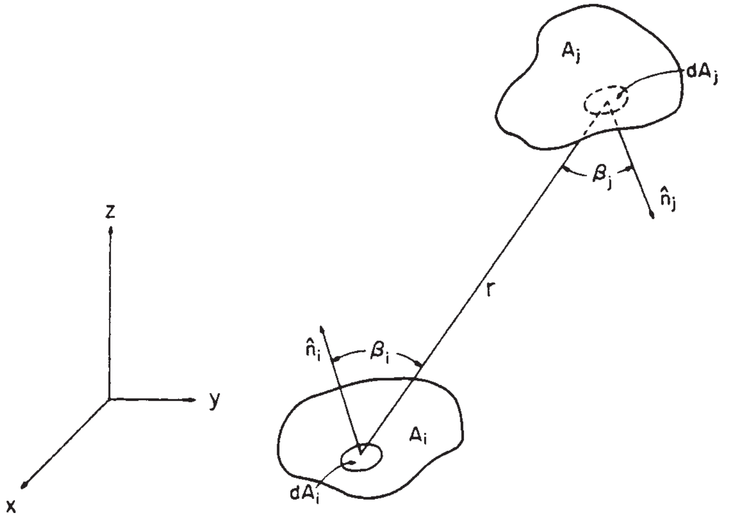

Figure 16.79 *Radiant interchange between two differential surfaces (Sparrow and Cess, 1978) (Courtesy of Brooks/ Cole Publishers)*

or as

$$= B_i \cos\beta_i \cos\beta_j \, dA_i \, dA_j/\pi r^2 \qquad [16.13.37]$$

An angle factor $dF_{dA_i} - {}_{dA_j}$ may be defined as the fraction of the radiation $B_i \, dA_i$ which is incident on dA_j. Then

$$dF_{dA_i - dA_j} = \cos\beta_i \cos\beta_j dA_j/\pi r^2 \qquad [16.13.38]$$

Similarly, an angle factor $F_{A_1 - A_2}$ may be defined for the radiation from finite surface A_1 to finite surface A_2. Angle factors are discussed in greater detail below.

It should be noted that such angle factors only take account of radiation from a source to a target and not of radiation back from the target to the source. In the applications of interest here, however, the latter is usually negligible.

Where it is necessary to consider radiation back from the target, an emissivity factor F_ϵ may be introduced. Then the product of the angle factor F_A and the emissivity factor F_ϵ is the overall interchange factor F_o

$$F_o = F_A F_\epsilon \qquad [16.13.39]$$

The application of these factors is described below.

There are a number of configurations which occur in engineering and for which simple solutions of the radiant flux are available. One is the case where a body with arbitrary radiation properties and at temperature T_1 is located inside a completely enclosed space with wall temperature T_2 such that black body radiation obtains. Then the net radiant heat transfer is

$$Q = A(\epsilon\sigma T_1^4 - \alpha\sigma T_2^4) \qquad [16.13.40]$$

For gray body conditions, Equation 16.13.40 reduces to

$$Q = A\epsilon\sigma(T_1^4 - T_2^4) \qquad [16.13.41]$$

Another case is where radiation occurs between black bodies consisting of two large parallel planes 1 and 2. For this case

$$Q = A\sigma(T_1^4 - T_2^4) \qquad [16.13.42]$$

For gray body conditions, following D.Q. Kern (1950), the radiant heat fluxes are

	Hot plane 1	*Cold plane 2*
Radiated	$e_1(= \epsilon_1\sigma T_1^4)$	$e_2(= \epsilon_2\sigma T_2^4)$
Returned	$e_1(1 - \epsilon_2)$	$e_2(1 - \epsilon_1)$
Radiated	$e_1(1 - \epsilon_2)(1 - \epsilon_1)$	$e_2(1 - \epsilon_1)(1 - \epsilon_2)$
Returned	$e_1(1 - \epsilon_2)(1 - \epsilon_1)(1 - \epsilon_2)$	$e_2(1 - \epsilon_1)(1 - \epsilon_2)(1 - \epsilon_1)$

Summation of these terms ε for the net radiant flux gives a series whose solution is

$$Q = A\frac{1}{(1/\epsilon_1) + (1/\epsilon_2) - 1}\sigma(T_1^4 - T_2^4) \qquad [16.13.43]$$

which reduces to Equation 16.13.42 for $\epsilon_1 = \epsilon_2 = 1$.

Equations 16.13.41 and 16.13.43 may be reformulated in terms of the angle and emissivity factors to give

$$Q = AF_A F_\epsilon \sigma(T_1^4 - T_2^4) \qquad [16.13.44]$$

where for Equation 16.13.41 $F_A = 1$ and $F_\epsilon = \epsilon$, and for Equation 16.13.43 $F_A = 1$ and

$$F_\epsilon = \frac{1}{(1/\epsilon_1) + (1/\epsilon_2) - 1} \qquad [16.13.45]$$

16.13.6 Heat radiation

The main application of radiant heat transfer in the present context is the estimation of the heat radiated from flames in accident conditions. Accounts of flame radiation are given in the standard texts on radiant heat transfer. A review relevant to process plant fires has been made by Considine (1984 SRD R297).

The radiant heat flux emitted by a flame in such a situation is given by the relation

$$E = \epsilon\sigma T^4 \qquad [16.13.46]$$

$$= \frac{Q_r}{A_f} \qquad [16.13.47]$$

with

$$Q_r = F_r Q_c \qquad [16.13.48]$$

where A_f is the surface area of the flame, E its surface emissive power, F_r the fraction of het released which is radiated, Q_c the total heat released by combustion and Q_r the total heat radiated.

The heat received by the target is

$$I = \alpha\tau FE \qquad [16.13.49]$$

where F is the view factor, $I\alpha\tau$ the heat radition intensity received by the target and τ is the atmospheric transmissivity.

These equations are used in conjunction with relations for the geometrty of the flame and for the heat radiated per unit area of the flame surface.

There are alternative approaches to the estimation of the heat radiated Q_r. One is to work in terms of the flame temperature and emissivity. Another is to use empirical values of the surface emissivity of the flame envelope. A third is to calculate the total heat generated and to apply an factor F_r for the franction of heat radiated.

16.13.7 Heat radiation: flame emissivity

If the first, and most fundamental, of these approaches is adopted, it is necessary to estimate the emissivity of the flame. The emissivity of a flame depends on the type of fuel and on the nature of the combustion. The heat radiated from a flame is emitted by gases, in particular the products of combustion CO_2, H_2O, N_2, CO and O_2 and by carbon particles, or soot. The former are band emitters while the later emit over a continuous range. A flame in which the radiation is emitted solely from the gaseous constituents is termed non-luminous and one in which there is soot is termed luminous.

CO_2 and H_2O

The principal gaseous contributors to flame emissivity are carbon dioxide and water vapour. The emissivity ϵ_g of a non-luminous flame may be estimated from that of these gases using the relation

$$\epsilon_g = \epsilon_c + \epsilon_w - \Delta\epsilon \qquad [16.13.50]$$

where ϵ_c and ϵ_w are the emissivities of CO_2 and H_2O, respectively, and $\Delta\epsilon$ is a correction term which allows for the overlap between the bands for these two gases.

Flame emissivity is required for many furnace calculations and there is a standard method of estimating it. The method is as follows. The emissivity for each gas species is a function of the partial product path length

$$e_c = f(p_c L) \qquad [16.13.51a]$$

$$\epsilon_w = f(p_w L) \qquad [16.13.51b]$$

where L is the mean path length, p_c is the partial pressure of CO_2 and p_w is the partial pressure of H_2O.

In process calculations, it is necessary to make a correction to the partial pressure path length products for carbon dioxide and water if the total pressure is other than atmospheric. Plots for the correction factors C_c and C_w are given in standard texts. These corrections are not required for flames at atmospheric pressure, which are those of prime interest here. The mean beam length L is considered below.

The correction term $\Delta\epsilon$ is a function of the ratio of the partial pressure of water to the sum that of the two gases

$$\Delta\epsilon = f\left(\frac{p_w}{p_c + p_w}\right) \qquad [16.13.52]$$

Graphs for the determination of the two gas emissivities ϵ_w and ϵ_c and the correction $\Delta\epsilon$ given by Hottel (1954), from the experiments of Hottel and Mangelsdorf (1935) and Hottel and Smith (1935) for carbon dioxide and the correlation of Hottel and Egbert (1942) on water vapour are shown in Figure 16.80.

Soot

An account of the properties of soot and of its occurrence in different types of flame is given by H.G. Wagner (1979). Soot usually forms in flames in the temperature range 1000–2500°C. The total amount of soot is only a small fraction of the carbon present. Theoretically, from the stoichiometry for a hydrocarbon, soot formation should start when the carbon/oxygen ratio (C/O) reaches unity, but in practice it starts around $C/O \approx 0.5$. In work on gaseous diffusion flames on burners it has been found that the soot concentration is a maximum along the axis, where measurements by Kunugi and Jinno (1967) gave concentrations of 3×10^2 particles/cm^3, or 10^{-7}–10^{-6} g/cm^3. In their classic work on turbulent diffusion flames, Dalzell, Williams and Hottel (1970) found axial concentrations of soot of 10^{-6}g/cm^3.

The characterization of the emissivity of soot is somewhat complex. The emissivity is a function of the wavelength, and the following expression has been, suggested

$$\epsilon_{s\lambda} = k_1/\lambda^{k_2} \qquad [16.13.53]$$

where $\epsilon_{s\lambda}$ is the emissivity of soot at wavelength λ, and k_1 and k_2 are constants. The value of the constant k_2 is of the order of unity.

As described by Markstein (1974), highly sooty flames satisfy gray gas models. This implies that the radiation is concentrated in a relatively narrow waveband, which in turn indicates that the emitting soot particles are distributed over a narrow temperature range.

A relation widely quoted for the emissivity of soot from non-gray analysis is

$$\epsilon_s = 1 - \frac{15}{\pi^4}\psi^{(3)}(1 + X) \qquad [16.13.54]$$

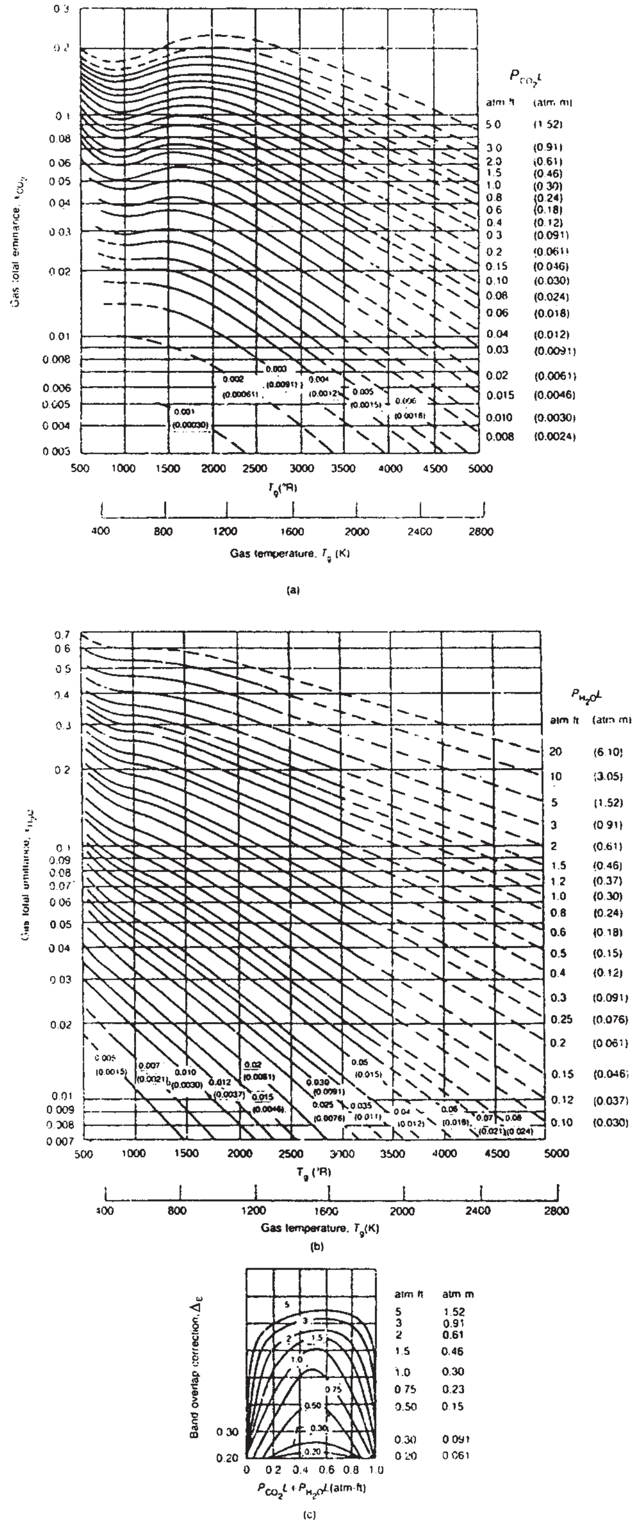

Figure 16.80 *Emissivity of carbon dioxide and water vapour (Siegel and Howell, 1991): (a) carbon dioxide; (b) water vapour and (c) overlap correction term (Courtesy of Hemisphere Publishing Corporation)*

with

$$X = \frac{cLT}{c_2} \qquad [16.13.55]$$

$$c = 36\pi f_v \frac{n^2 k}{[n^2 - (nk)^2 + 2]^2 + 4(nk)^2} \qquad [16.13.56]$$

where c is the effective soot concentration (volume fraction), f_v is the volume fraction of soot particles, L is the path length, T is the absolute temperature, X is a parameter and $\psi^{(3)}$ is the pentagamma function; c_2 is the Planck second constant, and k and n are the infrared-average optical constants of soot particles. The penta-gamma function is given by Abramowitz and Stegun (1974).

It has been shown by Dalzell and Sarofim (1969) that an alternative, and more convenient, equation which gives results similar to Equation 16.13.54 is

$$\epsilon_s = 1 - \frac{1}{(1+Y)^4} \qquad [16.13.57]$$

with

$$Y = \frac{k_3 CLT}{c_2} \qquad [16.13.58]$$

where C is the volume fraction of soot particles, Y is a parameter and k_3 is a constant. The value of the constant k_3 is discussed by Siegel and Howell who use a value $k_3 = 5.0$ in some of their calculations.

A method for the emissivity of soot has been given by Yuen and Tien (1977) based on a gray analysis. They take

$$\epsilon_s = 1 - \exp(-\kappa L) \qquad [16.13.59]$$

with

$$\kappa = 3.6 \frac{cT}{c_2} \qquad [16.13.60]$$

where T_m is the mean absolute temperature of the flame and κ is a parameter. The constant 3.6 is that required to ensure that Equation 16.13.59 yields results similar to those given by Equation 16.13.54.

These authors give a tabulation of values of these variables for a number of gaseous fuels, which includes:

Gas	*C/H*	c	κ (cm^{-1})	T_m (K)
Methane	0.25	2.00×10^{-5}	0.0645	1289
Ethane	0.33	1.60×10^{-5}	0.0639	1590
Propane	0.38	3.41×10^{-5}	0.1332	1561
n-Butane	0.40	3.12×10^{-5}	0.1259	1612
Ethylene	0.50	2.76×10^{-5}	0.1192	1722
Propylene	0.50	6.46×10^{-5}	0.2407	1490

Combined CO_2, H_2O and soot

For the emissivity ϵ_m of a gray gas containing CO_2, H_2O and soot, Yuen and Tien use the method just described for the emissivity ϵ_s of soot together with the relation

$$\epsilon_m = \epsilon_s + \epsilon_g(1 - \epsilon_s) \qquad [16.13.61]$$

A method for the estimation of the emissivity of a gray gas containing CO_2, H_2O and soot, i.e. a gas–soot mixture, has been described by P.B. Taylor and Foster (1974, 1975). These authors express the emissivity ϵ_m of such a mixture as

$$\epsilon_m = \sum_{n=1}^{3} a_{m,n}[1 - \exp(-K_{m,n}L)] \qquad [16.13.62]$$

with

$$K_{m,n} = \exp(q_{1,n} + q_{2,n}c) \qquad c > 0.0005 \qquad [16.13.63]$$

except that

$$K_{m,1} = 0.09 + 500c \qquad c \leq 0.0005 \qquad [16.13.64]$$

and with

$$a_{m,n} = r_{1,n} + r_{2,n}T \qquad n = 1 \text{ or } 2 \qquad [16.13.65]$$

$$a_{m,n} = 1 - (a_{m,1} + a_{m,2}) \qquad n = 3 \qquad [16.13.66]$$

where c is the concentration of soot (kg/m^3), L is the path length (m) and T is the absolute temperature (K); $a_{m,n}$ is a weighting coefficient, $K_{m,n}$ is an absorption coefficient and $q_{1,n}$, $q_{2,n}$, $r_{1,n}$ and $r_{2,n}$ are coefficients; subscript m denotes a mixture and n denotes the component of the mixture.

These relations are applicable to the combustion of oil ($p_w/p_c = 1$) and gas ($p_w/p_c = 2$) at atmospheric pressure with $p_c = 0.1$ atm over the temperature range 1400–2400 K for path lengths between 0.01 and 10 m.

The values given for the coefficients are:

	$p_w/p_c = 1$		$p_w/p_c = 2$	
n	$q_{1,n}$	$q_{2,n}$	$q_{1,n}$	$q_{2,n}$
1	−1.252	558.55	−1.274	590.82
2	−0.221	665.38	−0.233	672.04
3	2.608	839.62	2.452	692.61

and

Soot concentration, c (kg/m^3)	n	$p_w/p_c = 1$		$p_w/p_c = 2$	
		$r_{1,n}$	$r_{2,n}$	$r_{1,n}$	$r_{2,n}$
0.0001	1	0.8119	−0.0000355	0.7191	−0.0000336
	2	0.0280	0.0001013	0.0804	0.0001131
0.0005	1	0.5478	−0.0001869	0.6123	−0.0002489
	2	0.3846	0.0002071	0.2688	0.0002901
0.001	1	0.5478	−0.0001869	0.6123	−0.0002489
	2	0.3846	0.0002071	0.2688	0.0002901

Further values are given by the authors.

Mean beam length

In his treatment of radiant heat transfer Hottel (1954) introduced the concept of the mean beam path length L, generally known as the mean beam length or path length, as a means of taking into account the geometry of the situation considered. He states: 'The mean beam length L may be thought of as the radius of a gas hemisphere which will radiate to unit area at the center of its base the same as the average radiation, over A, from the actual gas mass', where A is the area of interest.

A distinction, amplified below, is made between flames which are optically thick and those which are optically thin. If the flame is optically thin, and thus $p_gL \approx 0$, the corresponding mean beam length L_o is equal to four times the mean hydraulic radius

$$L_o = 4V/A \qquad [16.13.67]$$

where A is the area of the enclosure, L_o is the mean beam length for the optically thin condition, p_g is the partial pressure of the radiating gases and V is the volume of the enclosure.

Thus, for example, for a sphere

$$L_o = \frac{4\pi D^3/6}{\pi D^2} = \frac{2}{3}D \qquad [16.13.68]$$

where D is the diameter of the sphere. For a long, thin cylinder

$$L_o = \frac{4\pi D^2/4}{\pi D} = D \qquad [16.13.69]$$

where D is the diameter of the cylinder.

For a gas which is optically thick, Equation 16.13.67 is modified to give

$$L = C_{bl}L_o \qquad [16.13.70]$$

where C_{b1} is a beam length correction factor. It is found that, as good approximation,

$$C_{bl} \approx 0.9 \qquad [16.13.71]$$

Then from Equations 16.13.67, 16.13.70 and 16.13.71

$$L \approx 0.9\frac{4V}{A} \qquad [16.13.72]$$

Following Hottel's original tabulation, values of the mean beam length L_o and of the beam length correction factor C_{bl}, more accurate than that of Equation 16.13.71, are listed for various geometries by Siegel and Howell (1991). Their results include:

System geometry	*Optical thickness tending to zero,* L_o	*Finite optical thickness,* L	*Correction factor,* C_{bl}
1. Sphere radiating to its surface	$2D/3$	$0.65D$	0.97
2. Cylinder with a height equal to twice its diameter radiating to the entire surface	$0.8D$	$0.73D$	0.91
3. Cube radiating to a face	$2X/3$	$0.6X$	0.90

where D is the diameter of the sphere or cylinder and X is the length of a side of the cube.

Optical thickness

Another aspect of effective flame emissivity is the extinction of radiation within the flame itself. The ratio of the heat radiated E to the heat radiated under black body conditions E_b is

$$\frac{E}{E_b} = 1 - \exp(-\beta L) \qquad [16.13.73]$$

where β is an effective extinction coefficient and the subscript b denotes a black body. If the product βL is large, the flame is said to be optically thick and, conversely, if $\beta L \to 0$ the flame is said to be optically thin.

For a flame where the optical thickness depends only on the partial pressure p_g of the radiating gases, the condition for optical thinness may be stated as $p_gL \to 0$.

Hydrocarbon flames

The flames of some hydrocarbons, such as natural gas, contain relatively little soot, whereas those of other hydrocarbons, such as kerosene, contain much larger amounts. In consequence, with natural gas, for paths through the flame which in this context are short, say 5 m in length, the radiation exhibits a background level due to soot emission with superimposed peaks due to gaseous emission. As the path length increases so does the.contribution of the soot, until at a path length of 10–20 m the emission spectrum becomes that of a black body.

Approximations

Frequently use is simply made of a point estimate of flame emissivity. A smoky flame is often assumed to be a black body radiator and thus to, have an emissivity of unity. Values of emissivity of 0.9–1.0 are commonly used for such flames. LPG is a typical material which gives a smoky flame. LNG, on the other hand, tends to give a less smoky flame, but also a wider range of emissivities.

16.13.8 Heat radiation: fraction radiated

If the alternative approach is adopted of applying a radiant heat factor R, it is necessary to have appropriate values of this factor. Hymes (1983 SRD R275) has quoted the following values given by Roberts:

Type of flame	*Radiant heat factor*
Flare and jet flames	0.2
Pool fires	0.3
Fireballs from vessels bursting below relief valve pressure	0.3
Fireballs from vessels bursting above relief valve pressure	0.4

In general, the fraction of heat radiated depends on the efficiency of combustion and the soot formation and on the heat lost by convection to the entrained air. Some flame models include correlations in which the fraction of heat radiated is a function of the operating conditions.

Further discussion of flame emissivity, the radiant heat factor and the generalized heat flux is given in the sections below on specific types of flame.

16.13.9 Atmospheric transmissivity

As described above, appreciable attenuation may occur when radiation is transmitted from a source to a target through the atmosphere. Accounts of gas transmissivity have been given by D.Q. Kern (1950) and McAdams (1954). These are concerned primarily with radiant transfer in process plant items such as furnaces.

Treatments of atmospheric transmissivity have been given by Glasstone (1962) and Glasstone and Dolan (1980), Raj *et al.* (1979), Simpson (1984 SRD R304), V.C. Marshall (1987), Wayne (1991) and the Committee for the Prevention of Disasters (CPD) (1992a). Other accounts of radiant heat transmission which include estimation of atmospheric transmissivity include those by R.O. Parker (1974), Lihou and Maund (1982) and Hymes (1983 SRD R275).

Attenuation of radiation in the atmosphere is due to absorption and scattering. The constituents of the atmosphere responsible for such attenuation are water vapour and carbon dioxide. Absorption of radiation is a function of the number of absorbing molecules in the path, while scattering is a function of the number and the size of the droplets.

Glasstone and Dolan (1980) state that, in general, the atmospheric transmissivity τ for estimation of the thermal radiation received by a target from a nuclear bomb explosion is a complex function which depends on the absorption, scattering and distance. For attenuation due only to absorption in a uniform atmosphere they give

$$\tau = \exp(-\kappa x) \qquad [16.13.74]$$

where x is the distance to the target and κ is the absorption coefficient. They also utilize this equation for the attenuation due to both absorption and scattering, but state that due to the latter κ, now an attenuation coefficient, is then not constant with distance x.

They give the following relations between atmospheric condition and visibility:

Atmospheric condition	*Visibility* (km)
Exceptionally clear	280
Very clear	50
Clear	20
Light haze	10
Haze	4
Thin fog	2
Light to thick fog	≤ 1

and the following values relating the attenuation coefficient κ to the visibility:

Visibility (km)	κ (km^{-1})
80	0.03
40	0.1
20	0.2

A number of workers have utilized Equation 16.13.74 with suitable values of the attenuation coefficient. Lihou and Maund have used values ranging from 0.4 km^{-1} for a clear day to 1.0 km^{-1} for a hazy day with an average of 0.7 km^{-1}. Hymes has used values of 0, 0.4, 1.0 and 2.0 km^{-1} for conditions ranging from zero absorption to foggy or smoky atmospheres. Simpson quotes values from Glasstone (1962) of 0.4, 1.0 and 2.01 km^{-1} for visual ranges of 10, 5 and 2 km, respectively.

A more fundamental treatment has been given by Simpson (1984 SRD R304). This SRD method involves the separate computation of the transmissivities based on absorption and on scattering and each of these transmissivities is calculated for a set of discrete 'windows' spanning the range of wavelengths. The overall atmospheric transmissivity is then obtained as the product of the transmissivities based on absorption and on scattering.

For the transmissivity based on absorption the approach followed is based on the transmission windows method of Elder and Strong (1953) and is as follows. The water absorption bands occur at wavelength $\lambda = 1.1, 1.38, 1.87, 2.7$ and 6.0 μm and the carbon dioxide bands at 2.7, 4.3 and 14.5 μm. The wavelength spectrum from 0.72 to 15.0 μm is divided into 8 windows, as shown in Table 16.56 separated by the water and carbon dioxide bands.

For a given window i the transmissivity based on absorption τ_{ai} is determined from the equations

$$\tau_{ai} = \exp(-A_i w^{1/2}) \qquad w < w_i \qquad [16.13.75a]$$

$$\tau_{ai} = k_i (w_i / w)^{\beta_i} \qquad w > w_i \qquad [16.13.75b]$$

where w is the concentration of water in the atmosphere (pr mm), w_i is the value of w which causes absorption in window i to go from weak band to strong band absorption (pr mm), and A_i, k_i and β_i, are constants. The units for water content refer to precipitable water (pr mm). Equation 16.13.75 is based on curve fitting of the plots given by Elder and Strong and on extensions by Simpson. Values of the parameters are given in Table 16.57.

For scattering transmissivity an empirical approach is taken. This transmissivity is given by the relation

$$\tau_{si} = \exp[-\beta(\lambda_i)x] \qquad [16.13.76]$$

where x is the path length and $\beta(\lambda_i)$ is the scattering coefficient for window i.

The scattering coefficient $\beta(\lambda_i)$ is reiated to the meteorological, or visible, range V. The meteorological range may be defined by the contrast between the sky and a distant black target. Taking a value of 2% contrast gives the relation

$$V = \frac{1.0}{0.02} \frac{1}{\beta n} \qquad [16.13.77]$$

Table 16.56 *Window limits for estimation of atmospheric transmissivity (Simpson, 1984 SRD R304) (Courtesy of the UKAEA Safety and Reliability Directorate)*

VII	0.9310	0.679	0.194	0.18
VIII	0.5980	0.784	0.122	0.165
I–VIII	0.2110	0.855	0.815	0.6

where n is the refractive index of the scattering particles. Following standard practice in evaluating the visual range at $\lambda = 0.55$ μm

$$\beta = 3.91/V \quad \lambda = 0.55 \qquad [16.13.78]$$

A widely used expression relating the scattering coefficient β to the wavelength λ is

$$\beta = A\lambda^{-q} \qquad [16.13.79]$$

where A is a constant and q is an index.

Then from Equations 16.13.76–16.13.79

$$\tau_{si} = \exp\left[-\frac{3.91}{V}\left(\frac{\lambda_i}{0.55}\right)^{-q} x\right] \qquad [16.13.80]$$

The value most often proposed for q is 1.3, but on exceptionally clear days it can be as high as 1.6 and for days in which haze reduces the visible range below 6 km a good estimate may be made from the relation

$$q = 0.585\ V^{1/3} \qquad [16.13.81]$$

The total transmissivity τ_{T_i} for window i is the product of the transmissivities based on absorption and on scattering:

$$\tau_{T_i} = \tau_{ai}\tau_{si} \qquad [16.13.82]$$

The radiation transmitted is then determined as follows. From the theoretical black body radiation spectrum a discrete black body radiation spectrum is derived with the radiation in each window i at a constant value. The discrete spectrum of transmitted radiation is then calculated by multiplying the theoretical values by the total transmissivity τ_{T_i} for each window i. The procedure is illustrated in Figure 16.81.

If desired, the overall transmissivily τ may then be determined as the ratio of the total radiation transmitted to the total black body radiation.

Values of the overall atmospheric transmissivity τ have been tabulated by Simpson. He considers black body flame temperatures of 1000, 1150, 1300, 1450 and 1600 K, ambient air temperatures of 0, 15 and 30°C, relative humidities of 10, 30, 70 and 100%, visual ranges of 2, 5, 10 and 20 km and actual ranges of from 5 m to 10 km. Some of the meteorological data for the United Kingdom given by Simpson are shown in Table 16.58. Values of the atmospheric transmissivity τ obtained by Simpson for some typical meteorological conditions are given in Table 16.59.

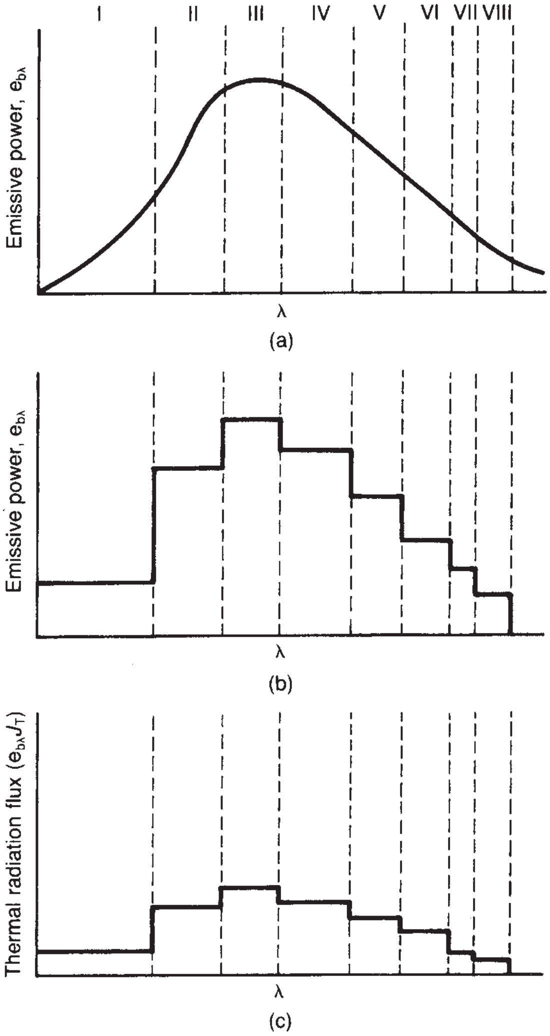

Figure 16.81 *Estimation of radiation transmitted through the atmosphere: (a) theoretical black body radiation spectrum; (b) black body radiation spectrum produced using the procedure outlined; (c) example of the effect of atmospheric transmission on the radiation spectrum (Simpson 1984 SRD R304). J_T thermal radiation flux (unattenuated) (Courtesy of the UKAEA Safety and Reliability Directorate)*

Simpson gives comparisons of results obtained with the SRD method with those obtained from the methods of Glasstone, Raj *et al.* and TNO. The Glasstone method gives higher values of the atmospheric transmissivity, which Simpson attributes primarily to the fact that the method neglects absorption. The agreement with the Raj method is better, though the latter gives higher values at the longer

distances, which Simpson attributes to the fact that the method neglects scattering. There is good agreement with the TNO method for the conditions where comparison can be made, but the SRD method is more comprehensive in that it takes into account the visual range.

A number of other treatments and expressions for atmospheric attenuation have been listed by Bagster and Pitblado (1989) and Satyanarayana, Borah and Rao (1991) as follows:

$$\tau = 1.382 - 0.135\log_{10}(p_{\mathrm{w}}x) \qquad \text{TNO (1979 } \textit{YellowBook}) \qquad [16.13.83]$$

$$\tau = 2.02(p_{\mathrm{w}}x)^{-0.09} \qquad \text{TNO revised} \qquad [16.13.84]$$

$$\tau = 1 - 0.058\ \ln x \qquad \text{Major Hazards Assessment Unit} \qquad [16.13.85]$$

where p_{w} is the partial pressure of water vapour (Pa) and x is the distance (m).

Wayne (1991) has given the following empirical method for the estimation of atmospheric transmissivity. The flame is assumed to be a black or gray body at a temperature of 1500 K, which is chosen as an average value lying between mat of a propane fire and that of an LNG fire. His equation is

$$\tau = 1.006 - 0.01171[\log_{10}X(\mathrm{H_2O})] - 0.02368[\log_{10}X(\mathrm{H_2O})]^2 - 0.03188[\log_{10}X(\mathrm{CO_2})] + 0.001164[\log_{10}X(\mathrm{CO_2})]^2 \qquad [16.13.86]$$

Table 16.59 *Some typical values of atmospheric transmissivity as a function of visual range (Simpson, 1984 SRD R 304) (Courtesy of the UKAEA Safety and Reliability Directorate)*

Visual range (km)	*Range* (m)	
	100	5000
1	0.581	0.003
2	0.631	0.046
3	0.656	0.115
4	0.662	0.176
5	0.665	0.224
10	0.665	0.341
50	0.421	–
100	0.426	–
500	0.426	–

with

$$X(\mathrm{CO_2}) = L\frac{273}{T} \qquad [16.13.87]$$

$$X(\mathrm{H_2O}) = R_{\mathrm{H}}LS_{\mathrm{mm}}\left(\frac{288.651}{T}\right) \qquad [16.13.88]$$

where L is the path length (m), is the fractional relative humidity, S_{mm} is the saturated vapour pressure of water at temperature T (mmHg), T is the atmospheric temperature (K),

$X(CO_2)$ is a function representing the amount of carbon dioxide in the path (m) and $X(H_2O)$ is a corresponding function for water vapour (µm). $X(H_2O)$ is actually defined as the thickness of the uniform liquid layer which would be obtained by notionally condensing the water vapour in an absorbing path of unit cross-sectional area onto its base. $X(H_2O)$ must not exceed a minimum value, assigned as 1 µm, which corresponds to a 10 m path through an atmosphere with $T = 253$ K and $R_H = 0.10$.

Another set of relations is that given by V.C. Marshall (1987), as described in Section 16.15.

16.13.10 Target absorptivity

The fraction of the incident radiant heat which the target absorbs depends on its absorptivity. As already described, absorptivity is closed related to emissivity. An account of the radiation properties of surfaces is given by Sparrow and Cess (1978).

Emissivity is generally tabulated as a property of the material. It should be borne in mind that it is dependent both on the surface condition and on the temperature. The emissivity of many materials has been tabulated by Hottel (McAdams, 1954). Hottel's table includes the following emissivities for steel:

Mild steel (after cleaning)	0.20–0.32
Rolled sheet steel	0.66
Rough steel plate	0.94–0.97

Numerous other tabulations are available.

In most flame radiation applications it is assumed that the absorptivity of a target is equal to the emissivity.

16.13.11 View factor

The treatment of radiant heat transfer from a source to a target is based on the concepts of the enclosure and of the angle factor. Estimation of the radiation incident on a surface requires that account be taken of the radiation arriving on that surface from all directions. In order to do this use is made of the concept of an enclosure for each surface of which the radiation properties and thermal state are defined. An enclosure is not necessarily bounded by solid surfaces; some surfaces may be open.

The other concept is that of the angle factor, also variously known as the shape, geometrical, configuration or view factor. Accounts of angle factors, or view factors, include those given by Hottel (1954), Hamilton and Morgan (1952), McGuire (1953), Sparrow and Cess (1978), Howell (1982) and Siegel and Howell (1991).

An expression for the angle factor between two differential surfaces dA_i and dA_j has been given in Equation 16.13.38 and is

$$dF_{dA_i-dA_j} = \cos\beta_i \cos\beta_j \, dA_j/\pi r^2 \qquad [16.13.89]$$

Similarly

$$dF_{dA_j-dA_i} = \cos\beta_j \cos\beta_i \, dA_i/\pi r^2 \qquad [16.13.90]$$

Hence from Equations 16.13.89 and 16.13.90

$$dA_i \, dF_{dA_i-dA_j} = dA_j \, dF_{dA_j-dA_i} \qquad [16.13.91]$$

Equation 16.13.91 is one of three reciprocity rules. The other two are

$$A_i dF_{dA_i-dA_j} = dA_j \, dF_{dA_j-dA_i} \qquad [16.13.92]$$

and

$$A_i F_{A_i-A_j} = A_j F_{A_j-A_i} \qquad [16.13.93]$$

A further property of angle factors which follows from the principle of energy conservation is

$$\sum_{j=1}^{N} F_{A_i-A_j} = 1 \qquad [16.13.94]$$

where N is the number of surfaces in the enclosure.

There are a number of methods for the derivation of angle factors. They include:

(1) direct integration;
(2) contour integration:
(3) short-cut methods
    (a) angle factor algebra,
    (b) elongated surfaces,
    (c) string method.

Angle factors have been derived for a large number of standard configurations. There are a number of tabulations available, including those of Hamilton and Morgan (1952), McGuire (1953), Stannard (1977), Sparrow and Cess (1978), Howell (1982) and Siegel and Howell (1991).

It is usual to give for each case the configuration diagram together with the governing equation. Angle factor algebra may be applied to derive an angle factor for a non-standard case from that for a standard case. As an illustration consider the derivation of the angle factor $F_{A_1-A_4}$ for the system shown in Figure 16.82. Applying the principle of energy conservation

$$A_1 F_{A_1-A_4} = A_{12} F_{A_{12}-A_4} - A_2 F_{A_2-A_4} \qquad [16.13.95]$$

where

$$A_{12} = A_1 + A_2 \qquad [16.13.96]$$

Applying the principle further

$$A_{12} F_{A_{12}-A_4} = A_{12} F_{A_{12}-A_{34}} - A_{12} F_{A_{12}-A_3} \qquad [16.13.97]$$

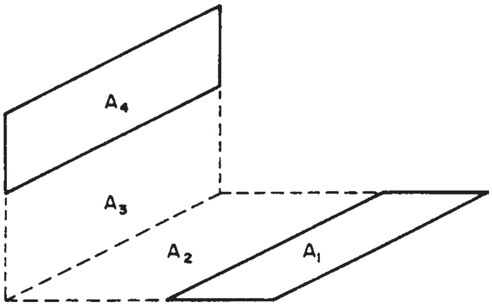

Figure 16.82 *Configuration for illustrative example of angle factor algebra (Sparrow and Cess, 1978) (Courtesy of Brooks/Cole Publishers)*

where

$$A_{34} = A_3 + A_4 \qquad [16.13.98]$$

and hence

$$A_2F_{A_2-A_4} = A_2F_{A_2-A_{34}} - A_2F_{A_2-A_3} \qquad [16.13.99]$$

Substituting from Equations 16.13.97 and 16.13.99 in Equation 16.13.95 yields

$$F_{A_1-A_4} = \frac{1}{A_1}(A_{12}F_{A_{12}-A_{34}} + A_2F_{A_2-A_3} - A_{12}F_{A_{12}-A_3} - A_2F_{A_2-A_{34}}) \qquad [16.13.100]$$

All the angle factors on the right-hand side of Equation 16.13.100 are obtainable from the single standard case of two adjacent surfaces at right angles to each other.

Treatments of view factors specifically oriented to process plant problems include those by Crocker and Napier (1986, 1988a,b) and B.C. Davis and Bagster (1989–).

An common situation is radiation from a source, which can be treated as a point source. In this case the radiation at a spherical surface is

$$E = \frac{Q_r}{4\pi r^2} \qquad [16.13.101]$$

where r is the radius of the spherical surface. Then, for simplicity, neglecting the absorptivity of the target and the atmospheric transmissivity, the heat radiation intensity received by the target is

$$I = \frac{FQ_r}{4\pi l^2} \qquad [16.13.102]$$

where l is the slant distance from the point source to the target.

Then from Equations 16.13.101 and 16.13.102, with Equation 16.13.49 the view factor for this case is

$$F \approx \frac{r^2}{l^2} \qquad [16.13.103a]$$

$$F \approx \frac{r^2}{x^2} \quad x \approx 1 \gg r \qquad [16.13.103b]$$

where l is the slant distance and x is the ground distance from the point source to the target.

An important class of flame is elevated flames such as flares and fireballs. These are frequently treated as point sources using Equations 16.13.101–16.13.103.

The view factor is affected by the orientation of the target. The implicit assumption in Equations 16.13.102 and 16.13.103 is that the surface of the target is normal to the line connecting it with the point source. For heat radiation from an elevated point source to a small, or differential, target, a correction is required if the target is, say, vertical or horizontal. For a target which is vertical, so that the line between the point source and the target makes an angle θ with the horizontal, the correction factor to be applied to the view factor is cos θ. For a target which is horizontal, so that the line between the point source and the target makes an angle ϕ with the vertical, the correction factor is cos ϕ. Then, since $\theta + \phi = 90°$, $\cos\phi = \sin\theta$. Hence for these two cases, from Equation 16.13.103

$$F = \frac{r^2}{x^2}\cos\theta \qquad \text{Vertical target} \qquad [16.13.104]$$

$$F = \frac{r^2}{x^2}\sin\theta \qquad \text{Horizontal target} \qquad [16.13.105]$$

Equations for view factors are often expressed not in terms of the angle θ but of the lengths of the two sides of the relevant triangle.

The expressions just given apply to differential elements, or, in practice, small objects. This is generally taken to include the human body. Larger objects, such as storage tanks, are finite surfaces.

For the purposes of determining a view factor, there are a number of different ways of treating a flame. They include treatment as (1) a single point source, (2) multiple point sources, (3) an equivalent radiator or (4) a solid flame. The equivalent radiator (ER) model treats the flame as a two-dimensional surface. For example, the flame on a pool fire is represented as a vertical rectangle. In the solid flame (SF) model the flame is treated as a three-dimensional solid body. For example, the pool fire flame is represented as a vertical cylinder. The point source (PS) and multiple point source (MPS) models are self-explanatory.

Table 16.60 gives references to certain standard view factors listed by Siegel and Howell (1991) which may be of use in work on radiant heat transfer in process plants. Relations for view factors for fireballs, pool fires, flares and jet flames are given in Sections 16.15 and 16.17–16.19, respectively.

16.14 Vapour Cloud Fires

A vapour cloud fire, or flash fire, occurs when a vapour cloud forms from a leak and is ignited, but without creation of significant overpressure. If such overpressure occurs, the event is a vapour cloud explosion (VCE) rather than a vapour cloud fire (VCF).

16.14.1 vapour cloud fire incidents

Release of flammable vapour from a process plant followed by ignition is a not uncommon occurrence. If the ignition is prompt, the cloud may be modest in size, but if the cloud has time to spread over an appreciable part of the site and is then ignited, a major vapour cloud fire may result. This occurs in only a very small proportion of ignited releases.

Large and destructive vapour cloud fires occurred at Port Newark, New Jersey, in 1951 and at Mexico City, Mexico, in 1984. These and other incidents are described in Section 16.38 and Appendix 4.

16.14.2 Experimental studies

Early experimental work on the combustion of vapour clouds from spills on land has been described by Raj (1977) and work at China Lake in 1978 on spills on water has been described by A.D. Little (1979).

Large-scale tests involving vapour cloud fires from spills of refrigerated liquefied gas on water have been conducted in association with other tests concerned with

heavy gas dispersion. The vapour cloud dispersion and fire tests at Maplin Sands have been described by Blackmore, Eyre and Summers (1982) and Hirst and Eyre (1983), and those at China Lake in 1980–81 have been described by Ermak *et al.* (1983). An account of the dispersion tests has already been given in Chapter 15.

The Maplin Sands trials involved the spillage onto the sea, dispersion and, in some cases, combustion of liquefied natural gas (LNG) and refrigerated liquid propane. Both quasi-instantaneous and continuous releases were made. In the trials involving combustion, seven were with LNG and four were with propane. Plate 9 shows the progress of Trial 27 at Maplin.

Ignition was effected by spark igniters located on certain pontoons. In two of the LNG tests flame failure occurred soon after ignition. Moreover, infrared measurements indicated that in several tests, both with LNG and with propane, at least one and sometimes two ignitions were followed by flame failure before the bulk of the cloud ignited. These latter failures were not visible to the eye. Flame failure was attributed to inhomogeneities of the concentration in the cloud.

The instantaneous and continuous releases differed in that, whereas in the latter a pool of liquefied gas was created which gave in effect a pool fire also, in the former there was no pool fire.

The combustion of the vapour cloud involved first burning of the pre-mixed part and then diffusive burning of the fuel-rich part. The flame in the pre-mixed burning did not propagate quickly across the top of the cloud, but remained as a 'wall of fire'.

Expansion of the combustion products was principally in the vertical direction. The unburnt gas was not pushed ahead of the flame front to any significant extent. Where a pool fire occurred, the height of the flame was appreciably greater.

The vapour clouds were made visible by the associated water fog. In the case of the LNG clouds the contour of the lower flammability limit (LFL) lay within that of the fog, and combustion was entirely within the visible fog; some of the visible cloud remained unburned. For the propane clouds the LFL contour lay outside the fog and combustion took place in part outside it.

The flame speeds measured during the combustion were relatively low, and far removed from the figure of 150 m/s often quoted as necessary for the generation of appreciable overpressure. For LNG in Test 27 the flame speed averaged 4 m/s with a maximum of 10 m/s, whilst for pronane in Test 51 the corresponding figures were 12 and 20 m/s, respectively.

Pressure deviations measured during the combustion were a maximum of 0.8 mbar for LNG and 0.4 mbar for propane. The maximum deviations were underpressures, the overpressures being rather less. The form of the decay of the overpressure was that the overpressure was inversely proportional to the distance.

With regard to thermal radiation, the surface emissive power of the cloud fires was measured as 173 kW/m^2 for both LNG and propane. For the pool fires the values obtained were 203 kW/m^2 for LNG but 43 kW/m^2 for propane. The authors suggest that a value of 200 kW/m^2 may be representative for larger vapour cloud fires and for LNG pool fires. The lower value for propane pool fires is in accordance with results for pool fires of propane on land, as described below.

The account of the combustion tests in the Coyote trials described by Ermak *et al.* (1983) gives broad confirmation of these findings. The tests involved 40 m^3 spills of LNG onto water. Again the flame velocities were modest. They lay in the range 11.9–18.9 m/s for wind speeds of 4.6–10.0 m/s, the values of the flame speed less the wind speed being 6.4–12.9 m/s. The flame velocities appeared to be high near the ignition source, whether a flare or a jet, and fell off rapidly. There was no indication of significant flame acceleration. The flame heights were somewhat higher than in the Maplin tests.

16.14.3 Empirical features

The foregoing description indicates some of the empirical features of a vapour cloud fire. A further account is given by Crawley (1982). The conditions favouring a vapour cloud fire are a prolonged release in conditions of poor dispersion.

Two main types of flame behaviour have been assumed. Raj and Emmons (1975) conceive the burning as a 'wall of fire', whilst Fay and Lewis (1977) propose the formation of a fireball by the rising thermal. No fireball effect is mentioned in connection with the tests just described. The wall of fire mode occurs in the combustion of the fuel-rich portion. Overall, the combustion is usually not especially rapid or violent, the flame progressing through the cloud at a speed of several metres per second.

Strictly, a vapour cloud combustion which generates overpressure has to be classed as a vapour cloud explosion. In practice, the latter term tends to be reserved for cases where the explosion causes significant destruction. For vapour cloud fires, the overpressures vary from the imperceptible up to those which may cause some window damage.

A vapour cloud fire may cover a wide area, perhaps some thousands of square metres. It results in scorching and depletion of oxygen, with potential for injury and damage. It may initiate BLEVEs and other releases of flammable material which then feed the fire. It also deposits soot.

16.14.4 Modelling of vapour cloud fires

The hazard from a vapour cloud fire is usually assessed by considering dispersion of the vapour cloud and ignition of this cloud and making some relatively simple assumption concerning the effects inside and outside the cloud.

In many assessments no explicit model of a vapour cloud fire has been utilized. Instead it has been assumed that: the contours of the burning cloud are those of the lower flammability limit concentration; persons inside the cloud suffer a denned degree of injury, generally a fatal injury; and those outside the cloud are subject to a level of thermal radiation based on an assumed surface emissive power at the edge of the burning cloud.

16.14.5 Eisenberg, Lynch and Breeding model

An early model for a flash fire is the Vulnerability model by Eisenberg, Lynch and Breeding (1975). The vapour cloud is assumed to be a half ellipsoid with volume V_r and area A_r given by the equations

$$V_r = \frac{2\pi}{3}\sigma_x\sigma_y\sigma_z(r_l^3 - r_u^3) \qquad [16.14.1]$$

$$A_r = \frac{2\pi}{3}(\sigma_x^2 + \sigma_y^2 + \sigma_z^2)(r_l^2 + r_u^2) \qquad [16.14.2]$$

with

$$r_l = 2\ \ln\left[\frac{2m}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z k_l}\right]^{1/2} \qquad [16.14.3]$$

$$r_u = 2\ \ln\left[\frac{2m}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z k_u}\right]^{1/2} \qquad [16.14.4]$$

where A_r is the area of radiation of the hot gas layer (m^2), k_l is the concentration at the lower explosive limit (kg/m^3), k_u is the concentration at the upper explosive limit (kg/ m^3), m is the total mass of vapour released (kg), r_l is a parameter of the cloud at the lower explosive limit, r_u is a parameter of the cloud at the upper explosive limit, V_r is the volume of the hot gas layer (m^3), and σ_x, σ_y and σ_z are dispersion coefficients in the downwind, crosswind and vertical (x, y and z) directions, respectively (m).

The heat loss q from the gas is predominantly by radiation, so that

$$q \approx A_r\sigma(\epsilon_g T_g^4 - \epsilon_a T_a^4) \qquad [16.14.5]$$

where q is the heat loss by radiation (W), T_a is the absolute temperature of the environment (K), T_g is the absolute temperature of the hot gas (K), ϵ_a is the emissivity of the environment, ϵ_g is the emissivity of the hot gas and ϵ is the Stefan-Boltzmann constant ($= 5.67 \times 10^{-8}$ W/m^{2}K^4).

The layer of radiating gas may be expected to be some tens or even hundreds of meters thick. Under these conditions the gas emissivity does not change much with layer thickness or temperature and has a value of about 0.5. The authors replace Equation 16.14.5 by the approximate relation

$$q \approx A_r\sigma(T_g^4 - T_a^4) \qquad [16.14.6]$$

The gas emissivity of unity in Equation 16.14.6 includes an allowance for the other modes of heat transfer.

The heat loss is also given by

$$q = -c_p\rho V_r\frac{dT_g}{dt} \qquad [16.14.7]$$

where c_p is the specific heat of the hot gas layer (J/ kg K), the time (s) and ρ is the density of the hot gas layer (kg/m^3). The hot gas layer is nearly always mostly air.

Equating the heat flows in Equations 16.14.6 and 16.14.7 gives

$$\frac{dT_g}{dt} = -k(T_g^4 - T_a^4) \qquad [16.14.8]$$

with

$$k = \frac{A_r\sigma}{c_p\rho V_r} \qquad [16.14.9]$$

Equation 16.14.8 has the solution

$$t = \frac{1}{2kT_a^3}\left\{\left[\tan^{-1}\left(\frac{T_g}{T_a}\right) - \frac{1}{2}\ln\left(\frac{T_g - T_a}{T_g + T_a}\right)\right] - \left[\tan^{-1}\left(\frac{T_{gi}}{T_a}\right) - \frac{1}{2}\ln\left(\frac{T_{gi} - T_a}{T_{gi} + T_a}\right)\right]\right. \qquad [16.14.10]$$

where subscript i denotes the initial value.

Equation 16.14.10 may be rewritten in terms of the half-life $t_{1/2}$ of the fire, or the time at which

$$T_g = \frac{T_{gi} + T_a}{2} \qquad [16.14.11]$$

Then

$$t_{1/2} = \frac{1}{2kT_a^3}\left[\tan^{-1}\left(\frac{\beta+1}{2}\right) - \tan^{-1}\beta - \frac{1}{2}\ln\left(\frac{\beta+1}{\beta+3}\right)\right] \qquad [16.14.12a]$$

or, in the equivalent form given by the authors,

$$t_{1/2} = \frac{1}{2kT_a^3}\left[\tan^{-1}(1/\beta) - \tan^{-1}\left(\frac{2}{\beta+1}\right) - \frac{1}{2}\ln\left(\frac{\beta+1}{\beta+3}\right)\right] \qquad [16.14.12b]$$

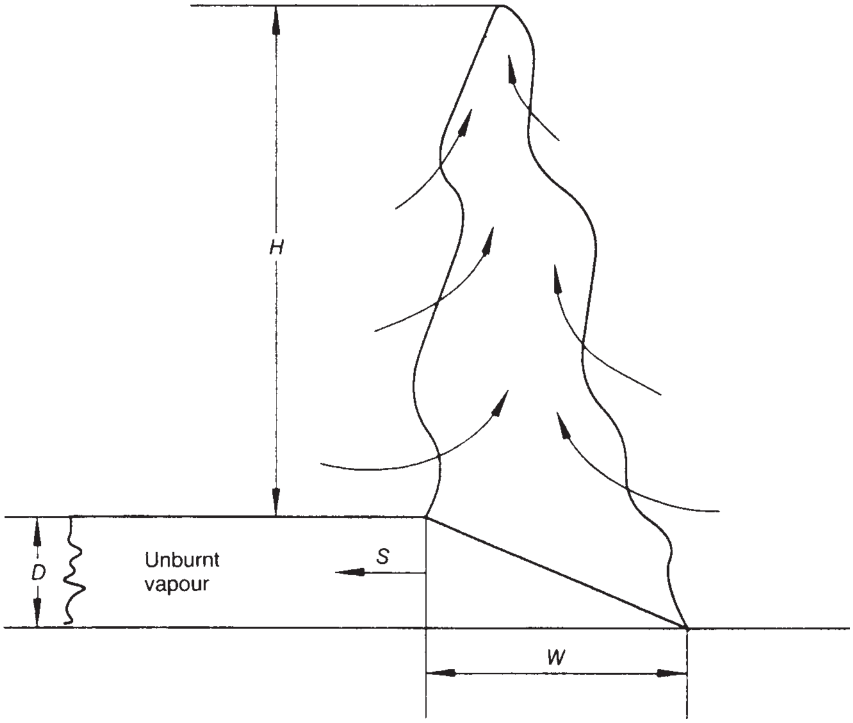

Figure 16.83 *Flame at the edge of a burning vapour cloud (after Raj and Emmons, 1975; CCPS, 1994/15) (Reproduced by permission of the American Institute of Chemical Engineers)*

with

$$\beta = T_{gi}/T_a \qquad [16.14.13]$$

where $t_{1/2}$ is the half-life of the flash fire (s).

The effective thermal radiation intensity is given by

$$I_r = \sigma(T_g^4 - T_a^4) \qquad [16.14.14]$$

where I_r is the effective thermal radiation intensity of the flash fire (W/m^2).

The effective time duration t_{eff} is

$$t_{eff} = 3t_{1/2} \qquad [16.14.15]$$

where t_{eff} is the effective time duration of the flash fire (s). The initial value of the absolute temperature of the hot gas T_{gi} is taken as the adiabatic flame temperature.

16.14.6 Raj and Emmons model

Another flash fire model is that of Raj and Emmons (1975). This model takes into account the speed of the flame propagating through the cloud. The assumptions made are that during the combustion of a vapour cloud there is a turbulent flame front propagating into the unburned cloud at a constant velocity which is roughly proportional to the wind speed, and that at high gas concentrations there is a tall flame plume at the edge of the unburned cloud.

This model is represented in Figure 16.83 in which a flame front is propagating at constant velocity S into an unburned cloud of depth D with a flame base of width W and a flame height H above the top of the cloud.

The treatment of flame height is based on the pool fire model of F.R. Steward (1964). The observed height of such flames is approximately twice that of the base ($H/W = 2$). Application of the conservation equations gives a relation between the flame height and the upward velocity of the gases. Then from a mass balance on the triangle formed by the flame and the base, a relation may be derived between the flame height H and the flame speed S.

This treatment forms the basis of the semi-empirical equation given by Raj and Emmons for the flame height of a flash fire:

$$H = 20D\left[\frac{S^2}{gD}\left(\frac{\rho_o}{\rho_a}\right)^2 \frac{wr^2}{(1-w)^3}\right]^{1/3} \qquad [16.14.16]$$

with

$$S = 2.3U_w \qquad [16.14.17]$$

where D is the cloud depth (m), g is the acceleration due to gravity (m/s^2), H is the visible flame height (m), r is the stoichiometric air–fuel mass ratio, S is the flame speed, or 'burning speed' (m/s), U_w is the wind speed (m/s), w is a parameter, ρ_a is the density of air (kg/m^3) and ρ_o is the density of the fuelair mixture (kg/m^3).

The parameter w represents the inverse of the volumetric expansion due to combustion in the plume and is strongly dependent on the composition of the cloud. For a cloud of pure vapour, $w \approx 1/9$, assuming the vapour is hydrocarbon, whilst for a cloud of stoichiometric composition or leaner, $w = 0$.

The application of the relation for w given by Raj and Emmons is somewhat complex. As described below, the Center for Chemical Process Safety (CCPS) has developed an alternative and more straightforward equation.

The expression for the flame speed S is derived by Raj and Emmons from a limited number of experimental observations.

The heat flux incident on a receptor may be estimated from Equation 16.13.49.

16.14.7 CCPS model

The set of hazard models given in the CCPS *Fire and Explosion Model Guidelines* (1994/15) includes a model for flash fires. The model is essentially that of Raj and Emmons with a modification of the expression for the parameter w. For this the CCPS gives

$$w = 0 \quad \phi \leq \phi_{st} \qquad [16.14.18a]$$

$$w = \frac{\phi - \phi_{st}}{\alpha(1 - \phi_{st})} \quad \phi > \phi_{st} \qquad [16.14.18b]$$

where α is the constant pressure expansion ratio for stoichiometric combustion, ϕ is the volumetric concentration of fuel (v/v) and the subscript st denotes stoichiometric. For hydrocarbons the value of α is typically about 8.

In applying the model for the estimation of thermal radiation the CCPS propose the use of the following two assumptions: (1) during the propagation of the flash fire, the cloud is stationary and is fixed and homogeneous in composition; and (2) the time-dependent flame surface is a plane cross-section moving through the cloud at the flame speed.

16.14.8 Considine and Grint model

Considine and Grint (1985) have given a model for a flash fire in the form of graphs of the distance to particular levels of fatal injury. This model is described in Section 16.39.

16.15 Fireballs

Another significant fire hazard is that from fireballs. Accounts of fireballs include those by Gayle and Bransford (1965), R.W. High (1968), Hardee and Lee (1973), Strehlow and Baker (1976), Fay and Lewis (1977), V.C. Marshall (1977a, 1987), Hardee, Lee and Benedick (1978), Hasegawa and Sato (1977, 1978), Fay, Desgroseillers and Lewis (1979), Williamson and Mann (1981), A.F. Roberts (1981/82, 1982), Crawley (1982), Lihou and Maund (1982), Moorhouse and Pritchard (1982), W.E. Baker *et al.* (1983), Pietersen (1985), Jaggers *et al.* (1986), Roper *et al.* (1986), D.M. Johnson and Pritchard (1991) and the CCPS (1994/15).

Most treatments of fireballs relate to liquefied gas. Here a distinction needs to be made between a fireball resulting from the bursting of a pressure vessel and one resulting from the formation of a vapour cloud. In the first case the bursting may occur under fire conditions and be part of a BLEVE or it may occur in the absence of fire. Momentum forces predominate if a fireball is formed from the bursting of a vessel, and buoyancy forces predominate in one formed from a vapour cloud.

There are two other types of event which may give rise to a 'fireball'. One is the ignition of a release on a liquefied gas pipeline, where the jet flame is preceded by a fireball in which unignited gas is burned. The other is an eruption in hot oil giving rise to a release of burning vapour. This is exemplified by the event that occurs when water is added to burning fat in a chip pan. Eruptions of burning vapour have occurred in some storage tank fires.

An instance has also occurred of a congested fireball following rupture and release of the flammable contents of a reactor into a building.

The type of fireball of particular interest, however, is that which occurs as part of a BLEVE and it is this type which is mainly treated here.

A quite different type of fireball is that associated with the explosion of a propellant or high explosive. Such fireballs are discussed in the next section.

Some studies on fireballs are given in Table 16.61.

16.15.1 Fireball incidents

Incidents involving fireballs are not uncommon. They usually occur as pan of a BLEVE when a vessel ruptures after it has been engulfed in fire or has been subjected to a directed flame. The vessels principally liable to such conditions are storage vessels, rail tank cars and road tankers.

Fireball incidents are generally associated with BLEVE incidents. BLEVEs are considered in Chapter 17, which contains in Table 17.37 a list of incidents involving fireballs with and without BLEVE.

A massive BLEVE fireball occurred at Crescent City, Illinois, in 1970 with an estimated diameter of 150–200 m (Case History A50). Other major BLEVE fireball inti-dents include those at Houston, Texas, in 1971 (Case History A53), Lynchburg, Virginia, in 1972 (Case Histoiy A59), Kingman, Arizona, in 1973 (Case History A63), Oneonta, New York, and West St Paul, Minnesota, in 1974, and Belt, Montana, in 1976. The estimated diameters of the fireballs at Houston, Kingman and Belt were 300 m. The disaster at Mexico City in 1985, described in Appendix 4, involved a series of fireballs from BLEVEs. Other fireball incidents have occurred at Eagle Pass, Texas, in 1975, Goldona, Virginia, in 1977, and Donnellson, Iowa (Case History A91) and Lewisville, Arkansas, in 1978. The estimated diameter of the fireball at Donnellson was 610 m and of those at Goldonna and Lewisville 320 and 310 m, respectively.

16.15.2. Experimental studies

Experimental research on fireballs has taken three main forms treating fireballs generated by: (1) explosives and propellants, (2) gas-filled bubbles and balloons and (3) containers undergoing BLEVE.

Early experimental investigations of fireballs were concerned with fireballs from propellants. Gayle and Bransford (1965) obtained data from 47 tests and incidents with the mass of combined propellant (fuel + oxidizer) in the range 10–250,000 lb.

A correlation for the diameter of the fireball of the propellant of the Saturn rocket of NASA, based on tests, has been given by R.W. High (1968).

Taking first small scale tests, Fay and Lewis (1977) studied the fireball from hydrocarbon fuels held initially,

inside soap bubbles with volumes in the range 20–190 cm^3. Hasegawa and Sato (1977) carried out a series of 22 tests on fireballs of *n*-pentane held in glass spheres with a fuel mass in the range 3.1–6.2 kg. These authors also performed a further series of 32 tests on fireballs with a fuel mass in the range 3.1–31.0 kg. Hardee, Lee and Benedick (1978) have described tests on fireballs of pure and pre-mixed methane held in balloons and polyethylene bags, with quantities in the range 0.1–10 kg. A.F. Roberts (1981/82) reports two unpublished tests by A. Baker (1979) with a fuel mass of the order of 10 kg. Lihou and Maund (1982) have described experiments on fireballs from hydrocarbons in bubbles with a fuel mass in the range 0.07–6 g.

Of the larger scale tests, most have been associated with BLEVEs. C. Anderson *et al.* (1975) have described a test on a fully loaded 125 m^3 rail tank car which was made to suffer a BLEVE. A single fireball experiment with a fuel mass of 452 kg has been described by Maurer *et al.* (1977) and Giesbrecht *et al.* (1980). In the work at Bundesanstalt für Materialprüfung (BAM) on fire engulfed vessels, described by Schulz-Forberg, Droste and Charlett (1984), Droste and Schoen (1988) and Schoen, Probst and Droste (1989), several of the vessels were taken to the point of a BLEVE. Other larger scale experiments on BLEVEs have been reported by D.M. Johnson and Pritchard (1991). In this work the mass of fuel involved was of the order of 1–2 te.

16.15.3 Empirical features

A fireball from the bursting of a pressure vessel containing liquefied gas is observed to pass through a number of fairly well-defined phases.

The development of a full-scale fireball is captured in the National Fire Protection Association (NFPA) film on BLEVEs. Crawley (1982) has described the development based on a frame-by-frame analysis of this film. The fireball passes through three phases: (1) growth, (2) steady burning and (3) burnout. The growth phase may be divided into two intervals, each of about 1 s duration. In the first interval the flame boundary is bright with yellowish-white flames indicating a flame temperature of about 1300°C. The fireball grows to about half its final diameter. Calculation indicates that fuel droplets of less than 4–5 mm diameter would vapoirize. This would give good mixing with air at the droplet scale. There would also be good bulk mixing.

In the second interval of the growth phase, the fireball grows to its final volume, but about 10% of the surface is dark and sooty with the rest being white, yellowish-orange or light red, indicating flame temperatures in the range 900–1300°C, with an estimated effective flame temperature of 110–1200°C.

In the second phase, which lasts some 10 s, the fireball, which is now roughly spherical, is no longer growing. At the start of this phase it begins to lift off. It rises and changes to the familiar mushroom-shape. The estimated effective flame temperature is 1100–1200°C.

In the third phase, which lasts some 5 s, the fireball remains the same size, but the flame become less sooty and more translucent.

Figure 16.84 illustrates the typical development of a fireball as a function of time.

The experimental work has also yielded useful information on aspects such as the fraction of the fuel which participates in the fireball, the fireball diameter and duration, the fraction of heat of combustion which is radiated, and the surface emissive power of the fireball. These aspects are discussed below.

16.15.4 Modelling of fireballs

The modelling of fireballs covers the following aspects: (1) the fireball regime, (2) the mass of fuel in the fireball, (3) the fireball development and timescales, (4) the fireball diameter and duration, (5) the heat radiated and (6) the view factor.

The treatment of the heat radiated from a fireball is a good illustration of the different approaches which may be taken to the modelling of fires in process plants. Specifically, there are three different ways of determining the heat radiated. One is to assume that it is a given fraction of the heat released. Another is to assume a given value for the heat radiated from the flame surface, or surface emissive power.

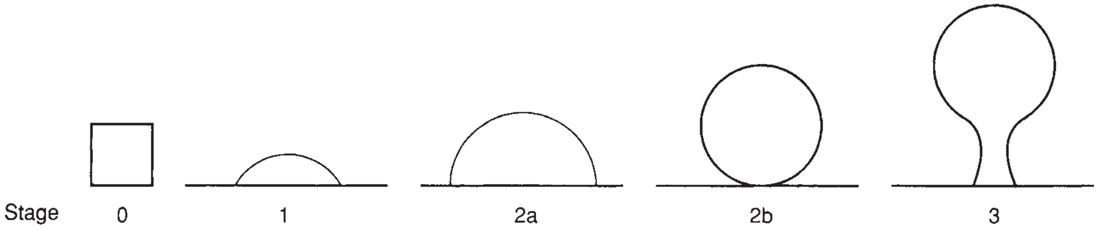

Figure 16.84 *Development of a typical fireball from a source at ground level*

The third is to estimate the heat radiated from the flame properties, such as flame temperature and emissivity.

Models of fireballs are of two broad types: correlations of diameter and duration time, and fundamental models.

In order to maintain some consistency with the notation of the original authors, the symbols M and W are both used for mass.

16.15.5 Fireball regimes

As stated earlier, there are two basic scenarios for the fireball of a liquefied gas. The case of prime interest is a fireball resulting from the bursting of a pressure vessel. The other case is a fireball from the burning of a stationary vapour cloud at atmospheric pressure.

These two situations constitute quite different regimes. The duration times for these are: for the bursting vessel where momentum forces dominate

$$t_d \propto M^{1/3} \qquad [16.15.1]$$

and for a vapour cloud where buoyancy forces dominate

$$t_d \propto M^{1/6} \qquad [16.15.2]$$

where M is the mass of fuel (kg) and t_d is the duration time (s).

For the situation where initially there is high momentum, a change of regime occurs as the momentum declines and gravity slumping begins.

The case of prime interest here is the bursting of a vessel, but that of a stationary vapour cloud is also treated in Subsections 16.15.17 and 16.15.18.

16.15.6 Mass of fuel

The mass of fuel in the fireball depends on the fraction of fuel which flashes off and on the further fraction which forms liquid spray.

For propane the relation between the theoretical adiabatic flash fraction and the liquid temperature and vapour pressure is shown in Figure 16.85 (A.F. Roberts, 1981/82). The 35% flash fraction occurs at 21°C and the 50% flash faction at 45°C.

Hasegawa and Sato (1977) found that when the theoretical adiabatic flash fraction reaches 35% virtually all the liquid released burns as a fireball.

From this, A.F. Roberts (1982) derives the relalions

$$f = \frac{M}{M_r} = 0 \quad \phi = 0 \qquad [16.15.3a]$$

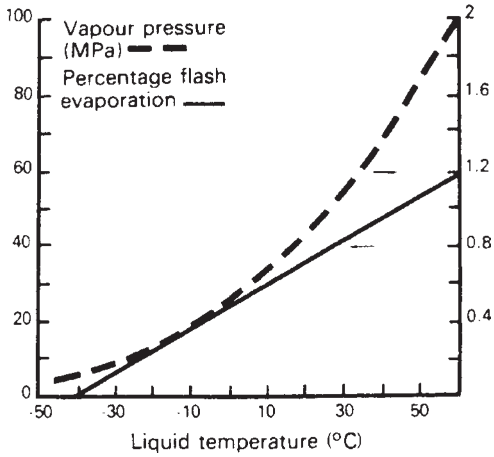

Figure 16.85 *Relation between the theoretical adiabatic flash fraction and temperature and vapour pressure prior to rupture for a fireball (A.F. Roberts, 1981/82). (Reproduced by permission of the Fire Safety Journal)*

$$f = 1 \quad \phi \geq 0.35 \qquad [16.15.3b]$$

where f is the fraction of fuel released entering the fireball, M is the mass of fuel in the fireball (kg), M_r is the mass of liquid released (kg) and ϕ is the fraction of liquid vaporized. Hence by linear interpolation

$$f = \frac{\phi}{0.35} \qquad 0 < \phi < 0.35 \qquad [16.15.3c]$$

This treatment is broadly equivalent to the rule of thumb commonly used for fireballs that the fraction of the fuel released which participates in the fireball is three times the flash fraction. This is the method used by the CCPS (1994/15) to determine the mass of fuel in the fireball.

Both the equations and the rule of thumb just quoted evidently derive from the Hasegawa and Sato's work. An essentially similar approach is taken in the treatment given by V.C. Marshall (1987), as described in Subsection 16.15.20, except that he makes a distinction between summer and winter conditions. Another commonly used, and conservative, approach is to assume that all the fuel released enters the fireball.

16.15.7 Fireball development and timescales

A fireball is of relatively short duration, but it passes in its life cycle through several distinct stages which need to be carefully defined if confusion is to be avoided. A discussion of these stages and of the associated time scales is given by A.F. Roberts (1981/82).

He distinguishes three distinct stages of fireball development. Stage 1 involves the rapid mixing of the fuel with air and rapid combustion of the fuel and is dominated by the initial momentum of release. In Stage 2, the residual fuel is mixed with air already in the cloud or entrained into it and is burned; this stage is more affected by buoyancy and combustion effects and less by the initial momentum. In Stage 3, with combustion essentially complete the fireball rises due to buoyancy, entraining further air and cooling; in this stage the size may be increasing or decreasing depending on the relative rates of air entrainment and of heat loss. These stages of development are illustrated for a small fireball in Figure 16.86.

Roberts defines five timescales. The time t_a is the duration of combustion in a system dominated by initial momentum effects. The time t_b is the duration of combustion in a system dominated by buoyancy effects, and t_c is the duration of combustion in a system dominated by deflagration effects; these are alternatives to time t_a. The time t_d is that at which visible radiation from the fireball ceases. The time t_e is that at which fireball lift-off occurs. Of the three combustion times, that of prime concern here is t_a which is that applicable to a fireball following bursting of a vessel.

16.15.8 Fireball diameter and duration

Fundamental models of fireballs are given below. The most widely used models, however, are essentially correlations of fireball diameter and duration time, of which there are a considerable number.

Various workers have correlated fireball diameter using a relation of the form

$$D = k_1 M^{n_1} \qquad [16.15.4]$$

where D is the diameter of the fireball (m), k_1 is a constant and n_1 is an index.

An early correlation of fireball diameter is that of R.W. High (1968), who gives

$$D = 9.82\ W^{0.320} \qquad [16.15.5a]$$

where D is the diameter of the fireball (ft) and W is the mass of propellant (fuel + oxidizer) (lb). Roberts converts this equation to

$$D = 2.95\ W^{0.320} \qquad [16.15.5b]$$

where D is the fireball diameter (m) and W is the mass of propellant (kg).

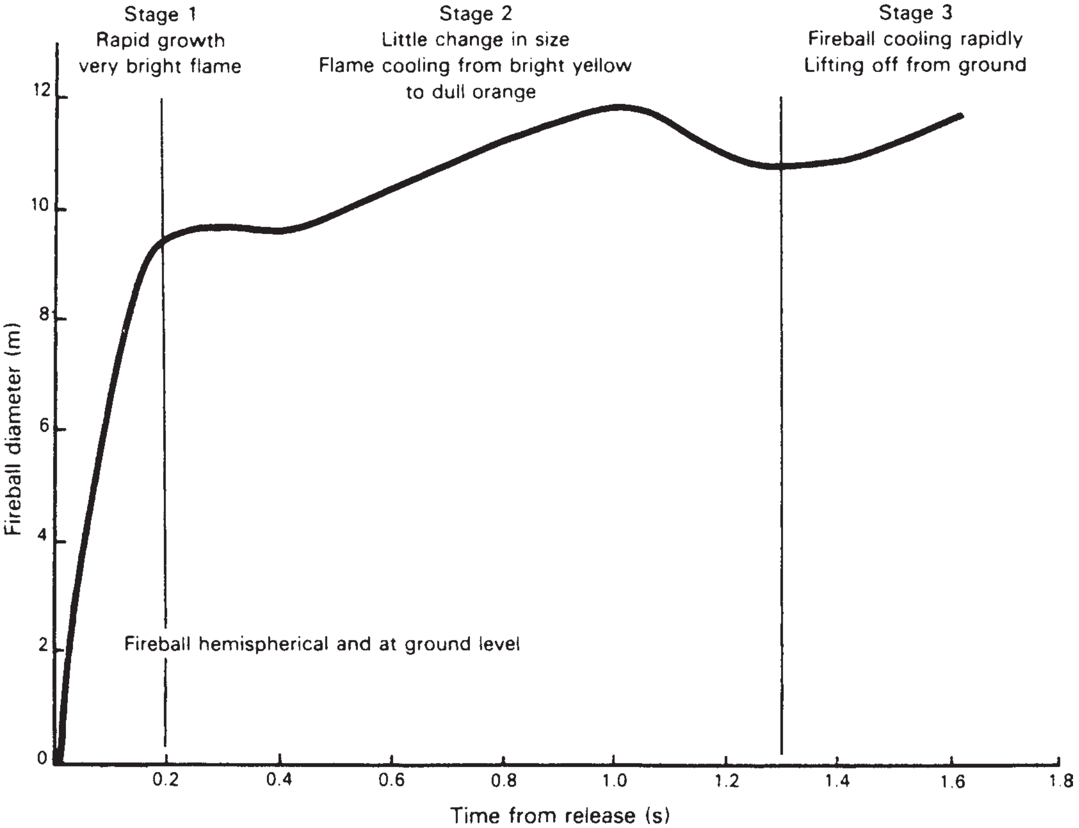

Figure 16.86 *Timescales for the development of a small fireball (A.F. Roberts, 1981/82). (Reproduced by permission of the Fire Safety Journal)*

Hasegawa and Sato (1978) give for their definitive correlation following their second series of tests

$$D = 5.25M^{0.314} \qquad [16.15.6]$$

The available experimental data on, and correlations for, fireball diameters have been reviewed by A.F. Roberts (1981/82) who obtained for hydrocarbons the following relation:

$$D = 5.8M^{1/3} \qquad [16.15.7]$$

This is now probably the mostly widely used correlation for fireball diameter.

Most correlations of the duration time t_d are of the form

$$t_d = k_2 M^{n_2} \qquad [16.15.8]$$

where k_2 is a constant and n_2 is an index.

An early equation for duration time is that of R.W. High (1968) who gives the following equation for the persistence time

$$d = 0.232\, W^{0.320} \qquad [16.15.9a]$$

where d is the persistence time (s) and W is the mass of propellant (lb). Roberts converts this to the equivalent relation

$$t_d = 0.49M^{0.320} \qquad [16.15.9b]$$

Hasegawa and Sato give equations for the duration time of their first set of experiments with smaller fireballs ($M < 6.1$ kg) and for the combined sets of experiments with smaller and larger fireballs. The exponents in their equations are 0.097 and 0.181, respectively.

These two sets of correlations reflect, therefore, the difference in the exponent discussed in Subsection 16.15.5.

Here it is the fireball from the bursting of a vessel which is of prime interest. From a review of the experimental data and correlations for duration time, Roberts obtains

$$t_d = 0.45M^{1/3} \qquad [16.15.10]$$

Equation 16.15.10 is not applicable, however, to larger masses, where the regime is dominated by buoyancy rather than momentum. These different regimes have been described in Subsection 16.15.5 and are treated again in the model of Jaggers, Roper et al. in Subsection 16.15.18. In the buoyancy-dominated regime, the index of M is approximately 1/6 rather than 1/3 as in the momentum dominated regime. The Major Hazards Assessment Panel (MHAP) (1988 LPB 82) has therefore proposed the following modification:

$$t_d = 0.45M^{1/3} \quad M < 30{,}000 \qquad [16.15.11]$$

$$t_d = 2.6M^{1/6} \quad M > 30{,}000 \qquad [16.15.12]$$

Pietersen (1985) gives for LPG fireballs the correlations

$$D = 6.48M^{0.333} \qquad [16.15.13]$$

$$t_d = 0.852M^{0.26} \qquad [16.15.14]$$

A summary of correlations of fireball diameter and duration time is given in Table 16.62. Further comparisons of such correlations are given by Bagster and Pitblado (1989), Satyanarayana, Borah and Rao (1991) and the CCPS (1994/15).

16.15.9 Heat radiated

There are three methods of estimating the heat radiated by a fireball. These are based on (1) the heat evolved and radiated, (2) the surface emissive power and (3) the flame temperature and emissivity.

The heat evolved may be obtained from the heat of combustion of the fuel.

For the fraction of heat radiated Roberts states that the work of Hasegawa and Sato suggests a value of the order of 0.25. He also proposes the following relation based on the results of these workers:

$$F_r = 0.27\, P^{0.32} \qquad 1.35 \leq P \qquad [16.15.15]$$

where F_r is the fraction of heat radiated and P is the vapour pressure at the moment of release (MPa). He states that extrapolation up to $P = 6$ MPa, about the highest pressure of interest, gives $F_r = 0.48$. A more refined treatment by Roberts is described below.

Another rule of thumb for the fraction of heat radiated is that given by Hymes (1983, SRD R275) which is that the fraction of heated radiated for a vessel bursting below the set pressure of the pressure relief valve may be taken as 0.3 and that for one bursting above this pressure as 0.4.

***Table 16.62** Some correlations of fireball diameter and duration time for hydrocarbons*[a]

Diameter D (m)	*Duration time,* t_d (s)	*Material*	*Reference*
$5.55\,M^{0.333}$	–	Propane	Hardee and Lee (1973)
$6.36\,M^{0.325}$	$2.57\,M^{0.167}$	Hydrocarbons	Fay and Lewis (1977); Hardee, Lee and Benedick (1978)

$5.5\,M^{0.333}$	$0.38\,M^{0.033}$	Hydrocarbons	V.C. Marshall (1987)

[a] *Sources*: Lihou and Maund (1982); Bagster and Pitblado (1989); Satyanarayana, Borah and Rao (1991); and original papers.

[b] These authors' earlier correlation (1977) was $D = 5.28\,M^{0.277}$.

A commonly used value for the fraction of heat radiated from a fireball is 0.3.

Several workers have quoted values of the surface emissive power. Estimates made by Roberts of the heat flux at the surface of the fireballs in the work of Hasegawa and Sato are in the range 141–196 kW/m^2 with individual values up to 450 kW/m^2. A review of the surface emissive power of fireballs by Moorhouse and Pritchard (1982) concludes that the realistic range is 150–300 kW/m^2. In large-scale experiments on BLEVEs, D.M. Johnson and Pritchard (1991) obtained surface emissive powers in the range 250–350 kW/m^2. Considine, Grint and Holden (1982) use a value of 350 kW/m^2 for hazard assessment. These figures are appreciably higher than those for pool fires.

Based on the work of Roberts, the MHAP give the following relation for surface emissive power:

$$E = 235\,P^{0.39} \quad P \leq 2 \qquad [16.15.16]$$

where E is the surface emissive power (kW/m^2) and P is the pressure (MPa). The limit on pressure given is equivalent to a limit on the surface emissive power of 308 kW/m^2.

A surface emissive power commonly used for fireballs is 350 kW/m^2.

The fraction of heat radiated is used in conjunction with the point source model of a fireball and the surface emissive power is used in conjunction with the solid flame model. The two quantities are not independent but are linked via the surface area of the fireball. Given a fireball diameter, and hence a surface area, a particular value of the surface emissive power implies a corresponding value of the fraction of heat radiated.

With regard to fireball temperature, Roberts states that the values which he derives for the surface emissive power in the work of Hasegawa and Sato, just mentioned, are in the range consistent with flame temperatures of 1000–1400°C, a flame emissivity of unity, and 50–100% excess air. As described in Subsection 16.15.3, Crawley (1982) has used film of an actual fireball to obtain estimates of effective flame temperature of the order of 1100–1200°C.

The proportionalities between the diameter D, the duration time t_d and the mass of fuel M given in Subsection 16.15.8 have an important consequence. The heat generation is proportional to the mass M of the fireball, the heat loss per unit time is proportional to the surface area A, the heat loss at a given fraction of the duration time is proportional to the product At_d, the surface area A is proportional to $M^{2/3}$ and the duration time t_d is proportional to $M^{1/3}$. It follows, according to this model, that for a given fuel the heat radiation and temperature at a given fraction of the duration time are the same for all masses of fuel, or, in other words, that there is a single heat radiation and temperature profile.

16.15.10 Fireball scenarios

Before considering the view factor it is necessary to say something about the scenarios usually considered in the modelling of thermal radiation from a fireball. The approach commonly taken is to assume that the fireball is a sphere with its base just touching the ground and that its diameter and duration are given by one of the sets of correlations just described.

A target close to the fireball may be engulfed by it and it is of interest to know the furthest distance at which engulfment occurs. For this purpose there are two fireball geometries which may be used. One is that of a fireball which is essentially spherical but slightly settled on the ground. This corresponds to the shape of the fireball over most of its life and the engulfment distance approximates to the radius of the fireball. The other geometry is that of a hemispherical fireball. This corresponds to the shape of the fireball during its initial expansion and the engulfment distance then approximates to the radius of this hemispherical fireball, being greater than the spherical case by a factor of about 1.25 ($2^{1/3}$). The period of engulfment in the hemispherical fireball is much shorter.

In the near field estimates of the thermal radiation from a fireball are subject to some inaccuracy.

The set of view factors available for fireballs covers both the near and far fields and includes view factors for targets beneath an elevated fireball. The more complex expressions for the view factor are those applicable to such near field situations.

16.15.11 View factor

For a spherical fireball the thermal radiation intensity at the surface is

$$E = \frac{Q_r}{4\pi r^2} \qquad [16.15.17]$$

where E is the surface emissive power, Q_r is the heat radiated and r is the radius of the fireball.

The heat received I by a target normal to the surface of the fireball is

$$I = \alpha\tau FE \qquad [16.15.18]$$

$$= \frac{\alpha\tau F Q_r}{4\pi r^2} \qquad [16.15.19]$$

$$= \frac{\alpha\tau Q_r}{4\pi l^2} \qquad [16.15.20]$$

where l is the distance between the centre of the fireball and the target, α is the absorptivity of the target and τ is the atmospheric transmissivity. Hence from Equations 16.15.19 and 16.15.20 the view factor F for such a target is

$$F = \frac{r^2}{l^2} \qquad [16.15.21]$$

A set of view factors for fireballs covering other situations has been given by the CCPS (1994/15). For a horizontal surface at a ground distance x the view factor is

$$F = \frac{r^2 h}{(x^2 + h^2)^{3/2}} \qquad [16.15.22]$$

where h is the height of the centre of the fireball $(h \geq r)$ and x is the distance from the point directly beneath the centre of the fireball and the target, or the ground distance.

The corresponding expression for a vertical surface is limited to the case where the surface is not directly beneath the fireball:

$$F = \frac{r^2 x}{(x^2 + h^2)^{3/2}} \quad x > r \qquad [16.15.23]$$

In the far field $(x \approx l \gg h)$ Equation 16.15.23 reduces to Equation 16.15.21.

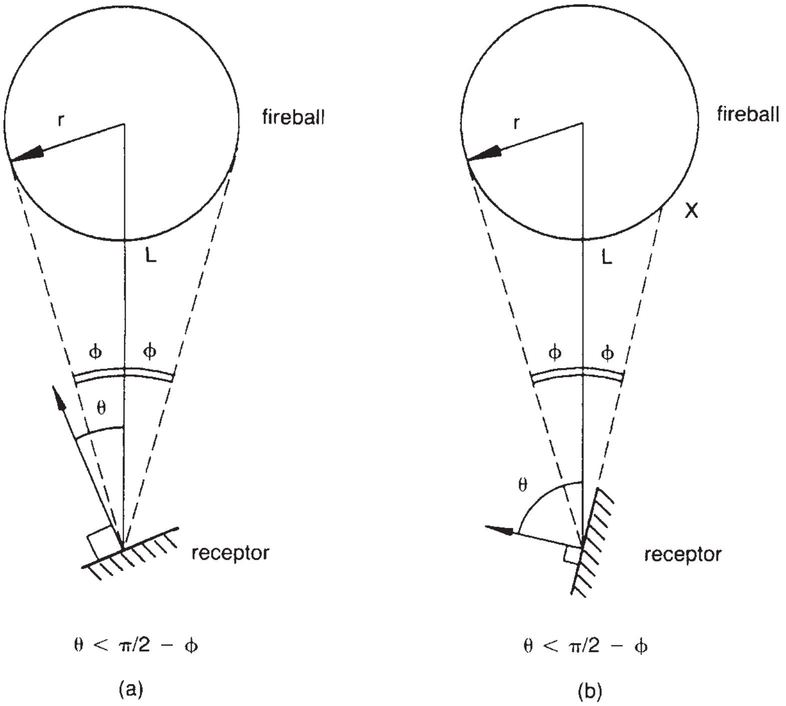

Figure 16.87 *View factor for fireballs (after CCPS, 1994/15): (a) the target 'sees' the whole fireball; and (b) the target 'sees' only part of the fireball (Courtesy of the American Institute of Chemical Engineers)*

For the case where the surface is beneath the fireball expressions exist both for a vertical surface and for a surface of any inclination. The latter is given here as being the more general case. Here two situations have to be considered, as shown in Figure 16.87. In Figure 16.87(a) the target 'sees' the whole fireball, whilst in Figure 16.87(b) it does not, the part of the fireball marked × being out of sight The expressions for the view factor in these two separate cases are

$$F = \frac{r^2}{l^2}\cos\theta \quad \theta \leq \frac{\pi}{2} - \phi \qquad [16.15.24]$$

$$F = \frac{1}{2} - \frac{1}{\pi}\sin^{-1}\left[\frac{(l^2 - r^2)^{1/2}}{l\sin\theta}\right] + \frac{r^2}{\pi l^2}\cos\theta$$

$$\times \cos^{-1}\left[-\frac{(l^2 - r^2)^{1/2}}{r}\cos\theta\right]$$

$$-\frac{1}{\pi l^2}(l^2 - r^2)^{1/2}(r^2 - l^2\cos^2\theta)^{1/2}$$

$$\theta > \frac{\pi}{2} - \phi \qquad [16.15.25]$$

The case to which these latter equations apply is a rather special one and, as indicated above, near field estimates are subject to some inaccuracy.

Crocker and Napier (1988a) have given relations for the view factor for a spherical fireball just touching the ground for the three cases of (1) a large vertical target, (2) a differential vertical target and (3) a differential horizontal target. Their expressions are equivalent, respectively, to Equation 16.15.21, or Equation 16.13.103; Equation 16.13.104; and Equation 16.13.105. These authors also treat the case of an elevated fireball.

16.15.12 Point source model

One of the simplest practical models for a fireball is the point source model. For this model the heat received by the target is

$$I = \frac{\alpha\tau F_r Q}{4\pi l^2} \qquad [16.15.26]$$

where Q is the heat release rate (kW).

Hymes (1983 SRD R275) has given a version of this model which effectively incorporates a combustion rate and an allowance for the effect on this of the mass of fuel. Introducing the term α to put the model on the same basis as the previous equation gives

$$I = \frac{2.2\alpha\tau F_r \Delta H_c M^{0.67}}{4\pi l^2} \qquad [16.15.27]$$

where ΔH_c is the heat oc combustion (kJ/kg).

16.15.13 Solid flame model

The other main alternative for practical use is the solid flame model

$$I = \alpha\tau FE \qquad [16.15.28]$$

16.15.14 Fireball modelling

Fireball models in the form of correlations of diameter and duration time have already been described. There are also a number of more fundamental models. Such models include those by Bader, Donaldson and Hardee (1971), Hardee and Lee (1973), Fay and Lewis (1977), Hardee, Lee and Benedick (1978), A.F. Roberts (1981/82, 1982), Williamson and Mann (1981), Lihou and Maund (1982), Jaggers *et al.* (1986), Roper *et al.* (1986) and V.C. Marshall (1987). Some of these models are now described.

16.15.15 Bader, Donaldson and Hardee model

An early fundamental model of a fireball is that by Bader, Donaldson and Hardee (1971). The model is for the fireball of a propellant such as the Saturn fireball. The fireball is assumed to be a homogeneous, isothermal body, which is spherical throughout. Other assumptions are that the rate of addition of propellant is constant, that no air enters the fireball either during or after the reaction period, that all the propellant participates in the reaction, and that the fireball radiates as a black body. For simplicity, it is assumed that the burnout and lift-off times coincide.

For a high temperature fireball such that the difference $\Delta\rho$ between the density of the air ρ_a and the density of the fireball gas ρ is approximated by $\Delta\rho \approx \rho$, the buoyancy force is

$$F_B = \frac{4}{3}\pi r^3 \rho g \qquad [16.15.29]$$

and the fluid resistance force of the fireball gas is

$$F_R = \frac{2}{3}\pi r^3 \rho \left[\frac{2}{r}\left(\frac{dr}{dt}\right)^2 - \frac{d^2 r}{dt^2}\right] \qquad [16.15.30]$$

where F_B is the buoyancy force (N/m^2), F_R is the resistance force (N/m^2), g is the acceleration due to gravity (m/s^2), r is the radius of the fireball (m), ρ is the density of the fireball (kg/m^3) and t is time (s). Equating these two equations yields

$$\frac{d^2 r}{dt^2} - \frac{2}{r}\left(\frac{dr}{dt}\right)^2 + 2g = 0 \qquad [16.15.31]$$

In this equation the first term is the inertia term and the second the added mass term due to the displacement of air by the gaseous products. The solution of Equation 16.15.31 is

$$r = \frac{g}{3}t^2 \qquad [16.15.32]$$

The radius of the fireball at burnout, and on lift-off, is

$$r_b = \left(\frac{3}{4\pi\rho}\right)^{1/3} W_b^{1/3} \qquad [16.15.33]$$

where r_b is the radius of the fireball at burnout (ft), W_b is the mass of propellant, and therefore of the fireball, at burnout (lb) and ρ is the density of the fireball gas (lb/ft^3). Taking a value of $\rho = 0.0055$ lb/ft^3 yields

$$r_b = 3.51 W_b^{1/3} \qquad [16.15.34]$$

Combining Equations 16.15.32 and 16.15.33 gives for the burnout time

$$t_b = 0.572\, W_b^{1/6} \qquad [16.15.35a]$$

$$\approx 0.6\, W_b^{1/6} \qquad [16.15.35b]$$

where t_b is the burnout time (s).

For the growth of the fireball

$$R = W/t \qquad [16.15.36]$$

$$= W_b/t_b \qquad [16.15.37]$$

where R is the rate of addition of propellant (lb/s), W is the mass of the fireball (lb), t is time (s) and the subscript b denotes burnout.

From Equations 16.15.35b and 16.15.37

$$R = \frac{5}{3} W_b^{5/6} \qquad [16.15.38]$$

The radius of the fireball may then be written as

$$r = \left(\frac{3Rt}{4\pi\rho}\right)^{1/3} \qquad [16.15.39]$$

where r is the radius of the fireball and ρ is its density. Utilizing Equation 16.15.38

$$r = \left(\frac{5W_b^{5/6}}{4\pi\rho}\right)^{1/2} t^{1/3} \qquad [16.15.40]$$

16.15.16 Hardee and Lee model

Another early fireball model is that by Hardee and Lee (1973). This model applies to the fireball following the rupture of a vessel containing a liquefied flammable gas. The assumptions made reflect those of the model of Bader, Donaldson and Hardee, with the changes necessary to treat the case in hand. It is assumed that a vapour cloud grows into which the rate of addition of fuel is assumed to be constant. Ignition occurs when the mixture is stoichiometric. The fireball is homogeneous, isothermal and spherical. Other assumptions are that all the available fuel is burned, that the fireball radiates as a black body, and that the burnout and lift-off times coincide. The model given is similar to that of Bader. Donaldson and Hardee and includes Equations 16.15.33, 16.15.35b, 16.15.38 and 16.15.40.

The authors obtain for a propane fireball a relation equivalent in SI units to

$$D = 5.55 M^{1/3} \qquad [16.15.41]$$

where D is the diameter of the fireball (m) and M is the mass of fuel (kg).

This model has been further developed by Hardee, Lee and Benedick (1978), who apply it to a fireball of LNG. Equation 16.15.35b may be rewritten in SI units as

$$t_b = 0.684\, W_b^{1/6} \qquad [16.15.42]$$

and then as

$$t_{\mathrm{b}} = 0.684(W_{\mathrm{b}}/W_{\mathrm{f}})^{1/6} W_{\mathrm{f}}^{1/6} \quad [16.15.43]$$

where t_b is the burnout time (s), W_b is the mass of the fireball, including air, at burnout (kg), W_f is the mass of fuel (kg). For a stoichiometric mixture of methane and air $W_b/W_f = 18.3$. Substituting this value in Equation 16.15.43 yields

$$t_{\mathrm{b}} = 1.11\, W_{\mathrm{f}}^{1/6} \quad [16.15.44]$$

Further, taking the density ρ as 0.160 kg/m^3 and the value of W_b/W_f as 18.3, and utilizing Equation 16.15.44 in Equation 16.15.40 yields

$$r = 3.12\, W_{\mathrm{f}}^{1/2} \quad [16.15.45]$$

where r is the radius of the fireball (m).

The resulting correlations for fireball diameter and duration time are therefore

$$D = 6.24 M^{0.333} \quad [16.15.46]$$

$$t_{\mathrm{b}} = 1.11 M^{0.167} \quad [16.15.47]$$

A critique of this model of an LNG fireball has been given by Gillette (1980), who makes detailed criticisms of the model itself and suggests that for LNG the occurrence of 'fireballs' is a speculation.

16.15.17 Fay and Lewis model

The model by Fay and Lewis (1977) is applicable to the quite different situation of a fireball formed from a compact, stationary cloud of pure fuel vapour ignited at the edge. In this scenario, the combustion products move upwards, promoting mixing with the air. When the volume of these products becomes comparable with the initial volume of the vapour, the mixture of fuel, air and products begins to rise, burning more vigorously as it accelerates, consuming virtually all the fuel.

In modelling the combustion, it is assumed that the volume of the unburned vapour is negligible compared with that of the products. Thus, for example, the volume of the products of the stoichiometric, adiabalic combustion of methane is 83 times that of the fuel vapour.

The authors state that it can be shown by dimensional analysis that the following proportionalities hold;

$$r_{\mathrm{p}} \propto g t^2 \quad [16.15.48]$$

$$r_{\mathrm{p}} \propto V_{\mathrm{f}}^{1/3} \quad [16.15.49]$$

$$z_{\mathrm{p}} \propto V_{\mathrm{f}}^{1/3} \quad [16.15.50]$$

$$t_{\mathrm{p}} \propto V_{\mathrm{f}}^{1/6}/g^{1/2} \quad [16.15.51]$$

where r is the radius of the cloud, t is the time, V_f is the volume of the initial cloud of fuel, z is the height of the centre of the cloud and subscript p denotes the products.

The growth of the cloud is modelled drawing on the entrainment hypothesis of B.R. Morton, Taylor and Turner (1956). The volumetric rate of growth is taken as being proportional to the product of the local surface area and the local rise velocity:

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{4}{3}\pi r^3\right) = \beta 4\pi r^2 \frac{\mathrm{d}z}{\mathrm{d}t} \quad [16.15.52]$$

where, β is the entrainment coefficient. The order of magnitude of β is one.

Integrating Equation 16.15.52 with the boundary conditions $r = 0$; $z = 0$ yields

$$r = \beta z \quad [16.15.53]$$

Hence

$$z = \frac{1}{\beta}\left(\frac{3V}{4\pi}\right)^{1/3} \quad [16.15.54]$$

Equating the forces of buoyancy and of the rate of change of vertical momentum

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{4}{3}\pi r^3 \rho_{\mathrm{p}}\left(\frac{\mathrm{d}z}{\mathrm{d}t}\right)\right] = \frac{4}{3}\pi r^3 g(\rho_{\mathrm{a}} - \rho_{\mathrm{p}}) \quad [16.15.55]$$

where ρ_a is the density of air.

Utilizing Equation 16.15.52 in the integration of Equation 16.15.55 gives

$$r = \frac{g\beta}{14}\left(\frac{\rho_{\mathrm{a}} - \rho_{\mathrm{p}}}{\rho_{\mathrm{p}}}\right)t^2 \quad [16.15.56]$$

Hence

$$t = \left[\frac{14\rho_{\mathrm{p}}}{g\beta(\rho_{\mathrm{a}} - \rho_{\mathrm{p}})}\right]^{1/2}\left(\frac{3V}{4\pi}\right)^{1/6} \quad [16.15.57]$$

where V is the volume of the fireball.

The radius r, height z and duration t have their maximum values when the cloud volume V equals the volume V_p of the combustion products. For a hydrocarbon C_nH_m

$$V_{\mathrm{p}} = \left[\frac{m\phi + 4.762(4n + m)}{4\phi}\right]\left(\frac{T_{\mathrm{p}}}{t_{\mathrm{r}}}\right)V_{\mathrm{f}} \quad [16.15.58]$$

where T_p is the absolute temperature of the products, T_r is that of the reactants, V_f is the volume of the fuel, V_p is that of the products and ϕ is the equivalence ratio.

The authors treat β and ϕ as parameters to be determined. From soap bubble experiments they obtain for the entrainment coefficient an average value of $\beta = 0.285$. Tliis is in reasonable agreement with the values given by Morton, Taylor and Turner. For the equivalence ratio the average value is $\phi = 0.217$, which corresponds to about 4.5 times the stoichiometric amount of air.

16.15.18 Jaggers, Roper *et al.* model

Studies of the conditions under which the buoyancy and momentum regimes apply have been described by Jaggers, Roper and co-workers (Jaggers *et al.*, 1986; Roper *et al.*, 1986).

Jaggers *et al.* (1986) give a set of relations based on dimensional analysis. For the case where the release velocity is low and buoyancy forces dominate those of momentum, they obtain

$$t_{\mathrm{b}} \propto \frac{1}{g^{1/2}}\left(\frac{M}{\rho_{\mathrm{a}}}\right)^{1/6} \quad [16.15.59]$$

whilst for the other limiting case where the release velocity is high and momentum forces dominate those of buoyancy

$$t_b g^{1/2}\left(\frac{\rho_a}{M}\right)^{1/6} \propto \frac{g^{1/2}}{v_o}\left(\frac{\rho_a}{M}\right)^{-1/6} \qquad [16.15.60]$$

Hence

$$t_b \propto \frac{1}{v_o}\left(\frac{M}{\rho_a}\right)^{1/3} \qquad [16.15.61]$$

where M is the mass of fuel, t_b is the burning time, v_o is the mean release velocity and ρ_a is the density of air. The mean release velocity v_o is defined as the ratio of the initial momentum of the release to the mass of fuel released.

16.15.19 Roberts model

The fireball model which is most widely used is probably that of A.F. Roberts (1981/82, 1982). The model comprises both fundamental and correlation models and covers the whole range of features of practical interest.

Fireball development

Roberts takes as his starting point for fireball growth the model by Hardee and Lee (1973). From this he obtains for a hemispherical fireball

$$r = \left(\frac{4\alpha M t}{\pi\rho_a}\right)^{1/4} \qquad [16.15.62]$$

$$\frac{dr}{dt} = \left(\frac{\alpha M}{64\pi\rho_a}\right)^{1/4} t^{-3/4} \qquad [16.15.63]$$

$$V = \frac{2\pi}{3}\left(\frac{4\alpha M t}{\pi\rho_a}\right)^{3/4} \qquad [16.15.64]$$

where M is the mass of fuel released (kg), r is the cloud radius (m), t is the time (s), V is the cloud volume (m^3), α is the momentum per unit mass (m/s) and ρ_a is the density of air (kg/m^3).

The concentration of the fuel may be determined from the mass released M and from the volume V of the cloud.

The term α is a function of the vapour pressure of the liquid in the vessel prior to failure. For a vapour pressure less than the atmospheric pressure, $\alpha = 0$. For propane at 28°C and a vapour pressure of 1 MPa, $\alpha = 220$ m/s.

For propane, the cloud volume given by Equation 16.15.64 may be written as

$$V = 118(Mt)^{3/4} \qquad [16.15.65]$$

Since for propane at the lower flammability limit the volume of the cloud is approximately $30M$, the lime t' required for the cloud to fall below the lower flammability limit (s) is

$$t' = \frac{35}{\alpha}M^{1/3} \qquad [16.15.66]$$

Some typical values for this time are

M (kg)	α (m/s)	t'(s)
1,000	220	1.6
100,000	220	7.4

The time t_g required for the transition from a regime dominated by momentum effects to one dominated by gravitational slumping is derived by Roberts from the work of Jagger and Kaiser (1981). The criterion given for transition is

$$N = \frac{gr\Delta\rho}{\rho_a(dr/dt)^2} = 1 \qquad [16.15.67]$$

where $\Delta\rho$ $(=\rho_v - \rho_a)$ is the density difference between of the vapour and the air (kg/m^3).

For the Hardee and Lee model

$$N = g\frac{(\rho_v - \rho_a)}{\rho_v}\frac{6t}{\alpha} \qquad [16.15.68]$$

Then for $N = 1$

$$t_g = \frac{\rho_v}{6g(\rho_v - \rho_a)}\alpha \qquad [16.15.69]$$

where t_g is the time to the transition from control by momentum to control by gravity slumping (s).

For propane from Equation 16.15.68 and with $N = 1$

$$t_g = 0.05\alpha \qquad [16.15.70]$$

Fireball volume and diameter

For the fireball volume and diameter Roberts gives the following treatment. The volume V of the fireball at the mean temperature T_f is

$$V = \frac{M_a + M_f}{\rho_f} \qquad [16.15.71]$$

$$= \frac{(M_a + M_f)T_f}{\rho_o T_o} \qquad [16.15.72]$$

and the enthalpy H is

$$H = c(M_a + M_f)(T_f - T_o) \qquad [16.15.73]$$

where c is the specific heat (kJ/kg K), H is the enthalpy rise of the fireball (kJ), M_a is the mass of air in the fireball (kg), M_f is the mass of fuel in the fireball (kg), T_f is the absolute mean temperature of the fireball (K), T_o is the absolute initial temperature of the reactants (K), ρ_f is the density of the products at temperature T_f (kg/m^3) and is the density of the products at temperature T_o (kg/m^3).

Then from Equations 16.15.72 and 16.15.73

$$V = \frac{M_a + M_f}{\rho_o}\left[1 + \frac{H}{T_o c(M_a + M_f)}\right] \qquad [16.15.74]$$

and hence

$$D = \left\{\frac{6}{\pi}\left[1 + \frac{H}{T_o c(M_a + M_f)}\right]\frac{M_a/M_f + 1}{\rho_o}\right\}^{1/3} M_f^{1/3} \qquad [16.15.75]$$

where D is the diameter of the fireball (m).

Different relations are required for the enthalpy H, depending on whether the mixture is fuel or oxygen rich. If R is the value of the ratio M_a/M_f for the stoichiometric mixture, then

$$H = \frac{\eta M_a Q}{R} \qquad \frac{M_a}{M_f} < R \text{ (fuel rich)} \qquad [16.15.76a]$$

$$H = \eta M_f Q \qquad \frac{M_a}{M_f} > R \text{ (oxygen rich)} \qquad [16.15.76b]$$

where Q is the heat of combustion (kJ/kg) and η the thermal efficiency. The thermal efficiency η takes account of heat losses during growth to the maximum diameter and losses due to unburned fuel.

Roberts uses Equation 16.15.75 to explore the effect of the air/fuel ratio parameter M_a/RM_f and the thermal efficiency η on the constant k_1 in Equation 16.15.4 for fireball diameter. The value of this constant is 5.8 for $M_a/RM_f = 1$ and $\eta = 1$ and it is relatively insensitive to M_a/RM_f over the range 0.8–3.0 and to η over the range 0.75–1.0.

Duration time

Roberts, argues that the behaviour of larger fireballs ($M > 5$ kg) appears to differ from that of smaller ones, and obtains for larger fireballs only the relation

$$t_d = 0.83\, M^{0.316} \qquad [16.15.77]$$

where t_d is the duration time (s).

The experimental correlations for duration time t_d therefore lie between Equation 16.15.10 and the relation

$$t_d = 0.90 M^{1/3} \qquad [16.15.78]$$

The data of Baker also lie between the lines given by Equations 16.15.10 and 16.15.78. The relation recommended by Roberts for the duration time t_d is Equation 16.15.10.

For the lift-off time t_e Roberts quotes the equation given by Hardee and Lee

$$t_e = 1.1 M^{1/6} \qquad [16.15.79]$$

where t_e is the lift-off time (s). Lift-off is determined by buoyancy effects and the exponent of 1/6 is well established for such effects.

The exponent of $\frac{1}{6}$ in Equation 16.15.79 for lift-off time t_e compares with that of $\frac{1}{3}$ in Equation 16.15.10 for the duration time t_d. Thus the lift-off time t_e may be less or greater than the duration time t_d. Roberts quotes the following typical figures obtained from these equations:

M (kg)	t_d(s)	t_e(s)
200	2.6	2.6
50,000	16	6.7

Thus for smaller fireballs combustion will tend to be complete before lift-off occurs, while for larger ones lift-off will tend to occur while combustion is still taking place. It is the duration time t_d which is used to characterize the period during which the fireball radiates heat.

Heat radiated

In the model given by Roberts for heat radiation from the fireball, it is assumed that such radiation occurs as a square wave pulse of duration t_d. The basic equation for heat radiation is

$$Q_r = \frac{F_r M \Delta H_c}{t_d} \qquad [16.15.80]$$

where ΔH_c is the heat of combustion (kJ/kg), F_r is the fraction of heat radiated and Q_r is the heat radiation rate (kW).

The intensity of thermal radiation at a target, neglecting target absorptivity and atmospheric transmissivity effects, is then

$$I = \frac{Q_r}{4\pi l^2} \qquad [16.15.81]$$

where I is the radiation intensity received by a target perpendicular to the direction of radiation (kW/m^2) and l is the distance from the centre of the fireball to the target (m). The relation between the term $(1/4\pi l^2)$ in Equation 16.15.81 and the view factor is given in Subsection 16.15.11.

Roberts' treatment of the fraction F_r of heat radiated has already been described, but for completeness is restated here. He quotes values in the range 0.2–0.4 as typical of both pool fires and fireballs. He also analyses the data of Hasegawa and Sato (1978), shown in Figure 16.88, and derives from these a relation between the heat radiation factor and the vapour pressure prior to rupture

$$F_r = 0.27\, P^{0.32} \qquad [16.15.82]$$

where F_r is the fraction of heat radiated and P is the vapour pressure just prior to rupture (MPa).

Equation 16.15.82 is thus derived for data with vapour pressures up to 1.3 MPa, but Roberts suggests it may be extrapolated up to 6 MPa at which pressure the value of F_r is 0.48.

Summary

Roberts' model for a fireball from a bursting vessel may be summarized as follows. The mass of fuel in the fireball is given by Equation 16.15.3, the diameter of the fireball by Equation 16.15.7, the duration time of the fireball by Equation 16.15.10, the fraction of heat radiated by Equation 16.15.82, the total heat radiated by Equation 16.15.80, and the thermal radiation received by the target (neglecting the target absorptivity and atmospheric transmissivity effects) by Equation 16.15.81.

16.15.20 Marshall model

Another model which is readily applied to practical situations is that by V.C. Marshall (1987). This model is based essentially on correlations for diameter and duration time, but again deals with the other features of practical interest.

The model may be summarized as follows. For the mass of fuel in the fireball

$$M = 2\phi\, M_s \qquad \text{Winter} \qquad [16.15.83a]$$

$$M = 3\phi\, M_s \qquad \text{Summer} \qquad [16.15.83b]$$

where M is the mass of fuel entering the fireball (te), M_s is the mass of fuel in the vessel (te) and ϕ is the theoretical adiabatic flash fraction (TAFF).

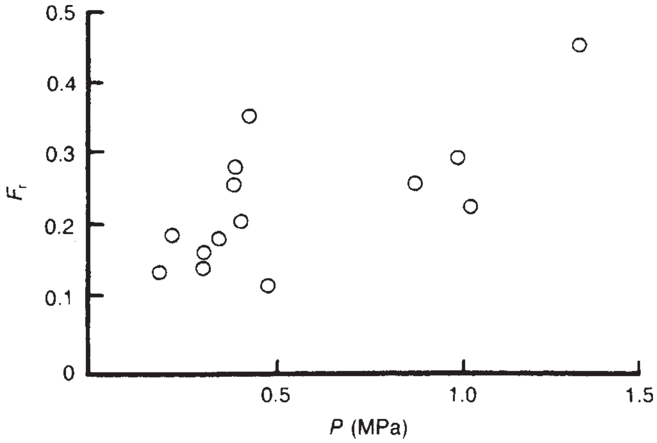

Figure 16.88 *Relation between the fraction of heat radiated and the vapour pressure prior to rupture for a fireball (A.F. Roberts, 1981/82). Data from Hasegawa and Sato (1978); 6.2 kg of pentane in each test (Reproduced by permissionof the Fire Safety Journal)*

The radius and duration time of the fireball are

$$R_{FB} = 27.5M^{1/3} \qquad [16.15.84]$$

$$D_{FB} = 3.8\ M^{1/3} \qquad [16.15.85]$$

where D_{FB} is the duration time of the fireball (s) and R_{FB} is its radius (m).

The heat released and fraction of heat radiated are

$$E_T = HM \qquad [16.15.86]$$

where E_T is the heat released (J) and H is the heat of combustion (J/te). The fraction F_r of heat radiated is taken as 0.3.

The radiative power and radiative power density are then

$$P_{FB} = E_T F_R / D_{FB} \qquad [16.15.87]$$

$$P_D = P_{FB}/V_{FB} \qquad [16.15.88]$$

where P_D is the radiative power density (W/m^3), P_{FB} is the radiative power (W) and V_{FB} is the volume of the fireball (m^3).

The thermal radiation intensity is

$$I_T = \frac{P_{FB}}{4\pi R_T^2} \qquad [16.15.89]$$

where I_T is the unattenuated thermal radiation at the radius where the target is located (W/m^3) and R_T is the distance from the centre of the fireball to the target (m). The effective surface temperature is

$$T_e = \left[\frac{E_T F_R}{\sigma D_{FB}(4\pi R_{FB}^2)}\right]^{1/4} \qquad [16.15.90]$$

where T_e effective fireball temperature (K) and σ is the Stefan–Boltzmann constant.

The atmospheric attenuation is given by

$$\tau = X - 0.12\ \log_{10} R_T \qquad [16.15.91]$$

where τ is the atmospheric transmissivity and X is a parameter. The values of X are 1.0, 0.96 and 0.92 for relative humidities of 0.2, 0.5 and 1.0, respectively.

The thermal radiation received by the target is then

$$I_{TA} = \tau I_T \qquad [16.15.92]$$

where I_{TA} is the thermal radiation received by the target, taking account of attenuation by the atmosphere (W/m^2).

Taking for hydrocarbons a heat of ombustion of 47 MJ/kg yields

$$E_T = 47 \times 10^9\ M \qquad [16.15.93]$$

$$P_{FB} = 1.24 \times 10^{10} F_r M^{2/3} \qquad [16.15.94]$$

$$I_T = 2.94 \times 10^8 M^{2/3}/R_T^2 \qquad [16.15.95]$$

As an illustration, consider the example given by Marshall of the fireball from a release of 20 te of propane. Then

$M = 20$ te
$H = 47 \times 10^9$ J/te
$R_{FB} = 74.6$ m
$D_{FB} = 10.3$ s
$E_T = 9.4 \times 10^{11}$ J
$F_R = 0.3$
$P_{FB} = 2.73 \times 10^{10}$ W
$I_T = 2.17 \times 10^9/R_T^2$

16.15.21 CCPS method

A model for a fireball was given in the CCPS *QRA Guidelines* (1989/5). A summary of this model has been published by Prugh (1994). A more recent model is that included in the

CCPS *Fire and Explosion Model Guidelines* (1994/5), where it is included as part of the treatment of BLEVEs.

The method covers the following features: (1) the mass of fuel participating in the fireball, (2) the diameter and duration of the fireball, (3) point source and solid flame models of the fireball, (4) the surface emissive power of the fireball, (5) the view factor and (6) the atmospheric transmissivity.

The mass of fuel in the fireball is taken as three times the flash fraction or, if this figure exceeds unity, the mass released. For the fireball diameter and duration, use is made of Roberts' equations (Equations 16.15.7 and 16.15.11 or 16.15.12).

Both point source and solid flame models are used. For the point source method use is made of Hymes' Equation 16.15.2. For the solid flame method Equation 16.15.28 is used in conjunction with a surface emissive power of 350 kW/m^2.

The view factors are those attributed to the CCPS in Subsection 16.15.11, especially Equation 16.15.23.

The atmospheric transmissivity is taken in the sample problem as unity, although several relationships are given for it.

The *Guidelines* give a sample problem involving BLEVE of a tank truck containing propane, for which two treatments are presented, one using the point source model and the other using the solid flame model.

16.15.22 Congested fireballs

A type of fireball which somewhat resembles one arising from a BLEVE is that which can occur following sudden rupture of a vessel, such as a reactor, with release of flammable contents and immediate ignition. An instance of this is given by Cates (1992), who terms the incident which he describes a 'congested fireball'. Since such an event gives an appreciable overpressure, it is considered in Chapter 17.

16.15.23 Fireballs on pipelines

An account of a fireball and a subsequent jet flame resulting from the rupture of a pipeline containing liquefied propane has been given by Hirst (1984, 1986). The photographs show at −10 s an unignited cylindrical cloud, at 1 s partial ignition, at 3 s a mushroom cloud and at 8 s an elongated jet flame. This work is described in IE. more detail in Section 16.19.

16.16 Fireballs from Explosives

The models just given are for fireballs of hydrocarbons. There may also be a requirement for a model of the fireball from a condensed phase explosive. There is a limited amount of information available on the fireballs from solid and liquid propellants and from high explosives. Accounts of work in this area are given by Jarrett (1952), Gayle and Bransford (1965), Rakaczky (1975), Stull (1977), Mallory (1980), Kovar *et al.* (1982), W.E. Baker *et al.* (1983) and Gilbert, Lees and Stilly (1994d).

16.16.1 Fireball incidents

Not surprisingly, data on the features of fireballs in incidents involving the explosion of high explosives are sparse. An exception is the explosion which occurred in Peterborough in the United Kingdom in 1989 on a truck carrying commercial explosives. According to the report by the HSE (1990c) the load was essentially nitroglycerine-based explosives with a total mass of some 800 kg. From the fact that one fireman was engulfed in flames at a distance of 18 m and another suffered slight burns at 25 m, the fireball diameter was taken as approximately 36 m.

16.16.2 Experimental studies

The experimental studies of main relevance here are the relatively large-scale tests done by Jarrett (1952) on fireballs from solid propellants and by Gayle and Bransford (1965) on fireballs from liquid propellants. This work is described below. There are also a number i of laboratory studies such as those by Mallory (1980) and Kovar *et al.* (1982).

16.16.3 Empirical features

Fireballs from high explosives tend to be of shorter duration than those of hydrocarbons for a given mass. Further, the mass involved in accidents tends to be less. Generally, therefore, the duration time of the fireball is short. The fireball diameter also appears to be less than for the same mass of hydrocarbons. On the other hand, the fireball temperatures are appreciably higher, particularly in the early stages.

16.16.4 Fireballs of munitions

For munitions fireballs, W.E. Baker *et al.* (1983) quote the following model by Rakaczky (1975). For the diameter

$$D = 3.76\, M^{0.325} \qquad [16.16.1]$$

and for the duration time

$$t_d = 0.258\, M^{0.349} \qquad [16.16.2]$$

where D is the diameter of the fireball (m), M is the mass of chemicals (kg) and t_d is the duration time (s).

Baker *et al.* state that these relations were obtained by fitting data from the literature, but no limits of applicability are given and the equations should be used with caution.

16.16.5 Fireballs of solid propellants

An investigation of the fireball from solid propellants has been described by Jarrett (1952). The work was done in connection with the storage of explosives. Its purpose was to determine the maximum extent of flame travel at ground level when a store of propellant explodes. Experiments were conducted with quantities of cordite in the range 50−175,000 lb.

For the flame radius at ground level, correlations were obtained which may be written as

$$D = 0.906\, M^{0.38} \qquad \text{Peripheral ignition} \qquad [16.16.3]$$

$$D = 0.906\, M^{0.44} \qquad \text{Central ignition} \qquad [16.16.4]$$

16.16.6 Fireballs of liquid propellants

In another early study, Gayle and Bransford (1965) described an investigation of the fireballs from liquid propellants and from high explosives, based on a literature survey and measurements taken from photographs in experimental work. The propellents considered were RP-1/LOX, LH_2/LOX, RP-1/LH_2/LOX and N_2O_4/UDMH-hydrazine (LH_2, liquid hydrogen; LOX, liquid oxygen). These liquid propellants are therefore strictly bipropellants incorporating their own oxidizer for combustion. The high explosive tests are considered further below.

Gayle and Bransford comment that the fireball diameters for the liquid propellants were governed almost exclusively by the mass involved. The diameters effectively obeyed the cube root law.

They state further that there was little difference in the diameters of the fireballs from the liquid bipropellants and from high explosives. They give separate equations for the diameter of the fireball for individual liquid bipropellants and the following equation for the combination of liquid bipropeliants and high explosives:

$$d = 9.56\ W^{0.325} \qquad [16.16.5]$$

where d is the diameter of the fireball (ft) and W is the mass of material (fuel + oxidizer) (lb). In SI units

$$D = 3.77\ M^{0.325} \qquad [16.16.6]$$

The duration times of the fireballs were relatively variable. These authors attribute this partly to variations in photographic variables and partly to the difficulty of defining the end of the visible fireball in an unambiguous manner. For the combined set of liquid bipropeliants V. they give for the duration time:

$$t_d = 0.196\ W^{0.349} \qquad [16.16.7]$$

where W is the mass of material (fuel + oxidizer) (lb). In SI units

$$t_d = 0.258\ M^{0.349} \qquad [16.16.8]$$

where M is the mass of material (fuel + oxidizer) (kg).

The duration times of the high explosive fireballs were appreciably shorter, but no correlation is given.

For liquid bipropellants, R.W. High (1968) has given the following model:

$$d = 0.82\ W^{0.320} \qquad [16.16.9]$$

$$t_d = 0.232\ W^{0.320} \qquad [16.16.10]$$

where W is the mass of bipropellant (lb). In SI units

$$D = 3.86\ M^{0.320} \qquad [16.16.11]$$

$$t_d = 0.299\ M^{0.320} \qquad [16.16.12]$$

High gives graphs showing experimental data for the diameter and duration time of a number of liquid bipropeliants together with his correlation lines. The data cover the range $10-10^5$ kg.

Fireballs from liquid propellants are one of the hazards reviewed in the *Hazards of Chemical Rockets and Propellants Handbook* (Jensen, 1972). The authors quote Equations 16.16.6 and 16.16.8 from the work of Gayle and Bransford and give some additional results, as described below.

They make the point that the fireball can be very asymmetrical. The Titan test with 100,000 lb of RP-1/LOX gave maximum horizontal dimensions of 800–1000 ft, whereas the equivalent diameter from Equation 16.16.5 is some 400 ft.

They describe work on fireballs in Project Pyro and quote the following equations for the duration time of experiments done with 25,000 lb of liquid bipropellants:

$$t_d = 0.113\ W^{0.333} \qquad \mathrm{RP-1/LOX} \qquad [16.16.13]$$

$$t_d = 0.077\ W^{0.333} \qquad \mathrm{LH_2/LOX} \qquad [16.16.14]$$

They also describe further work on fireballs of propellant ANB-3226, which has a mass fraction of 69% oxidizer and 15% aluminium, in Project Sophy and give tabulated data.

There are several points of interest in the data given. The ratio of the maximum height of the fireball to its maximum diameter is an indication of the extent to which it undergoes a transition from hemispherical to spherical shape. This ratio is in the range 1.5–2.4. In other words, in most cases the fireball grows to a nearly spherical shape. The times to maximum diameter and to maximum height, and the ratio of these to the duration time are also significant. The ratio of the time to maximum height to the time to maximum diameter is generally of the order of 3, but can vary between 1.5 and nearly 10. If the ratio of the time to maximum diameter to the duration time is considered, this tends to be small, typically in the range 0.03–0.15.

16.16.7 Fireballs of high explosives

There is relatively little in the literature by way of models for high explosive fireballs. The high explosive experiments of Gayle and Bransford (1965), mentioned earlier, consisted of some 14 explosions involving TNT, Composition C-4 and pentolite. For the fireballs from these explosions they obtained the following equation:

$$d = 8.50\ W^{0.341} \qquad [16.16.15]$$

where d is the diameter (ft) and W is the mass of explosive (lb). The quantities of explosive were in the range $3-10^6$ lb. In SI units

$$D = 3.3\ M^{0.341} \qquad [16.16.16]$$

As stated above, Gayle and Bransford did not give a correlation for the duration time of a high explosive fireball. They give some limited data which indicate that for a mass of explosive of 23 kg the duration time obtained was 0.23 s.

Stull (1977) quotes for TNT the following model:

$$d = 0.5\ W^{0.333} \qquad [16.16.17]$$

$$t_d = 0.23\ W^{0.333} \qquad [16.16.18]$$

He gives for these correlations two separate sources: for fireball diameter, the work of van Dolah and Burgess (1968); and for the fireball duration, that of Strehlow and Baker (1975).

Not all the models quoted are original. High quotes the work of Gayle, prior to publication of the report by Gayle and Bransford, and his model, although not the same as that of the latter authors, appears to be based on some of their data. The model given by Rakaczky appears to be the one by Gayle and Bransford. The model of Stull also is very similar to that by Gayle and Bransford.

16.16.8 Fireball temperature

According to W.E. Baker *et al.* (1983), typical fireball temperatures are

Hydrocarbons	1350 K
Solid propellants	2500 K
Liquid propellants	3600 K
High explosives	5000 K

These authors suggest that the Rakaczky model is probably applicable to fireballs with temperatures of 2500 K. They also state that a temperature of 2500 K is typical of gun propellant fireballs. Gilbert, Silly and Lees infer that Rakaczky's model applies to gun propellant rather than liquid propellant or high explosive fireballs.

The temperatures of fireballs of liquid bipropellants are discussed by R.W. High (1968). He gives as typical a temperature of 2400 K. He also quotes computed values of 2690 and 2610 K, assuming unity and estimated emissivities, respectively. The *Rocket and Propellants Handbook* (Jensen, 1972) quotes temperatures of 2300 K obtained in Project Pyro for liquid bipropellants.

The temperatures given by Baker *et al.* for propellants and high explosives appear high.

16.16.9 Gilbert, Lees and Scilly model

A model for the fireball from a high explosive has been given by Gilbert, Lees and Scilly (1995d). The model is based partly on theoretical and partly on empirical considerations.

The combustion processes in the fireball pass through two stages: (1) detonation and (2) combustion of the detonation products. The first stage is very rapid.

The growth of the fireball passes through several all stages: (1) expansion following detonation; (2a) growth to the maximum diameter as a hemisphere; (2b) formation of a sphere at ground level, lift-off and rise to maximum height as a sphere and (3) persistence at this height as a sphere until cooled.

Following detonation, air is entrained in the fireball. For oxygen deficient explosives, this air provides the oxygen required for secondary combustion of the products. The air contributes to the growth of the fireball.

It is assumed in the model that the time t_c to complete combustion is equal to the time t_s for the fireball to form the maximum size hemisphere on the ground. In other words, the end of Stage 2 of the combustion processes is taken as the end of Stage 2a of the growth process.

The model consists of relations for the diameter and the duration time of the fireball and for the profile of shape and temperature with time, and has three stages. In Stage 1 the detonation reaction occurs and gives the gaseous detonation products without admixture of air. In Stage 2 the detonation products undergo complete combustion with entrained air, except that for oxygen deficient explosives some solid carbon survives, the amount being a function of the extent of the deficiency. In Stage 3 the air entrainment decreases gradually to zero and the fireball cools. The model gives the diameter of the fireball and its temperature from the end of the detonation stage onwards.

The differences in the diameters of the fireballs in the hemispherical and spherical stages are not large. The temperatures range from approximately 2000–4200 K at the end of Stage 1 to 1150–2500 K in Stage 2.

In the overall model, the relations for the diameter and the duration time are based on the empirical models described above. The relation for the diameter is cross-checked with the heat balance model. The relations given in the model for the diameter and duration time of the fireball of a high explosive are

$$D = 3.5\ M^{0.333} \qquad [16.16.19]$$

$$t_d = 0.3\ M^{0.333} \qquad [16.16.20]$$

Equation 16.16.19 is applicable to any high explosive. Equation 16.16.20 is specific to explosives similar in oxygen balance to TNT.

For the profile of the shape and temperature the approach taken is as follows. The time required for the fireball to reach its maximum diameter is a small fraction of the total duration time. The authors define a time t_s at which the shape of the fireball changes from the maximum diameter hemisphere to a sphere, still at ground level:

$$t_s = \phi t_d \qquad [16.16.21]$$

where ϕ is a fraction. They use a value for ϕ of 0.25.

The temperature profile of the fireball is obtained from a heat balance model. In this model the detonation is taken as virtually instantaneous and the adiabatic flame temperature is determined. For an explosive which is oxygen deficient it is assumed that the rate of release of the remaining energy and the rate of entrainment of air are constant from time zero to time t_s. At time t_s combustion ceases, although air continues to be entrained at a linearly diminishing rate falling to zero at t_d. The temperature at the termination of the fireball T_f is taken as 1150 K.

The authors give for four explosives the generalized temperature profiles shown in Figure 16.89. These profiles are expressed as functions of the duration time calculated from Equation 16.16.20. This equation applies to TNT, and for this explosive the duration time is used directly. For the other explosives, an effective duration may be obtained from the graphs using a suitable value of the termination temperature T_f, taken as 1150 K.

As stated earlier, it is an implication of the values of the indices in the pair of Equations 16.16.19 and 16.16.20 that for a given explosive the temperature and thermal radiation at a given fraction of the duration time are the same for all masses of explosive.

The authors note that in the example which they give for a fireball of TNT that the fraction of heat radiated over the duration time is about 0.44.

A comparison between the diameter of the fireball in the Peterborough incident with that predicted by the model, as given in Equation 16.16.19, gives a predicted value of 33 m (spherical) or 40 m (hemispherical) compared with an apparent observed value of 36 m.

16.17 Pool Fires

A pool fire occurs when a flammable liquid spills onto the ground and is ignited. A fire in a liquid storage tank is also a form of pool fire, as is a trench fire. A pool fire may also occur on the surface of flammable liquid spilled onto water.

There is a considerable literature on pool fires, including the work of Burgoyne and Katan (1947), Rasbash, Rogowski and Stark (1956), Blinov and s Khudiakov (1957), Hottel (1959), Burgess and Zabetakis (1962 BM RI 6099), Welker and Sliepecevich (1965). P.M. Thomas (1963), P.H. Thomas, Pickard and Wraight (1963), A.F. Roberts (1966, 1971b), Werthenbach (1971a,b, 1973), Yumofo (1971b), A.R. Hall (1972, 1973), de Ris and Orloff (1972), L.E. Brown, Wesson and Welker (1974a, b, 1975), Seeger (1974), Escudier (1975), Modak (1977, 1978, 1981), Raj, Moussa and Aravamudan (1979a,b), de Ris (1979), Orloff (1980), Mizner (1981), Mizner and Eyre (1982, 1983). Moorhouse (1982), Moorhouse and Pritchard (1982), Orloff and de Ris (1982), Babrauskas (1983, 1986b), Heskestad (1983a), Hirst and Eyre (1983),

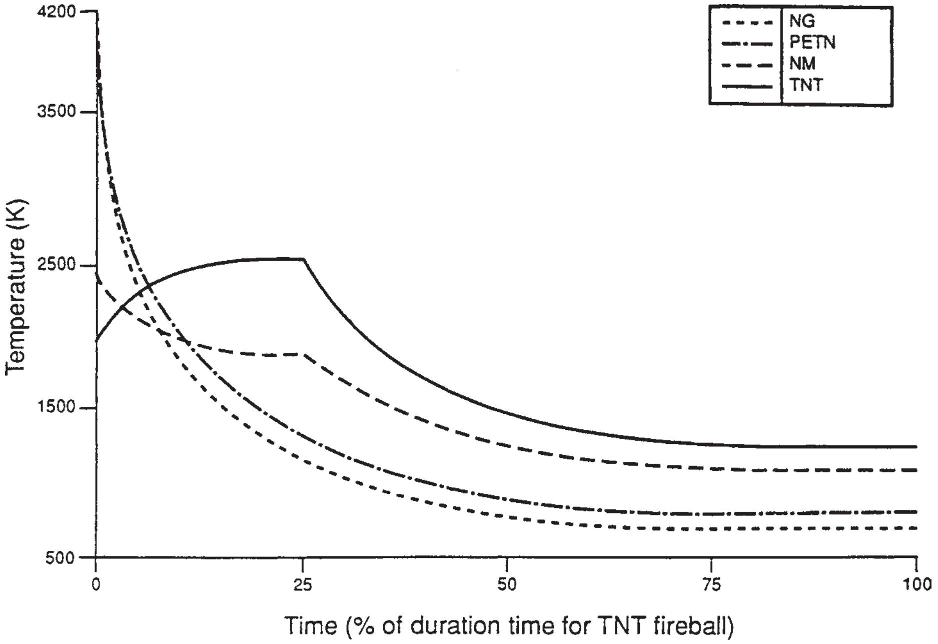

Figure 16.89 *Estimated temperatures of the fireballs of four explosives (Gilbert, Lees and Scilly, 1994e) NG, nitroglycerin; NM, nitromethane; PETN, pentaerythrito! tetranitrate; TNT, trinitrotoluene*

Considine (1984 SRD R297), Mudan (1984c), and Crocker and T. Napier (1986).

Some studies of pool fires are given in Table 16.63. Most work on pool fires deals with circular pools. A particular type of circular pool fire is the storage tank fire, which is considered in Subsection 16.17.1. A non-circular pool fire is a slot fire, which is treated in Subsection 16.17.15.

16.17.1 Experimental studies

There is a considerable experimental literature related to pool fires. Apart from the large number of publications on pool fires themselves, there are many relevant studies on flames such as those on combustion processes in, and heat radiation from, flames.

Much of the early work was done on relatively small diameter pool fires. Subsequent studies indicate that the effect of pool diameter is important and that it is preferable to carry out studies on large pool fires.

This initial work tended to be concerned with the determination of the liquid burning rate, of heat transfer to the liquid surface and of the fraction of heat radiated. Experimental studies on these aspects were conducted by Rasbash, Rogowski and Stark (1956) and by Blinov and Khudiakov (1957).

The work of Blinov and Khudiakov covered a wide range of pool diameters. Hottel (1959) analysed their data to show that, as the diameter of pool fire is increased, there is progression from a laminar to a transition and finally to a turbulent regime.

Burgess and Zabetakis (1962 BM RI 6099) carried out experiments on small pool fires to determine the liquid burning rate and fraction of heat radiated.

Yumoto (1971b) has done experiments to study the relative contribution of radiation and convection to heat transfer to the liquid surface in large pool fires.

Large-scale tests on pool fires of LNG have been undertaken as an American Gas Association (AGA) project as described by L.E. Brown, Wesson and Welker (1975), who give correlations for the liquid burning rate and the heat radiated.

Experiments on pool fires of aviation fuels have been done by Fu (1972).

Large-scale tests on pool fires of ethylene have been performed as part of the experiments done by the Ministry of International Trade and Industry (MITI), (1976) described earlier.

Modak (1981) has reported experiments on pool fires of polymethylmethacrylate (PMMA). Tests on large pool fires of LPG and LNG have been described by Mizner and Eyre (1982).

There is also a number of studies of fires in storage tanks. These include the work of Burgoyne and Katan (1947), Werthenbach (1971a,b, 1973), Seeger (1974), Lois and Swithenbank (1979) and Kobori, Handa and Yumoto (1981).

Investigations have also been carried out of fires on spills of flammable liquids on water, particularly for LNG. Closely related to these are tests on the spread of liquids on water. Experimental studies of the spreading of LNG on water have been done by Burgess, Murphy and Zabetakis (1970 BM RI 7448). A model of fire on a spill of LNG has been derived from this work by Burgess, Biordi and Murphy (1972 BM PMSRC 4177).

Large-scale tests of the spreading of spills and of fire on spills of LNG on water have been carried out as part of the Liquefied Gaseous Fuels (LGF) Spill Effects program by

the Lawrence Livermore National Laboratory (LLNL) at the Naval Weapons Center, China Lake, California. The work has been described by Hogan, Ermak and Koopman (1981).

Other large-scale tests on fire on spills of propane and LNG have been done by Shell at Maplin Sands as described by Blackmore, Eyre and Summers (1982) and Mizner and Eyre (1983).

Figure 16.90 shows a typical pool fire.

16.17.2 Empirical features

A pool fire is a complicated phenomenon and the theoretical treatment is correspondingly complex. It is appropriate, therefore, to describe first some of the empirical features of pool fires.

A pool fire burns with a flame which is often taken to be a cylinder with a height twice the pool diameter. In still air the flame is vertical, but in wind it tilts. Wind also causes the base of the flame to extend beyond the downwind edge of the pool, thus exhibiting flame drag. With some pool fires blowout can occur at a wind speed of about 5 m/s.

The characteristics of a pool fire depend on the pool diameter. The liquid burning rate increases with diameter until for large diameters it reaches a fixed value. The heat radiated from the flame behaves similarly.

Some fuels, such as LNG, burn with a relatively clear flame, while others, such as kerosene and LPG, give a smoky flame. The extent of the smoke affects the heat radiation.

The fraction of heat radiated by a pool fire usually lies in the range 0.2–0.4.

A few fuels do not burn stably but at a certain temperature exhibit boilover.

16.17.3 Modelling of pool fires

The modelling of pool fires covers the following aspects: (1) flame geometry, (2) liquid burning rate, (3) flame characteristics, (4) heat radiated and (5) view factor.

The approach to modelling the heat radiated from a pool fire is broadly similar to that taken for fireballs. Again, there are three different ways of determining the heat radiated: (1) the use of a value of the fraction of the heat radiated; (2) the use of a value for the surface emissivity; and (3) the estimation from the flame properties such as flame temperature and emissivity.

Reviews of pool fire models have been given by several authors, including de Ris (1979), Considine (1984 SRD R297), Mudan (1984c) and Cracker and Napier (1986).

16.17.4 Fire regimes

As just mentioned, Hottel (1958) analysed the work of Blinov and Khudiakov and showed that as the pan diameter increases the fire regime changes from laminar to turbulent. He gave the graph shown in Figure 16.91, in which burning velocity and flame height are plotted against pan diameter.

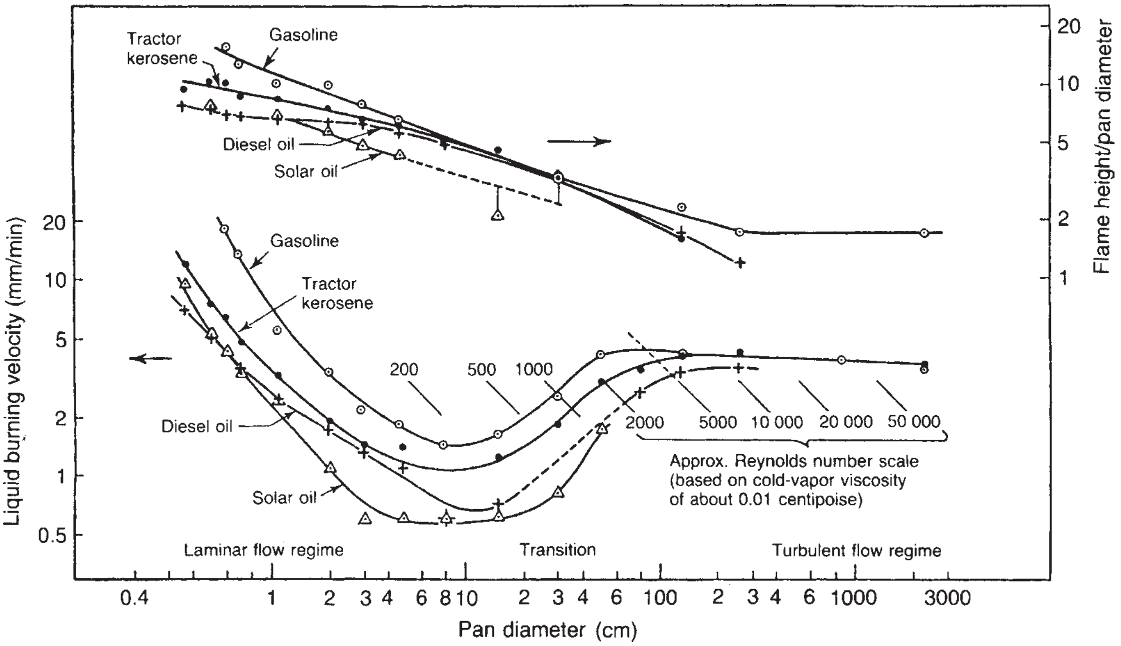

Figure 16.91 Liquid burning rate and flame height as function of fire regime in pool fires (after Hottel, 1958; reproduced with permission)

He defined a Reynolds number based on the vapour phase and related it to the parameters of the liquid phase as follows:

$$\mathrm{Re} = \frac{u_g d \rho_g}{\mu_g} \qquad [16.17.1a]$$

$$= \frac{u_l d \rho_l}{\mu_g} \qquad [16.17.1b]$$

where d is the pan diameter, u is the velocity, μ is the viscosity, ρ is the density and subscripts g and l refer to the vapour and liquid phases, respectively. The vapour phase Reynolds number was calculated using the cold gas values. The liquid velocity u_l is the liquid burning velocity v. Since the Reynolds number is proportional to the product vd, the lines of constant Reynolds number lie across the plot in Figure 16.91 from top left to bottom right with a slope of –1, as shown.

At a Reynolds number of about 20 the regime is laminar and the burning velocity decreases with increasing pan diameter. In the transition regime between Reynolds numbers of 20 and 200, the burning velocity first decreases, then increases and finally levels off with increase in pan diameter. Above Reynolds numbers of 500 the regime is turbulent and the burning velocity remains constant with increasing pan diameter. The pan diameter at which the regime becomes turbulent is about 1 m.

The flame height decreases with increasing pan diameter in the laminar and transition regimes and then remains constant with pan diameter in the turbulent regime.

16.17.5 Flame geometry

The flame on a pool fire has often been assumed to be an upright cylinder, as shown in Figure 16.90, with a length L twice the diameter D. An L/D ratio of 2 is used, for example, by Hearfield (1970) and R.B. Robertson (1976b). The work of Blinov and Khudiakov (1957) described above and shown in Figure 16.91 includes measurements of this ratio. It can be seen that for large diameters the value obtained is approximately 2.

Alternatively, the flame may be assumed to have a conical shape, but this assumption is less common and, unless otherwise stated, it is assumed in the following that the flame is treated as a cylinder.

An equation for flame length in still air has been given by P.H. Thomas (1963). This is

$$\frac{L}{D} = 42\left[\frac{m}{\rho_a (gD)^{1/2}}\right]^{0.6} \qquad [16.17.2]$$

where D is the flame diameter (m), g is the acceleration due to gravity (m/s^2), L is the flame height (m), m is the mass burning rate (kg/m^{2}s) and ρ_a the density of the ambient air (kg/m^3). Equation 16.17.2 is based on experiments on wood crib fires.

Steward (1970) has given a similar equation which takes into account the properties of the fuel.

Another expression for flame length is that of Heskestad (1983a). The basic relation is

$$\frac{L}{D} = f(N) \qquad [16.17.3]$$

where

$$N = \left[\frac{c_p T_o}{g\rho_a^2(\Delta H_c/r_s)^3}\right]\frac{Q^2}{D^2} \qquad [16.17.4]$$

where c_p is the specific heat of air (kJ/kg K), ΔH_c is the heat of combustion of the fuel (kJ/kg), N is a dimensionless group, Q is the total heat release rate (kW), r_s is the stoichiometric air to volatiles mass ration, T_o is the absolute temperature of the ambient air (K) and ρ_a is the density of the ambient air (kg/m^3).

The air/volatiles ratio r_s for a fuel $C_\alpha H_\beta O_\gamma$ burning in air is

$$r_s = 137.9\frac{\alpha + \beta/4 - \gamma/2}{12\alpha + \beta + 16\gamma} \qquad [16.17.5]$$

Heskestad has shown theoretically that for large values of N

$$\frac{L}{D} \propto N^{1/5} \qquad [16.17.6]$$

and has correlated experimental data with the relation

$$\frac{L}{D} = -1.02 + 15.6N^{1/5} \qquad [16.17.7]$$

The flame length in storage tank fires has been studied by Werthenbach (1971a,b, 1973). He gives an analysis, the point of departure of which is the ratio of the buoyancy to the momentum forces as given by the Archimedes number Ar:

$$\mathrm{Ar} = \frac{gD}{u^2}\frac{\Delta\rho}{\rho} \qquad [16.17.8]$$

where g is the acceleration due to gravity (m/s^2), u is the vapour velocity (m/s), ρ is the density of the vapour (kg/m^3) and $\Delta\rho$ is the difference between the density of the vapour and that of air (kg/m^3). Werthenbach correlates his results in terms of the Froude number Fr:

$$\frac{L}{D} = A\ \mathrm{Fr}^{0.2} \qquad [16.17.9]$$

with

$$\mathrm{Fr} = \frac{u^2}{gD^2} \qquad [16.17.10]$$

where A is a constant characteristic of the fuel. Values obtained for A were 29 for methane and natural gas and 40 for propane and gasoline. The vapour velocities were of the order of 0.75–1.0 cm/s. The author comments that these values are much lower that those in burner flames and that an attempt to apply the correlation for such flames to those on pool fires may be misleading.

Wind has several effects on the flame: it causes it to tilt, alters its length and extends it along the ground on the downwind side.

P.H. Thomas (1963) has provided an equation for flame length for a tilted flame also. This is

$$\frac{L}{D} = 55\left[\frac{m}{\rho_a(gD)^{1/2}}\right]^{0.67}(u^*)^{-0.21} \qquad [16.17.11]$$

with

$$u^* = u/u_c \qquad [16.17.12]$$

$$u_c = \left(\frac{gmD}{\rho_a}\right)^{1/3} \qquad [16.17.13]$$

where u is the wind velocity (m/s), u_c is a characteristic velocity (m/s) and u^* is a dimensionless wind velocity. The basis of Equation 16.17.11 is again experiments on fires on wood cribs.

The AGA (1973) has given an equation of the same general form as Equation 16.17.11, but with different parameters:

$$\frac{L}{D} = \left[\frac{m}{\rho_a(gD)^{1/2}}\right]^{-0.19}(u^*)^{0.06} \qquad [16.17.14]$$

Equation 16.17.14 therefore exhibits behaviour different from that of the Thomas equation 16.17.11.

Moorhouse (1982) has made correlations of available data which yield

$$\frac{L}{D} = 6.2\left[\frac{m}{\rho_a(gD)^{1/2}}\right]^{0.254}(u_{10}^*)^{-0.044} \qquad \text{Cylindrical flame} \qquad [16.17.15a]$$

$$\frac{L}{D} = 4.7\left[\frac{m}{\rho_a(gD)^{1/2}}\right]^{0.2104}(u_{10}^*)^{-0.1144} \qquad \text{Conical flame} \qquad [16.17.15b]$$

with

$$u_{10}^* = u_{10}/u_c \qquad [16.17.16]$$

where u_{10} is the wind speed at a height of 10 m and u_{10}^* is the dimensionless wind speed at that height. These equations are valid for wind speeds $u_{10} > u_c$, while for wind speeds $u_{10} < u_c$ the dimensionless wind speed term is taken as unity.

Considine (1984 SRD R297) gives an analysis in which it is shown that, given certain assumptions, the use of a constant fraction of heat radiated implies a constant L/D ratio.

Thomas has also provided an equation for flame tilt

$$\cos\theta = 0.7(u^*)^{-0.49} \qquad [16.17.17]$$

where θ is the angle of tilt from the vertical (rad). The basis of Equation 16.17.17 is again experiments on wood crib fires.

The AGA (1973) has given an equation of the same form

$$\cos\theta = (u^*)^{-0.5} \qquad [16.17.18]$$

This equation is based on tests on large LNG fires.

Another correlation for flame tilt is that of Welker and Sliepcevich (1965)

$$\frac{\tan\theta}{\cos\theta} = 3.2\left(\frac{Du\rho_a}{\mu_a}\right)^{0.07}\left(\frac{u^2}{Dg}\right)^{0.7}\left(\frac{\rho_g}{\rho_a}\right)^{-0.6} \qquad [16.17.19]$$

where μ_a is the viscosity of air (kg/m s), and ρ_g is the density of the fuel vapour at the normal boiling point (kg/m^3).

Equation 16.17.19 is based on experiments on small pool fires.

Moorhouse (1982) has correlated the available data to obtain equations of the form given by Thomas and of that given Welker and Sliepcevich. These are, respectively,

$$\cos\theta = 0.86(u_{10}^{*})^{-0.250} \qquad \text{Cylindrical flame} \qquad [16.17.20a]$$

$$\cos\theta = 0.87(u_{10}^{*})^{-0.272} \qquad \text{Conical flame} \qquad [16.17.20b]$$

and

$$\frac{\tan\theta}{\cos\theta} = 1.19\left(\frac{Du\rho_{\mathrm{a}}}{\mu_{\mathrm{a}}}\right)^{0.050}\left(\frac{u^2}{Dg}\right)^{0.399} \qquad \text{Cylindrical flame} \qquad [16.17.21a]$$

$$\frac{\tan\theta}{\cos\theta} = 3.0\left(\frac{Du\rho_{\mathrm{a}}}{\mu_{\mathrm{a}}}\right)^{0.011}\left(\frac{u^2}{Dg}\right)^{0.422} \qquad \text{Conical flame} \qquad [16.17.21b]$$

For flame drag, Welker and Sliepcevich (1966) give the following equation

$$\frac{D'}{D} = 2.1\left(\frac{u^2}{Dg}\right)^{0.21}\left(\frac{\rho_{\mathrm{g}}}{\rho_{\mathrm{a}}}\right)^{0.48} \qquad [16.17.22]$$

where D' is the elongated flame base (m). The experimental basis of Equation 16.17.22 is wind tunnel tests on small pool fires.

Moorhouse (1982) has correlated the available data to obtain the equations

$$\frac{D'}{D} = 1.5\left(\frac{u^2}{Dg}\right)^{0.069} \qquad \text{Cylindrical flame} \qquad [16.17.23a]$$

$$\frac{D'}{D_{\mathrm{w}}} = 1.6\left(\frac{u^2}{Dg}\right)^{0.061} \qquad \text{Conical flame} \qquad [16.17.23b]$$

where D_{w} is the maximum pool dimension in the direction of the wind (m).

16.17.6 Liquid burning rate

The review by Hottel (1959) of the work of Blinov and Khudiakov includes a simple analysis of the heat q transferred from the flame to the pool, which may be written as

$$q = q_{\mathrm{c}} + q_{\mathrm{r}} + q_{\mathrm{rim}} \qquad [16.17.24]$$

where q_{c} is the heat transferred to the pool by conduction, q_{r} is the heat transferred by radiation and q_{rim} is the heat transferred by the pan rim. The heats transferred by convection and by radiation are

$$q_{\mathrm{c}} = \frac{\pi}{4}d^2U(T_{\mathrm{f}} - T_{\mathrm{b}}) \qquad [16.17.25]$$

$$q_{\mathrm{r}} = \frac{\pi}{4}d^2\sigma F(T_{\mathrm{f}}^4 - T_{\mathrm{b}}^4)[1 - \exp(-kd)] \qquad [16.17.26]$$

where d is the pool diameter, F is the view factor, k is the extinction coefficient, T_{b} is the absolute temperature of the burning liquid surface, T_{f} is the absolute temperature of the flame, U is the heat transfer coefficient and σ is the Stefan–Boltzmann constant. He considers heat transfer to a gasoline pool assuming $F = 0.25$, $T_{\mathrm{f}} = 1100$ K and $U = 1$ BTU/ft^{2}h.

For small pans q_{rim} will be large and the liquid burning rate will be high. For large pans q_{rim} will be negligible, q_{c} will be constant and q_{r} will be dominant with large kd and hence a large and constant value of the term $[1 - \exp(-kd)]$. For intermediate size pans q_{rim} will again be negligible, but q_{r} will not be so large due to the thinness of the flame. Hence the liquid burning rate will pass through a minimum for intermediate pan diameters. This analysis agrees with the experimental results shown in Figure 16.91.

An equation for the regression rate of a burning liquid surface under windless conditions has been given by Burgess and Zabetakis (1962 BM RI 6099) as follows:

$$v = v_{\infty}[1 - \exp(-k_1 d)] \qquad [16.17.27]$$

$$v_{\infty} = k_2\left(\frac{-\Delta H_{\mathrm{c}}}{\Delta H_{\mathrm{v}}}\right) \qquad [16.17.28]$$

where d is the diameter of the pool (cm), ΔH_{c} is the net heat of combustion (negative) (kJ/kmol), ΔH_{v} is the total heat of vaporization (kJ/kmol), v is the liquid burning rate (cm/min), v_{∞} is the liquid burning rate for a pool of infinite diameter (cm/min), and k_1, k_2 are constants ($k_2 = 0.0076$).

Liquid burning rate parameters for Equation 16.17.27 for selected substances are given in Table 16.64. For LNG the maximum liquid burning rate given in Table 16.64 is 0.66 cm/min, but in further experimental work at Bruceton and Lake Charles described by these authors considerably higher values were obtained. In one experiment the burning rate was 1.16 cm/min.

Equation 16.17.27 also be written in the form

$$m = m_{\infty}\,[1 - \exp(-k_1 d)] \qquad [16.17.29]$$

$$m_{\infty} = v_{\infty}\rho_{\mathrm{l}} \qquad [16.17.30]$$

where m is the mass liquid burning rate (kg/m^2 s), m_{∞} is the mass burning rate for a pool of infinite diameter (kg/m^2 s) and ρ_{l} the liquid density (kg/m^3).

Brown, Wesson and Welker used Equation 16.17.29 to correlate the mass burning rate for large LNG fires in the AGA tests. In British Units they give for the parameters m_{∞} a value of 0.6 (in./min) and k_1 a value of 0.2 (ft^{-1}).

Work on the heat transfer from the flame to the liquid pool has been reviewed by Yumoto (1971b). This work was limited to smal-scale fires. He decribes experimental work on fires in pools up to 3 m diameter in which measurements were made of the relative contribution of convective and radiant heat transfer. As shown in Figure 16.92 the contribution of convection falls and that of radiation rises as the pool diameter increases, until both contributions reach a constant value.

Sibulkin (1973) discusses the ratio $q_{\mathrm{r}}/q_{\mathrm{c}}$. He assumes in his analysis that q_{c} is constant and that

$$q_{\mathrm{r}} \propto \epsilon \qquad [16.17.31]$$

where ϵ is the flame emissivity. He gives for the latter

$$\epsilon = 1 - \exp(-k_3 L_{\mathrm{m}}) \qquad [16.17.32]$$

where L_m is the mean beam length and k_3 is a constant. But for pools of intermediate diameter

$$\epsilon \propto L_m^{1/2} \qquad [16.17.33]$$

$$L_m \propto D \qquad [16.17.34]$$

Hence

$$\epsilon \propto D^{1/2} \qquad [16.17.35]$$

$$\frac{q_r}{q_c} \propto D^{1/2} \qquad [16.17.36]$$

For large diameter pools $\epsilon = 1$, and hence

$$\frac{q_r}{q_c} \propto \text{Constant} \qquad [16.17.37]$$

An extensive review of liquid burning rates is given by A.R. Hall (1973), who considers among other things the effects of (1) the fuel, (2) fuel mixtures, (3) fuel containing dispersed water, (4) the liquid surface temperature, (5) the liquid temperature distribution, (6) the pool diameter, (7) the heat transfer from the flame to the liquid and (8) the wind speed.

Table 16.64 *Parameters for liquid burning rate on pools of selected substances (Burgess and Zabetakis, 1962 BM RI 6099) (Courtesy of the Bureau of Mines)*

	v_∞ (cm/min)	k_1 (cm^{-1})
Hydrogen	1.4[a]	0.07[a]
Butane	0.79	0.027

Benzene	0.60	0.026
Methanol	0.17	0.046
LNG	0.66[b]	0.03[b]

[a] Uncertain value.
[b] Value calculated.

Work on the burning rates of fuels of solid plastics has been reviewed by de Ris (1979) in the context of pool fires. He tabulated for the fuels including polymethylmethacrylate (PMMA), polypropylene (PP) and polystyrene (PS) a large number of potentially relevant variables and found that the actual volumetric heat release rate appears to be independent of the fuel. He explained this by the fact that the heat released per unit mass of oxygen consumed is essentially the same for most organic fuels, despite incomplete combustion, whilst the rate of oxygen consumption is controlled by the overall rate of turbulent mixing, which is driven by temperature differences that are generally insensitive to the fuel.

Babrauskas (1983, 1986b) distinguishes the following burning modes of pool fires:

Pool diameter (m)	*Burning mode*
<0.05	Convective, laminar
<0.2	Convective, turbulent
0.2–1.0	Radiative, optically thin
>1.0	Radiative, optically thick

and uses the relations

$$m = m_\infty[1 - \exp(-k\beta D)] \qquad [16.17.38]$$

with

$$m_\infty = \frac{\sigma T_f^4}{\Delta h_g} \qquad [16.17.39]$$

where Δh_g is the total heat of gasification (kJ/kg), k is an absorption–extinction coefficient (m^{-1}), T_f is the absolute temperature of the effective equivalent gray gas (K) and β is a mean beam length corrector. He discusses whether the mean beam length corrector β can be derived, and concludes that it cannot. He gives tabulations of m_∞ and ($k\beta$) from work on large pool fires reported by some 20 authors. These data are given in Table 16.65.

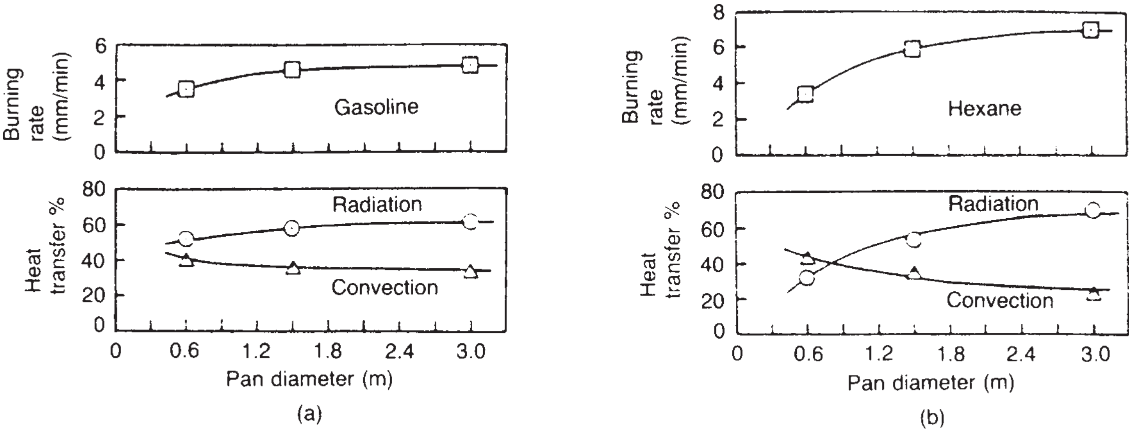

Figure 16.92 *Liquid burning rate and heat transfer to the liquid surface in large pool fires (after Yumoto, 1971b): (a) gasoline fire; (b) hexane fire (Courtesy of Combustion and Flame)*

Table 16.65 *Pool fire parameters for selected substances (after Babrauskas, 1983) (Courtesy of Fire Technology)*

Material	ρ_l (kg/m^3)	m_∞ (kg/m^{2}s)	$k\beta$ (m^{-1})	χ_r
H_2 (liquid)	700	0.169	6.1	0.25
LNG (mostly CH_4)	415	0.078	1.1	0.16–0.23
LPG (mostly C_3H_6)	585	0.099	1.4	0.26
Butane	573	0.078	2.7	0.27–0.30
Hexane	650	0.074	1.9	0.20–0.40
Heptane	675	0.101	1.1	
Methanol	796	0.017		0.17–0.20
Ethanol	794	0.015		0.20
Benzene	874	0.085	2.7	0.14–0.38
Xylenes	870	0.090	1.4	
Acetone	791	0.041	1.9	
Diethyl ether	714	0.085	0.7	
Gasoline	740	0.055	2.1	0.18
Kerosene	820	0.039	3.5	
JP-4	760	0.051	3.6	0.35
JP-5	810	0.054	1.6	
Transformer oil (hydrocarbon)	760	0.039	0.7	
Fuel oil (heavy)	940–1000	0.035	1.7	
Crude oil	830–880	0.022–0.045	2.8	0.18

Babrauskas (1986b) also addresses some of the factors affecting the liquid burning rate, including (1) pool diameter, (2) lip effects and (3) wind speed.

For very large pool fires with diameters greater than 5–10 m, there is some evidence of a slight decrease in burning rate. This is presumably due to poor mixing with air. Babrauskas suggests that this effect is unlikely to reduce the burning rate by more than 20%.

Effects of lip, or freeboard, on large pool fires involve all three modes of heat transfer. A lip can affect the temperature distribution in the wall of a storage tank and hence heat transfer by conduction. It can promote turbulence and enhance heat transfer by convection. It tends to make the flame more stable and emissive, thus increasing heat transfer by radiation. Babrauskas quotes the following work of Orloff (1981), on fires of one fuel, PMMA, on the effect of the ratio d/D of the freeboard height to the pool diameter on the ratio ϕ_{br} of the liquid burning rate to it base value with no lip:

d/D	ϕ_{br}
0	1.0
0.07	1.6
0.2	2.0
>0.2	Slow decrease

With regard to wind speed there is some work showing an increase in burning rate and other work indicating a decrease. Relevant studies include those of Blinov and Khudiakov (1957) and Lois and Swithenbank (1978).

Some spot values of the liquid burning rate are as follows. In the experiments of Blinov and Khudiakov on gasoline, kerosene, diesel oil and solar oil, the liquid burning rate in the turbulent regime was 0.5 cm/min. In one of the large-scale tests on the pool burning of ethylene conducted by MITI (1976) a liquid burning rate of 0.88 cm/min was obtained. Values of liquid burning rate are given in the ICI *LFG Code* (ICI/RoSPA 1970 IS/74) and by Hearfield (1970) and R.B. Robertson (1976b) and liquid burning rate is treated in Chapter 22 in relation to heat radiation from fires to storage tanks.

A liquid burning rate of 0.75–1.0 cm/min is quoted in the fourth edition of the Dow *Guide* (Dow Chemical Company, 1976). This value is given in relation to the fireproofing of structures as part of the 'Recommended Minimum Fire Prevention and Protection Features', which do not appear as such in later editions.

16.17.7 Flame characteristics

Important characteristics of the flame on a pool fire are the nature of the flame, its temperature and its emissivity.

Some flammable liquids burn with a relatively clear flame, while others give a more smoky flame. The difference is well illustrated by the work of Mizner and Eyre (1982) on LNG and LPG pool fires. The LPG flames were smoky, the LNG flames much less so. Figure 16.93 illustrates the difference. The presence of carbon particles in the flames has several effects. One is that the soot enhances the emissivity of the flame. Another is that smoke may shroud the flame from the target.

Several authors refer to a flame temperature of 1100 K. This is the typical value taken by Hottel (1959). Craven (1976) also mentions this figure, but states that this is not necessarily the maximum value which may be attained. Some data on pool fire flame temperatures given by Babrauskas are shown in Table 16.65 and further data on flame temperature and surface emissive power given by Mudan (1984c) are shown in Table 16.66. Further information on flame temperatures is given in relation to engulfing fires in Section 16.20.

As far as emissivity is concerned, pool fires of most hydrocarbon fuels become optically thick when the diameter reaches about 3 m. For such fires it is often stated that the emissivity of the flame may be taken as unity. More refined estimates of flame emissivity may be made using the relations given in Section 16.13.

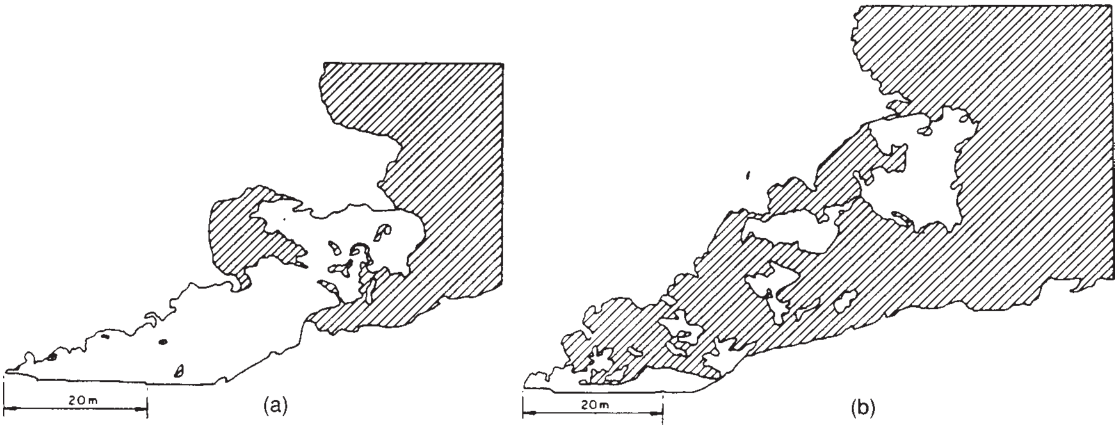

Figure 16.93 Smokiness of flames in large pool fires (after Mizner and Eyre, 1982): (a) LNG fire; (b) LPG fire (Courtesy of the Institution of Chemical Engineers)

Table 16.66 Some data on the measured flame temperature and surface emissive power of flames of flames on pool fires (Mudan, 1984c)(Courtesy of Progress in Energy and Combustion Science)

Material	*Pool fire dimensions* (m)	*Flame radiation temperature* (K)	*Surface emissive power* (kW/m^2)	*Reference*
LNG on water	8.5–15	1500	210–280	Raj, Moussa and Aravamudan (1979b)
LNG on land	20	–	150–220	Mizner and Eyre (1982)
LPG on land	20	–	48	Mizner and Eyer (1982)
Pentane	1.0		61	Modak (1978)
Ethylene	2.5		130	Modak (1978)
Gasoline	1.0–10	1240	60–130 (max)	Hägglund and Persson (1976)
Kerosene	30–80	1600	10–25 (av.)	Japan Institute for Safety Engineering (1982)
JP-4	5.8	1200		NASA (1979)
JP-5	1.0–30		30–50	Modak (1978)

The conditions which give rise to smokiness in the flame are also given in Section 16.13. If the flame is smoky, the unobscured parts of the flame will emit radiation to the target, while the obscured parts will not.

A method of taking account of obscuration of the flame has been given by Considine (1984 SRD R297). He divides the flame into unobscured section with a surface emissive power q and obscured sections with 'blooms' of radiation where the average emissive power is 0.3 q. From photographs of flames the relative proportion of unobscured flame varied from about 30% for fires a few metres in diameter to zero for flames 50 m or more in diameter. He analyses the following three cases:

(1) flame radiating continuously over entire height;
(2) flame radiating 30% continuously, 70% in blooms;
(3) flame radiating in blooms over entire height.

He suggests that for flames in the range 5–25 m diameter the bottom 30% be taken as radiating continuously and the rest radiating in blooms, and that flames >25 m diameter be taken as radiating in blooms over their entire height. The view factor for such a flame is considered below.

16.17.8 Heat radiated

There are three methods of estimating the heat radiated by a pool fire. These are based on:

(1) heat evolved and radiated;
(2) surface emissive power;
(3) flame temperature and emissivity.

The heat evolved in the flame may be determined from the liquid burning rate. The heat radiated from the flame is then usually calculated as a fraction of the heat evolved by using an empirical factor. Some data on this radiant heat factor have been given by Burgess and Zabetakis in the work already described and are shown in Table 16.67. They suggest that the fraction of heated radiated generally does not exceed half that evolved.

It is stated by Roberts that the fraction of heat radiated both by fireballs and pool fires is typically in the range 0.2–0.4. He suggests a value of 0.3 for this radiant heat factor.

Large pool fires are affected by smoke blockage. The following data of Hägglund and Persson (1976) for the

***Table 16.67** Fraction of heat radiated from flames burning on liquid pools (Burgess and Zabetakis, 1962 BM RI 6099) (Courtesy of the Bureau of Mines)*

	Pool diameter (cm)	*Heat radiated* (fraction)
Hydrogen	33	0.25
Butane	76	0.27
Benzene	122	0.36
Methanol	122	0.17
LNG	76	0.23

effect of pool diameter on the fraction of heat radiated in JP-4 fuel fires is quoted by Babrauskas:

Pool diameter (m)	*Fraction of heat radiated*
1.0	0.35
1.5	0.39
2.0	0.34
3.0	0.31
5.0	0.16
10.0	0.10

He states, however, that similar information is not available for other fuels and suggests that a conservative estimate can be obtained by disregarding smoke blockage.

The intensity of heat radiation may then be calculated by dividing the heat radiated by the area of the flame envelope.

The second method is to use directly information on the heat radiation intensity, or emissive power, of the flame surface. Values of surface emissive power of hydrocarbon fires have been reviewed by P. Nash (1974a). He lists values of heat fluxes, extrapolated from experimental fires of different sizes, in the range 30–189 kW/m^2.

In the context of safety distances, a value of 170 kW/m^2 has been suggested by law (1969). This aspect has also been discussed by Craven (1976), who concludes that the value of 170 kW/m^2 given by Law provides a realistic initial estimate.

Further data on surface emissive power are given by Mudan (1984c). His tabulated values are given in Table 16.66; he also gives other values in the text.

There are wide differences in surface emissive power, depending on the smokiness of the flame. Mizner and Eyre (1982) obtained in their work surface emissive powers of 35 kW/m^2 for kerosene, 48 kW/m^2 for LPG but 153 kW/m^2 for LNG.

Reviewing work on pool fires on land and water, Moorhouse and Pritchard (1982) conclude that for large pool fires of hydrocarbons, excluding liquefied gases, the surface emissive power is unlikely to exceed 60 kW/m^2 and state that for such fires the value of 170 kW/m^2 often quoted is based on small scale tests and is not appropriate.

With regard to pool fires of LNG, small fires clearly burn with a particularly clean flame. Evidence of soot formation is found only when the pool diameter reaches about 10 m or when most of the fuel has been consumed and the proportion of higher hydrocarbons is rising rapidly. Optical thickness is approached only when the flame is some meters wide. Moorhouse and Pritchard quote for pool fires of LNG the surface emissivities of the order of 200 kW/m^2 obtained by Raj, Moussa and Aravamudan (1979a).

Values of the surface emissive power for pool fires on water obtained in the experiments on the dispersion and burning of vapour clouds at Maplin Sands have been given by Blackmore, Eyre and Summers (1982), Hirst and Eyre (1983) and Mizner and Eyre (1983). This work has been described in Section 16.14. Pool fires formed on the liquefied gas spilled on the sea. The surface emissive power for these pool fires, as opposed to the vapour cloud fire, were 203 kW/m^2 for LNG and 43 kW/m^2 for propane. The authors suggest a value of 200 kW/m^2 as being representative for LNG pool fires.

Further indications of surface emissive power are provided in the work on engulfing fires described in Section 16.20.

L.E. Brown, Wesson and Welker (1975), in the work on LNG fires described earlier, have derived for such fires the following equation for surface emissive power:

$$q = q_\infty[1 - \exp(k_4 d)] \qquad [16.17.40]$$

where d is the diameter of the fire (ft), q is the heat flux from the surface (BTu/h ft^2), q_∞ the heat flux from the surface of a 'large' fire (BTU/h ft^2) and k_4 a constant (ft^{-1}). The values given for the parameter q_∞ is and the constant k_4 are 45,000 and 0.055, respectively.

Mudan (1984c) suggests that for hazard assessment the surface emissive power be taken as a weighted value for the unobscured and obscured portions of the flame. For example, for a flame comprising 20% luminous spots and with 80% obscured by smoke

$$q = 0.2 \times 130 + 0.8 \times 20 = 42 \text{ kW/m}^2$$

Similarly, Considine (1984 SRD R297) proposes that for hydrocarbons, but not LNG, the surface emissive power of the flame be taken as 120 kW/m^2 over the part radiating continuously and as 0.3 × 120 = 36 kW/m^2 over the part radiating in blooms.

A further discussion of the intensity of heat radiation is given in the ICI *LFG Code* and is described in Chapter 22 in relation to heat radiation from fires to storage vessels.

The third method is to determine the heat radiated from the temperature and emissivity of the flame. The heat radiated is

$$E = \epsilon\sigma T_f^4 \qquad [16.17.41]$$

where E is the surface emissive power (kW/m^2). The heat so radiated may be assumed to come either from a point source or from the flame surface. The estimation of the emissivity ϵ is discussed in Section 16.13.

In order to determine the heat incident on a target it is necessary to take into account the target absorptivity, the atmospheric transmissivity and the view factor. The determination of the latter is now considered.

16.17.9 View factor

The targets for heat radiated form a pool fire include both the liquid surface and objects outside the flame. There are therefore two different types of view factor relevant to relevant to pool fires.

As mentioned earlier, Hottel (1959) has used for the view factor of the liquid pool a value of 0.25.

For an object outside the flame there are several different treatments. For heat radiation from a flame treated as a vertical or tilted cylinder to a target the three principal models are:

(1) point source model;
(2) solid flame model;
(3) equivalent radiator model.

These models and their application have been described by Crocker and Napier (1986).

For a point source the radiation at a surface a distance r from the source is

$$E = \frac{Q_r}{4\pi r^2} \qquad [16.17.42]$$

and the radiation incident on the target is

$$I = \alpha\tau\frac{FQ_r}{4\pi l_s^2} \qquad [16.17.43]$$

where E is the surface emissive power (kW/m^2), F is the view factor, I is the thermal radiation intensity (kW/m^2), Q_r is the heat radiated (kW), r is a surface radius (m), l_s is the slant distance between the source and the target (m), α is the absorptivity of the target and τ is the transmissivity of the atmosphere.

Then from Equation 16.17.42 and 16.17.43 for a point source with a target surface normal to the line joining it to the source, as given in Equation 16.13.100

$$F = \frac{r^2}{l_s^2} \qquad [16.17.44]$$

The expressions for vertical and horizontal targets are given by Equations 16.13.101 and 16.13.102.

The geometry of this model is shown both for pool fires and for storage tanks in Figure 16.94. This approach has been used by a number of workers (e.g. Hearfield, 1970) for pool and tank fires. The point source model is not accurate for a target close to the flame and for this situation other methods should be used.

Of the more accurate methods, the more widely used appears to be the solid flame model. Methods for the calculation of the view factor for a vertical cylinder have been described by Hamilton and Morgan (1952) and Sparrow, Miller and Jonsson (1962), and for a tilted cylinder by Rein, Sliepcevich and Welker (1970), Merriam (1972) and Raj and Kalelkar (1974). A collection of view factors is given by Howell (1982).

For a vertical cylinder with a target with a vertical surface, as shown in Figure 16.95(a), the view factor given by Hamilton and Morgan (1952) (Howell, configuration B-29) is

$$F = \frac{1}{\pi X}\tan^{-1}\left[\frac{L}{(X^2-1)^{1/2}}\right] + \frac{L}{\pi}\left(\frac{(A-2X)}{X(AB)^{1/2}} \times \tan^{-1}\left\{\frac{[\mathrm{A}(X-1)]^{1/2}}{[\mathrm{B}(X+1)]^{1/2}}\right\} - \frac{1}{X}\tan^{-1}\left[\frac{(X-1)^{1/2}}{(X+1)^{1/2}}\right]\right) \qquad [16.17.45]$$

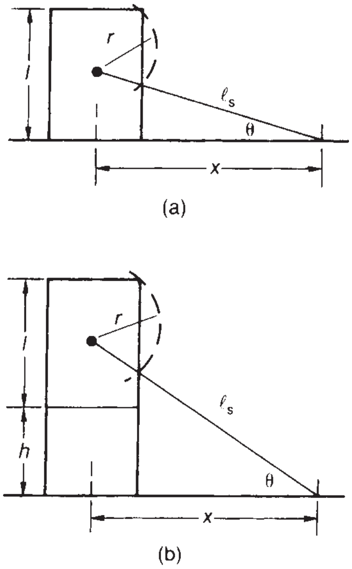

Figure 16.94 *View factor for pool and tank fires – point source model: (a) pool fire; (b) tank fire*

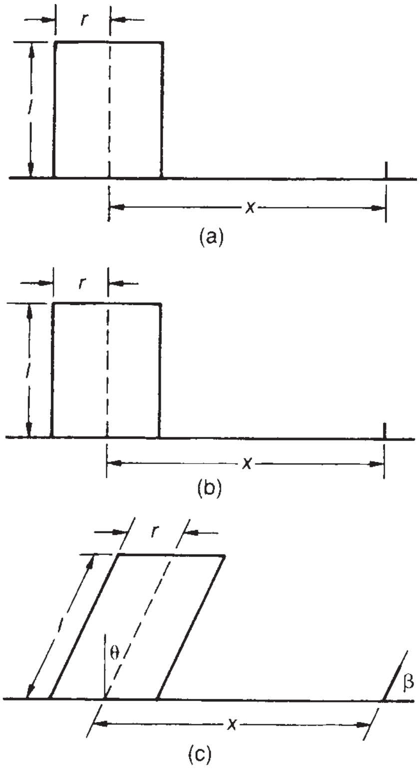

Figure 16.95 *View factor for pool fires – solid flame model: (a) vertical cylindrical flame, vertical target; (b) vertical cylindrical flame, horizontal target; (c) tilted cylindrical flame, angled target*

with

$$L = l/r \qquad [16.17.46a]$$

$$X = x/r \qquad [16.17.46b]$$

$$A = (X+1)^2 + L^2 \qquad [16.17.46c]$$

$$B = (X-1)^2 + L^2 \qquad [16.17.46d]$$

where r is the radius of the cylinder.

For a vertical cylinder with a target with a horizontal surface, as shown in Figure 16.95(b), the view factor given by Sparrow, Miller and Jonsson (1962) (Howell, configuration B-27) is

$$F = \frac{1}{2\pi}\cos^{-1} R + \frac{1}{\pi}\left\{\tan^{-1}\left[\frac{R}{(1-R^2)^{1/2}}\right] - \frac{(1+L^2-R^2)}{X} \times \tan^{-1}\left[\frac{X\tan(0.5\cos^{-1} R)}{1+L^2+R^2-2R}\right]\right\} \qquad [16.17.47]$$

with

$$R = r/x \qquad [16.17.48a]$$

$$L = l/x \qquad [16.17.48b]$$

$$X = [(1+L^2+R^2)^2 - 4R^2]^{1/2} \qquad [16.17.48c]$$

For a vertical cylinder, an expression based on the more approximate subtended solid angle method has been given by Stannard (1977)

$$F = \frac{2}{\pi}\sin^{-1}(r/x)\sin\{\tan^{-1}[l/(x-r)]\} \qquad [16.17.49]$$

For a tilted cylinder with a circular base tilted at an angle θ to the horizontal and with the target having a surface at an angle β to the horizontal, as shown in Figure 16.95(c), the view factor has been given by Mudan (1984c), following work by Raj and Kalelkar (1974), and is

$$F = \frac{1}{\pi}[(\cos\beta\sin\theta - \sin\beta\cos\theta)(A_1\cos\phi + LA_2) + \cos\beta(A_3 - A_4)] \qquad [16.17.50]$$

with

$$L = l/r \qquad [16.17.51a]$$

$$X = x/r \qquad [16.17.51b]$$

$$\phi = \sin^{-1}(1/X) \qquad [16.17.51c]$$

$$A_1 = \frac{1}{B_1}\left\{\tan^{-1}\left[\frac{L-(X-1/X)\sin\theta}{B_1}\right] + \tan^{-1}\left[\frac{(X-1/X)\sin\theta}{B_1}\right]\right\} \qquad [16.17.51d]$$

$$B_1 = [(X^2-1)\cos^2\theta + (1-1/X^2)\sin^2\theta]^{1/2} \qquad [16.17.51e]$$

$$A_2 = \int_0^{\pi/2} f(v)\mathrm{d}v \qquad [16.17.51f]$$

$$f(v) = \frac{\sin v}{(1+L^2+X^2-2XL\sin\theta) + 2(L\sin\theta - X)\sin v} \qquad [16.17.51g]$$

$$A_3 = \int_0^{\pi/2} \frac{(X\sin v - 1)\ \mathrm{d}v}{(1+X^2-2X\sin v)} \qquad [16.17.51h]$$

$$A_4 = \int_0^{\pi/2} \frac{(X\sin v - 1)\ dv}{[(1+L^2+X^2-2L\sin\theta) + 2(L\sin\theta - X)\sin v]} \qquad [16.17.51i]$$

For a tilted cylinder with a target with a vertical surface ($\beta = 90°$), Equation 16.17.50 reduces to

$$F = \frac{1}{\pi}\cos\theta(A_1\cos\phi + LA_2) \qquad [16.17.52]$$

Stannard has given an expression based on the subtended solid angle method for a tilted cylinder also

$$F = \frac{2}{\pi}\sin^{-1}\left[\frac{r}{r+(x-r)\cos\theta}\right] \times \left\{\sin\theta + \sin\tan^{-1}\left[\left(\frac{1}{(x-r)\cos\theta}\right) - \tan\theta\right]\right\} \qquad [16.17.53]$$

The third approach is the equivalent radiator method. For a vertical cylinder the view factor has been given by Hamilton and Morgan (1952). For a target with vertical surface as shown in Figure 16.96(a) the view factor for a half-radiator is

$$F = \frac{1}{2\pi}\left\{\frac{R}{(1+R^2)^{1/2}}\tan^{-1}\left[\frac{L}{(1+R^2)^{1/2}}\right] + \frac{L}{(1+L^2)^{1/2}} \times \tan^{-1}\left[\frac{R}{(1+L^2)^{1/2}}\right]\right\} \qquad [16.17.54]$$

and for a target with a horizontal surface as shown in Figure 16.96(b) the view factor for a half-radiator is

$$F = \frac{1}{2\pi}\left\{\tan^{-1} R - \frac{1}{(1+L^2)^{1/2}}\tan^{-1}\left[\frac{2}{(1+L^2)^{1/2}}\right]\right\} \qquad [16.17.55]$$

with

$$R = r/x \qquad [16.17.56a]$$

$$L = l/x \qquad [16.17.56b]$$

Since the view factors given by Equations 16.17.54 and 16.17.55 are for half the radiator surface, they must be doubled to give the full view factors.

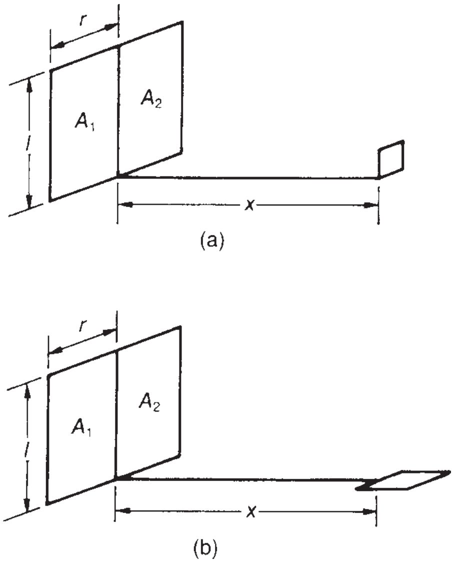

Figure 16.96 *View factor for pool fires – equivalent radiator model: (a) vertical cylindrical flame, vertical target and (b) vertical cylindrical flame, horizontal target*

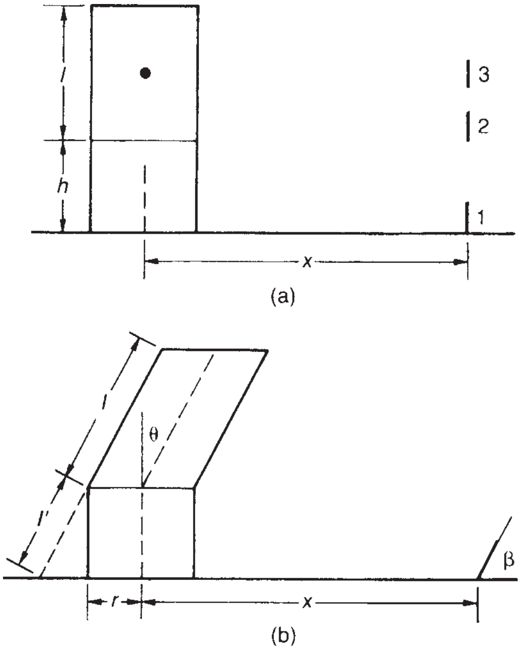

Figure 16.97 *View factor for tank fires – solid flame model: (a) vertical cylindrical flame, vertical target; and (b) tilted cylindrical flame, angled target*

The maximum view factor F_m is the geometric mean of the view factor F_v for a vertical surface and the view factor F_h for a horizontal surface:

$$F_m = (F_v + F_h)^{1/2} \qquad [16.17.57]$$

The application of the view factors just given to tank fires has been discussed by Crocker and Napier (1986). For a vertical flame and for targets with vertical surfaces three possible configurations are shown in Figure 16.97(a). Using the solid flame model for target 2 on a level with the base of the flame, the view factor for a vertical flame may be used as it is. For target 3 on a level with the centre of the flame the view factor for a vertical flame may again be used, but the value is doubled to take account of the two halves of the falme. For target 1 the view factor may be obtained as follows:

$$F = F[(l + h), x] - F[h, x] \qquad [16.17.58]$$

This view factor is therefore the difference between view factors. A similar approach may be used for view factors based on the equivalent radiator model.

For a tilted flame with a target at ground level with a surface at an angle β to the horizontal, the configuration is as shown in Figure 16.97(b). Using the solid flame model given in Equation 16.17.50 the view factor is

$$F = F[(l + l'), x'] - F[l', x'] \qquad [16.17.59]$$

Further expressions for more complex situations are given by Crocker and Napier.

A set of graphs for the view factors for pool fires of LPG are given in the IP *LPG Code*. Figure 16.98 (a) shows a vertical cylindrical flame and Figure 16.98(b) the corresponding maximum view factor, whilst Figure 16.99(a) shows a tilted cylindrical flame and Figure 16.99(b) the maximum view factor for a cylindrical flame with an angle of tilt of 30°.

The view factor for a flame partially obscured by smoke is given by Considine (1984 SRD R297). He also gives the view factor where there is obstruction by an obstacle.

16.17.10 Pool fire models

A review of pool fire models has been given by Mudan (1984c) who describes the principal elements of pool fire models, but does not present a preferred selection. An earlier review by de Ris (1979) concentrates particularly on flame emissivity.

There are a number of Models of pool fires including those by R.O. Parker (1974), Modak (1977), Mizner and Eyre (1982), Moorhouse (1982), Ndubuzu *et al.* (1983), Considine (1984 SRD R297), Tunc and Venart (1984/85a) and Babrauskas (1986b).

R.O. Parker (1974) describes a pool fire model said to give satisfactory results in accident investigation.

Modak (1977) has described a relatively complex, model consisting of a fairly large set of equations. The model is capable of determining the heat radiation to the liquid surface and to objects outside the flame. Another relatively complex model is that by Ndubuzu *et al.* (1983).

Considine (1984 SRD R297) proposes the use of the Thomas equation for flame height, the method for surface emissive power which takes account of smoke obscuration and appropriate view factors and atmospheric transmissivity.

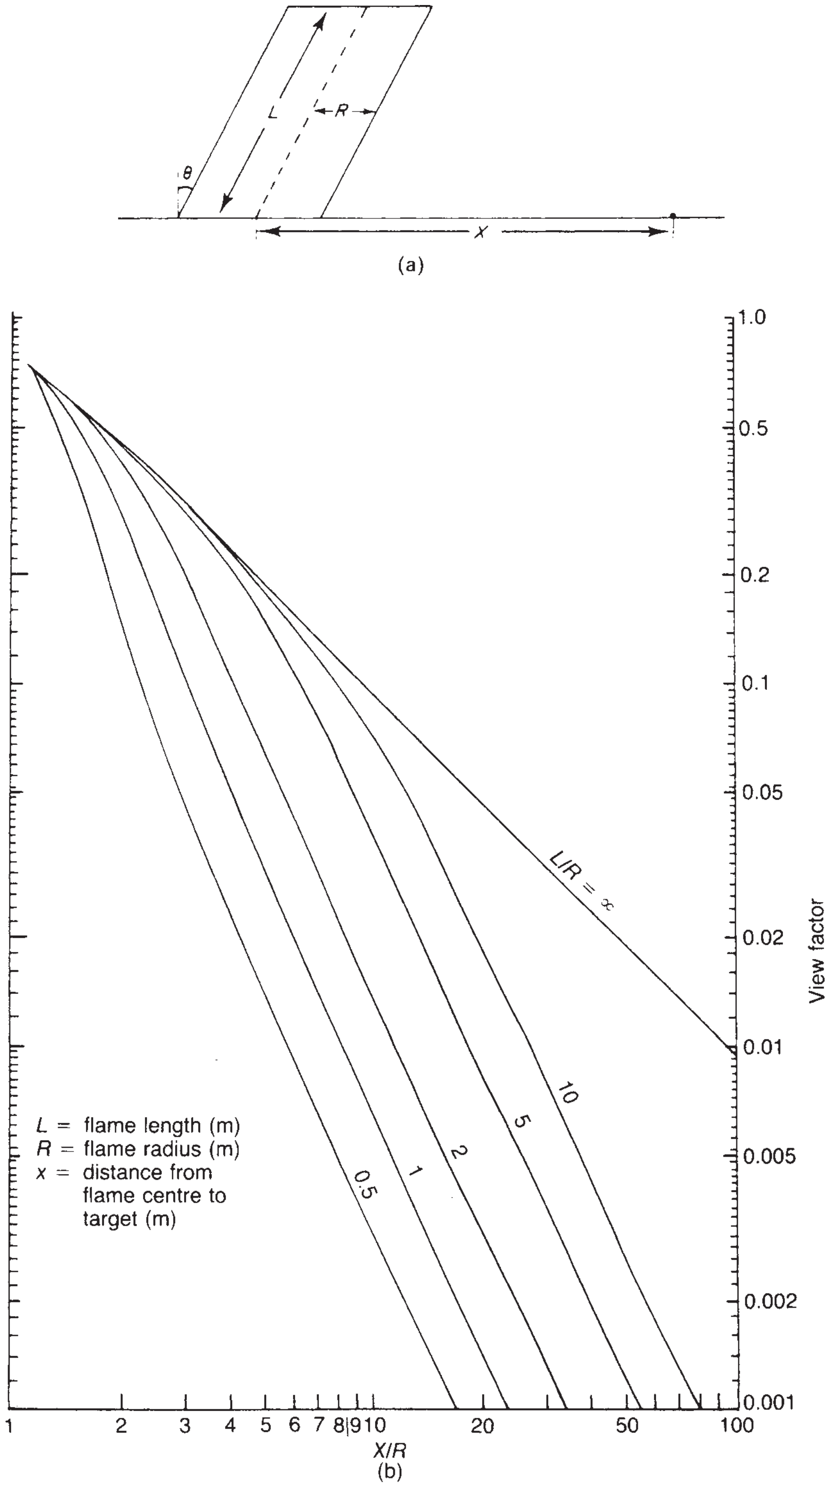

Figure 16.99 *View factor for pool fires: tilted cylinder – IP LPG Storage Code (Institute of Petroleum, 1987 MCSP Pt 9): (a) Flame and (b) view factor. Angle of title 30° (Courtesy of the Institute of Petroleum)*

Tunc and Venart (1984/85a) have given a model of the same general type intended for the estimation of the heat radiated to a cylindrical object, such as a rail tank car, inside the flame.

Some of the other models mentioned are now described.

16.17.11 Mizner and Eyre model

Mizner and Eyre (1982) review the relations available for a pool fire. In particular, they quote for the length of flame Equation 16.17.2 and for the angle of tilt Equation 16.17.19. Their preferred values for the surface emissive power are given in Subsection 16.17.8.

16.17.12 Moorhouse model

The set of original correlations given by Moorhouse (1982) and Moorhouse and Pritchard (1982) constitute another pool fire model. These authors emphasize that the flame may have a conical rather than cylindrical shape. Their model contains pairs of relations, one for a cylindrical and one for a conical flame. These are: for the length of flame, Equations 16.17.15a and 16.17.15b; for the angle of tilt, Equations 16.17.20a and 16.17.20b, or Equations 16.17.21a and 16.17.21b; and for flame drag, Equations 16.17.23a and 16.17.23b. Surface emissive powers are given in Subsection 16.17.8.

16.17.13. Babrauskas model

Another pool fire model is that given by Babrauskas (1986b). The model uses the author's treatment of liquid burning rates described in Subsection 16.17.6.

With regard to flame geometry Babrauskas argues that, given the approximation involved in treating the flame as a cylinder with uniform diameter, refined methods for flame height are not justified. In his model the flame is represented as a cylinder with diameter D and height h, For a target on the ground at distance l the following quantities are defined:

$$H = h/D \qquad [16.17.60]$$

$$L = l/D \qquad [16.17.61]$$

where D is the pool diameter (m), h is the height of the flame (m) and l is the distance from its centre to the target (m). For a flame with diameter $D > 0.1$ m it is sufficient to take $H = 1.5$.

The heat radiated by the flame is expressed in terms of the radiative power P where

$$P = \chi_r \Delta h_c m \left(\frac{\pi D^2}{4}\right) \qquad [16.17.62]$$

where Δh_c is the heat of combustion (kJ/kg), m is the mass burning rate (kg/m^{2}s), P is the radiative power (kW) and x_r is the fraction of heat radiated.

The radiative power can also be expressed for the far field as

$$P = 4\pi l^2 q_i \qquad L > 4 \qquad [16.17.63]$$

where q_i is the thermal radiation incident on the target (kW/m^2). Hence from Equations 16.17.62 and 16.17.63

$$q_i = \frac{\chi_r \Delta h_c m}{16L^2} \qquad L > 4 \qquad [16.17.64]$$

For the near field a more accurate estimate of the thermal radiation is

$$q_i = F\epsilon_f \sigma T_f^4 \qquad 1/2 < L < 4 \qquad [16.17.65]$$

where F is the view factor, T_f is the absolute flame temperature (K) and ϵ_f is the emissivity of the flame.

For the view factor F a suitable approximation is

$$F \approx H/\pi L^2 \qquad [16.17.66]$$

Then from Equations 16.17.64–16.17.66

$$\epsilon_f \sigma T_f^4 = \frac{\pi \chi_r \Delta h_c m}{16H} \qquad [16.17.67]$$

which for $H = 1.5$ and for $D \to \infty$ reduces to

$$(\epsilon_f \sigma T_f^4)_\infty = 0.131 \chi_r \Delta h_c m_\infty \qquad [16.17.68]$$

Combining Equations 16.17.38, 16.17.64, 16.17.65 and 16.17.68 yields the relations for thermal radiation

$$q_i = \frac{\chi_r \Delta h_c m_\infty}{16L^2}[1 - \exp(-k\beta D)] \qquad L > 4 \qquad [16.17.69]$$

$$q_i = F(0.131\chi_r \Delta h_c) m_\infty [1 - \exp(-k\beta D)] \qquad \frac{1}{2} < L < 4 \qquad [16.17.70]$$

where k is the extinction coefficient (m^{-1}) and β is the mean beam length corrector.

For the fractuion of heat radiated Babrauskas refers to the data of Hägglund and Persson (1976) quoted in Table 16.65.

16.17.14 Storage tank fires

A type of pool fire which is of special interest is a storage tank fire. Such fires are usually treated as pool fires. The differences are that the liquid surface, and hence the base of the flame, is elevated and that it is surrounded by a metal wall. Another important feature is that the targets of interest usually include other storage tanks. This means that the targets may be close to the flame and that it may be necessary to consider targets at levels other than ground level and heat transfer by modes other than radiation.

Burgoyne and Katan (1947) conducted experiments on the heat wave moving through the liquid in a tank fire.

Tank fire experiments have been carried out at the Forschungsstelle für Brandschutztechnik described by Werthenbach (1971, 1971a,b, 1973) and Seeger (1974). Tank diameters up to 2 m were used. Agreement between theoretical estimates of heat radiated based on Equations 16.17.41 and 16.17.42 was obtained using a flame temperature and emissivity of 900°C and 0.9, respectively.

Seeger also investigated numerically the view factor for a vertical cylindrical flame on a tank to a target with a vertical surface on a level with the base of the flame. The effect on the view factor of altering the height of the flame or of moving the target to a level halfway up the flame was slight.

Lois and Swithenbank (1979) have used wind tunnel experiments to study fire in an array of tanks. Features considered include the effect of wind on the flame and the interaction of the wind with the tank array.

Kobori, Handa and Yumoto (1981) have studied the interactions between a tank that is on fire and a neighbouring tank that is not on fire, including heat transfer to the unignited tank by convection as well as radiation, formation of vapour in the unignited tank, induction into the fire of the vapour from that by the air drawn into flame, and flashback to the unignited tank.

Crocker and Napier (1986) have reviewed the main elements of pool fire models as they apply to tank fires, have listed the applicable view factors and have considered the implications for storage tank layout.

16.17.15 Slot fires

Another type of pool fire is the slot, trench or channel fire. Such a fire may occur on a spill of flammable liquid which has entered a trench or channel of any kind. A characteristic feature is that there is a high aspect ratio. One situation in which this type of fire may occur is the burning of a liquid spill directed to a high aspect ratio catchment area.

Slot fires are discussed briefly by Moorhouse and Pritchard (1982). One approach is to treat the fire as a series of individual pool fires and then apply the relations for circular pools. This approach appears to fit the results of small-scale experiments described by Welker (1965) and Gollahalli and Sullivan (1974). Further, data reported by Alger and Capener (1972) on the burning rates of large-scale fires of JP-5 on a pool of aspect ratio greater than 2 are consistent with those from circular pool fires. Moorhouse (1982) states that the work on LNG pool fires which he describes included some limited tests on LNG fires with an aspect ratio of 1 to 2.5.

Work on trench fires of LNG with aspect ratios up to 30 has been conducted by Mudan and Corce (1984) and is summarized by Mudan (1989b). The work indicates that in such fires the flame height is influenced more by the width than by the length of the trench and that the flame geometry is more sensitive to wind conditions than is the case in fires on circular pools.

Mudan and Croce obtained for LNG the following correlations for flame height, angle of tilt and flame drag:

$$\frac{H}{W} = 2.2 \qquad \mathrm{Fr}' \geq 0.25 \qquad [16.17.71a]$$

$$\frac{H}{W} = 0.88(\mathrm{Fr}')^{-0.65} \qquad 0.1 < \mathrm{Fr}' < 0.25 \qquad [16.17.71b]$$

$$\frac{H}{W} = 4.0 \qquad \mathrm{Fr}' < 0.1 \qquad [16.17.71c]$$

$$\cos\theta = 0.56 \qquad \mathrm{Fr}' > 0.25 \qquad [16.17.72a]$$

$$\cos\theta = 0.36\,(\mathrm{Fr}')^{-0.32} \qquad 0.042 < \mathrm{Fr}' < 0.25 \qquad [16.17.72b]$$

$$\cos\theta = 1 \qquad \mathrm{Fr}' < 0.042 \qquad [16.17.72c]$$

$$\frac{W'}{W} = 3.5 \qquad \mathrm{Fr}' > 0.25 \qquad [16.17.73a]$$

$$\frac{W'}{W} = 23.3\,(\mathrm{Fr}')^{1.37} \qquad 0.1 < \mathrm{Fr}' < 0.25 \qquad [16.17.73b]$$

$$\frac{W'}{W} = 1 \qquad \mathrm{Fr}' < 0.1 \qquad [16.17.73c]$$

with

$$\mathrm{Fr}' = u_{\mathrm{w}}/2(gW)^{1/2} \qquad [16.17.74]$$

where Fr′ is a modified Froude number, g is the acceleration due to gravity (m/s^2), H is the length pf the flame, u_{w} is the wind speed (m/s), W is the width of the trench (m), W' is the extended width of the flame base (m) and θ is the angle of tilt (°). For calm conditions, where the value of Fr′ is very low, the flame geometry depends only on the trench width. For values of Fr′ which are higher but still less than about 0.25, the flame length decreases but the angle of tilt and flame drag increase with wind speed. For still higher values of Fr′ the flame geometry is independent of wind speed. The correlations are not strictly applicable where the wind direction is parallel to the axis of the trench.

The application of these relations to liquid fuels other than LNG is uncertain.

16.18 Flares

A jet flame occurs when flammable gas issuing from a pipe or other orifice is ignited and burns on the orifice. Historically, treatments of such flames have been concerned mainly with flames which are there by design, such as the flames on burners and flares. It is convenient, therefore, to start by considering flares.

The fundamentals of combustion in flares have been studied by Brzustowski and co-workers (e.g. Bzrustowski, 1973, 1977; Brzustowski and Sommer, 1973; Bzruztowski *et al.*, 1975) and by others.

16.18.1 Experimental studies

There is vast literature on flames. Discussion here is limited to some of the studies which have been concerned specifically with flare systems. Some of the studies on flares are tabulated in Section 16.19.

Conventionally, flares have been designed to give a flame which is vertical in still air. The use of flares on offshore oil production platforms, where helicopter access is necessary, has prompted the development of flares with an inclined flame. The models developed for inclined flares are relevant to jet flames arising from accidents.

A series of experimental studies of flares has been reported by Brzustowski and co-workers. The correlations obtained by Brzustowski and Sommer (1973) are the basis of the more elaborate flare model given in API RP 521, as described below.

Various workers have found that the API methods tend to overpredict the incident heat radiation. The need for tighter design of flares offshore, where space is limited, has given an incentive to obtain improved methods.

Experiments on flares have been conducted by Shell and are described by Chamberlain (1987). Ranges of some of the parameters in these trials were as follows: gas molecular weight 16–44; pipe diameter 0.006–1.07 m; Mach number 0.06–0.9; gas exit velocity 14–554 m/s; and wind speed 2.7–13 m/s. This work is the basis of the Chamberlain flare model given below

Chamberlain's work has been extended in the model by A.D. Johnson, Brightwell and Carsley (1994), also described below. This work was on natural gas. The ranges of some of the parameters were: pipe diameter 0.02–0.152 m; gas mass flow 2.8–8.4 kg/s; and wind speed 0.3–6.9 m/s.

Other experiments have been carried out by British Gas, as described by D.K. Cook, Fairweather, Hammonds and Hughes (1987). The experiments were on natural gas and the flows were both subsonic and sonic. Ranges of some of the other parameters in these trials were as follows: pipe diameter 0.051–0.59 m; gas exit velocity 89–402 m/s; and wind speed 1.0–13 m/s.

16.18.2 Hajeck and Ludwig model

An equation which has been widely used for the determination of the thermal radiation from a flame on a flare stack is that of Hajek and Ludwig (1960)

$$I = \frac{F_r Q}{4\pi r^2} \qquad [16.18.1]$$

where F_r is the fraction of heat released which is radiated, I is the radiation intensity on the target (kW/m^2), Q is the net heat release rate (kW) and r is the radius from the centre of the flame (m).

Combustion in the flare is a complex process. In Equation 16.18.1 this complexity is subsumed in the factor F_r. This factor has traditionally been taken as a property of the fuel only. It has been shown, however, that the F_r factor is discussed by Brzustowski (1977). and by Straitz *et al.* (1977) Some values of the fraction F_r of heat radiated are given in Table 16.68.

For the determination of radiation expsoure, the current version of API RP 521 gives Equation 16.81.1 in the form

$$D = \left(\frac{\tau F_r Q}{4\pi K}\right)^{1/2} \qquad [16.18.2]$$

where D is the distance from the centre of the flame to the target (m) K is the allowable radiation (kW/m^2) and τ is the atmospheric transmissivity.

Table 16.68 *Fraction of heat radiated by a flare*

A Fraction of heat release F_r: overall values

Gas	*F*	*Reference*
Methane	0.16	Brzustowski and Sommer (1973)
Propane	0.33	Kent (1964)
Butane	0.30	Brzustowski and Somer (1973)
Ethylene	0.38	Brzustowski and Sommer (1973)

B Fraction of heat release F_r: values as function of burner diameter[a]

Gas	*Burner diameter* (cm)	F_r (%)
Hydrogen	8.4	0.16
	20.3	0.15
	40.6	0.17
Butane	8.4	0.29
	20.3	0.28
	40.6	0.30
Methane	8.4	0.15
Natural gas	20.3	0.19
	40.6	0.23

16.18.3 API RP 521 models

Flare models which have been widely used are those given in the successive aditions of API RP 521 *Guide for Pressure-relieving and Depressuring Systems*. API RP 521: 1990 gives two models. The first is described as a simplified approach. The second is based on the method of Brzustowski and Sommer (1973).

The simplified model is as follows. The Mach number Ma at the flare tip is

$$\mathrm{Ma} = 11.61 \times 10^{-2} \frac{W}{Pd^2}\left(\frac{T}{kM}\right)^{1/2} \qquad [16.18.3]$$

where d is the flare diameter (m), k is the ratio of the specific heats of the gas, M is the molecular weight of the gas, P is the absolute pressure just inside the flare tip (kPa), T is the absolute temperature of the gas (K) and W is the mass flow of gas (kg/s).

The flare diameter is determined by setting a suitable value of the Mach number. The *Guide* gives as examples values of 0.2 and 0.5.

The length of the flame is a function of the heat release and is determined from Figure 16.100.

The distortion of the flame caused by the wind velocity is defined in terms of the horizontal deviation $\sum \Delta x$ and the vertical deviation $\sum \Delta y$ of the flame tip and is a function of the ratio of the velocity at the flare tip u_j to the wind velocity u_∞. The flare tip exit velocity u_j is obtained as

$$u_j = \frac{V}{\pi d^2/4} \qquad [16.18.4]$$

or as

$$u_j = \mathrm{Ma}\ u_s \qquad [16.18.5]$$

with

$$u_s = 91.2\left(\frac{kT_j}{M_j}\right)^{1/2} \qquad [16.18.6]$$

where u_j is the exit velocity of the gas at the flare tip (m/s) , u_s is the velocity of sound (m/s) , u_∞ is the velocity of the wind (m/s), V is the volumetric flow of gas (m^3/s) and subscript j denotes the flare tip exit. The co-ordinates of the flame tip are determined using Figure 16.101.

This method does not give an explicit relation for the intensity of heat radiation on a target, but use may be made of Equation 16.18.2.

16.18.4 Brzustowski and Sommer model

In the second method given in API RP 521, the Brzustowski and Sommer model, the flare diameter is determined in the same manner by using Equation 16.18.3. The centre of the flame is then determined as follows. The horizontal distance x_c and the vertical distance y_c from the flare tip to the centre of the flame are

$$x_c = f(\bar{C}_L, d_j R) \qquad [16.18.7]$$

$$y_c = f(\bar{C}_L, d_j R) \qquad [16.18.8]$$

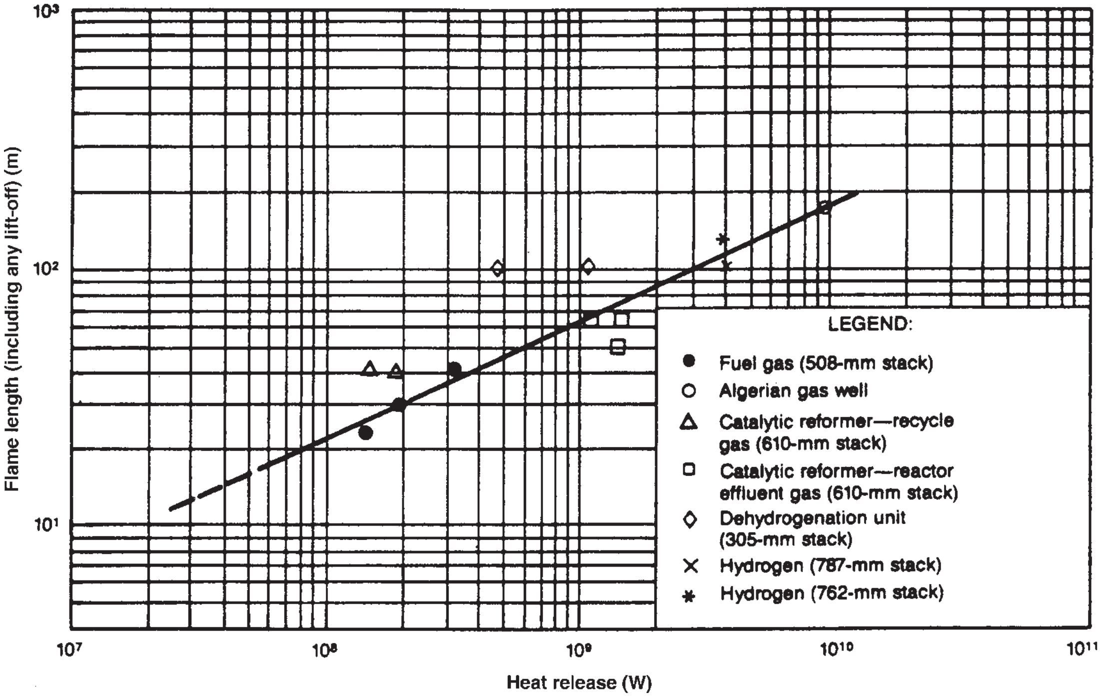

Figure 16.100 *Flare flames: flame length (API RP 521: 1990; reproduced with permission). (Multiple points indicate separate observations or different assumptions of heat content)*

with

$$\bar{C}_{\mathrm{L}} = C_{\mathrm{L}} \frac{u_{\mathrm{j}}}{u_{\infty}} \frac{M_{\mathrm{j}}}{29} \qquad [16.18.9]$$

$$R = \frac{u_{\mathrm{j}}}{u_{\infty}} \left(\frac{T_{\infty} M_{\mathrm{j}}}{T_{\mathrm{j}}} \right)^{1/2} \qquad [16.18.10]$$

where C_{L} is the lower explosive limit (volume fraction), R is a parameter, T_{∞} is the absolute temperature of the air (K), x_{c} and y_{c} are the horizontal and vertical distances of the flame centre from the flame tip (m) and $\bar{C}_{\mathrm{L}}$ is a modified lower explosive limit (volume fraction). The coordinates of the flame centre are determined using Figure 16.102.

Equation 16.18.2 is used to determine the intensity of heat radiation incident on a target.

16.18.5 de Faveri *et al.* model

Another flare model is that by de Faveri *et al.* (1985). These workers performed wind tunnel experiments on small 'flares' in a wind and obtained correlations for various features of the flare such as the downwind position of the flame tip and the axis of the flame.

This model has been discussed by Crocker and Napier (1988b) in relation to multiple point source modelling of flare radiation.

16.18.6 Chamberlain model

The flare model given by Chamberlain (1987) of Shell is based on the flame shown in Figure 16.103. The geometric components of the model are (1) the effective diameter of the source D_{s} (2) the length of the flame in still air L_{o}, (3) the length of the flame in the pertaining conditions L, (4) the angle between the axis of the orifice and that of the flame α, (5) the lift-off distance of the frustrum of the flame b, (6) the length of the frustrum R_{L}, (7) the width of the base of the frustrum W_1, (8) the width of the top of the frustrum W_2 and (9) the area of the flame A.

The parameters which define the model geometry are determined as functions of the velocity ratio R

$$R = v/u_{\mathrm{j}} \qquad [16.18.11]$$

where u is the gas velocity (m/s) , v is the wind velocity (m/s) and subscript j denotes the expanded jet.

The model equations are as follows. As described in Chapter 15, use is made of D_{s} for the source. For unchoked flow

$$D_{\mathrm{s}} = d_{\mathrm{o}} \left(\frac{\rho_{\mathrm{j}}}{\rho_{\mathrm{a}}} \right)^{1/2} \qquad [16.18.12]$$

with

$$\rho_{\mathrm{j}} = \rho_{\mathrm{g}}^{\mathrm{o}} \frac{273}{T_{\mathrm{j}}} \qquad [16.18.13]$$

where d_{o} is the throat diameter of an imagined flow nozzle (m), D_{s} is the effective diameter of the source (m), T_{j} is the temperature of the gas in the expanded jet (K), ρ_{a} is the

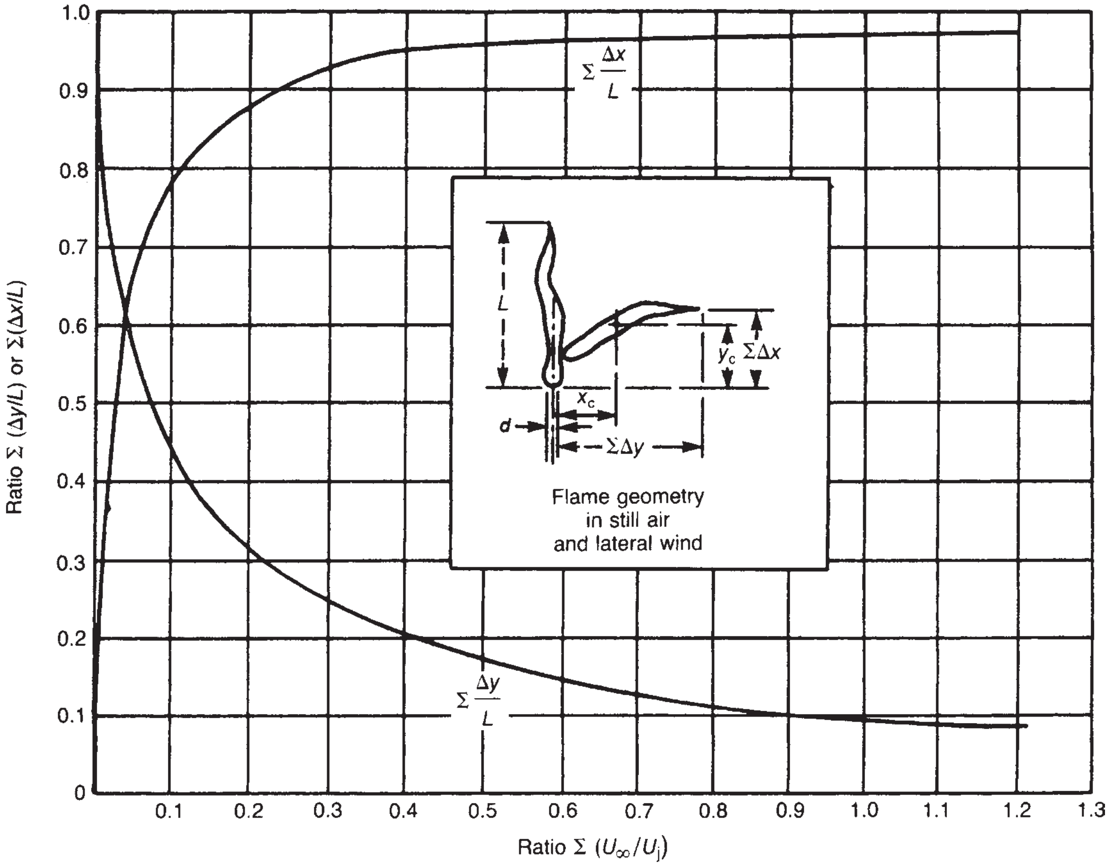

Figure 16.101 *Flare flames: distortion due to wind (API RP 521: 1990; reproduced with permission). U_∞, Lateral wind velocity; U_j exit gas velocity from the stack*

density of air (kg/m^3), ρ_g^o is the density of the gas under standard conditions (kg/m^3) and ρ_j is the density of the gas in the expanded jet (kg/m^3). For choked flow the jet expands to atmospheric pressure at a plane downstream of the exit hole, the plane then acting as a virtual source of diameter d_j. Then

$$D_s = d_j \left(\frac{\rho_j}{\rho_a}\right)^{1/2} \quad [16.18.14]$$

with

$$d_j = \left(\frac{4\dot{m}}{\pi u_j \rho_j}\right)^{1/2} \quad [16.18.15a]$$

$$= \frac{4\dot{m}}{\pi P_o \mathrm{Ma}_j}\left(\frac{R_c T_j}{\gamma M_k}\right)^{1/2} \quad [16.18.15b]$$

where d_j is the diameter of the virtual source (m), $\dot{m}$ is the mass flow of gas (kg/s), M_k is the kilogram molecular weight of the gas (kg/mol), Ma_j is the Mach number of the expanded jet, P_o is the absolute atmospheric pressure (N/m^2), R_c is the universal gas constant (J/kmolK), u_j is the velocity of the gas in the expanded jet (m/s) and γ is the ratio of the specific heats of the gas.

For the length L_{Bo} of the flame in still air the implicit equation of Kalghatgi (1984) is used:

$$\Psi(L_{Bo}) = 0.2 + 0.024\xi(L_{Bo}) \quad [16.18.16]$$

with

$$\Psi(L_{Bo}) = \left(\frac{D_s \beta}{L_{Bo} W}\right)^{2/3} \quad [16.18.17]$$

$$\xi(L_{Bo}) = \left(\frac{g}{D_s^2 u_j^2}\right)^{1/3} L_{Bo} \quad [16.18.18]$$

$$\beta = \left(\frac{M_a T_1}{M_p T_a}\right)^{1/2} \quad [16.18.19]$$

where g is the acceleration due to gravity (m/s^2), L_{Bo} is the length of the flame in still air (m), M is the molecular weight of the gas, T is the absolute temperature (K), u is the velocity

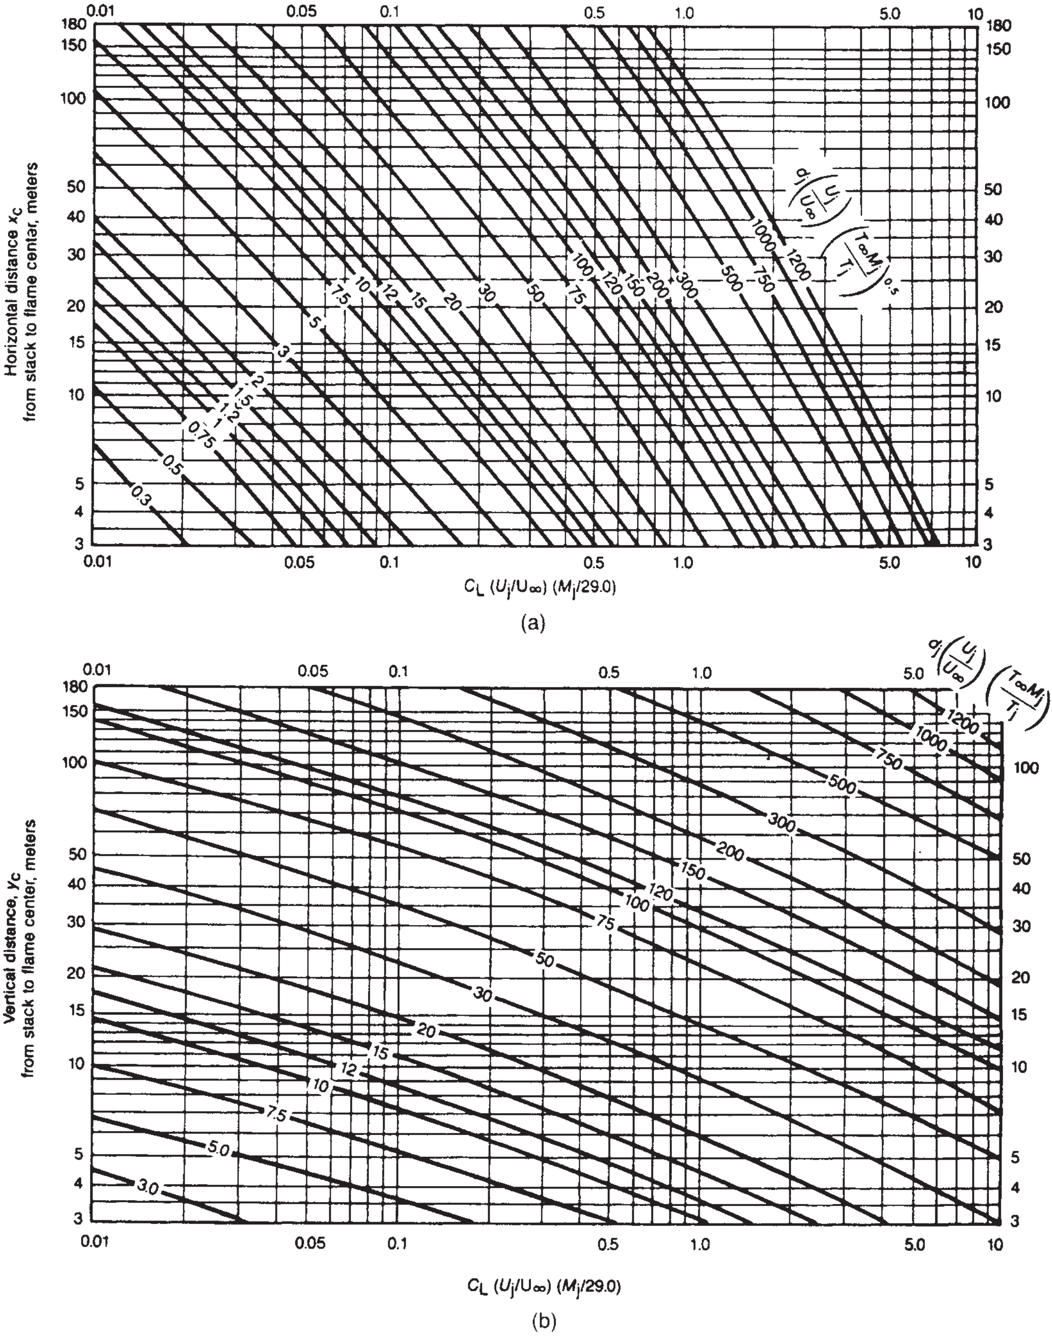

Figure 16.102 *Flare flames: location of flame centre (API RP 521: 1990; reproduced with permission): (a) Horizontal distance* x_c *of the flame centre from the orifice and (b) vertical distance (m) of the flame centre from the orifice.* C_L*, lower explosive limit;* y_c*, volume fraction;* d_i*, inside diameter of flare tip (m);* M_j*, molecular weight of the gas;* T_j*, temperature of the gas (K);* T_∞*, temperature of the air (K);* U_j*, gas exit velocity (m/s);* U_∞*, average wind velocity (m/s)*

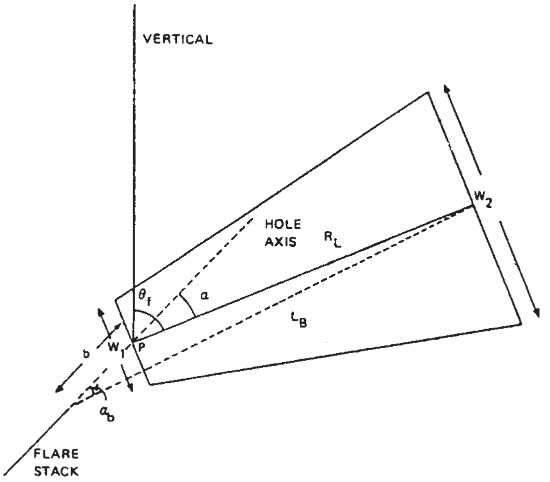

Figure 16.103 *Flare flames: flame dimensions for Chamberlain model (Chamberlain, 1987). (Note that point P is always at the intersection of the hole and frustrum axes) (Courtesy of the Institution of Chemical Engineers)*

of gas, W is the mass fraction of the fuel in a stoichiometric mixture with air, and ξ is the Richardson number based on the flame length in still air. The subscript a denotes air, j the conditions in the expanded jet, p the mean product value and 1 adiabatic combustion conditions.

For a paraffin of molecular weight M the mass fraction W of fuel in a stoichiometric mixture with air is

$$W = \frac{M}{15.816M + 39.5} \qquad [16.18.20]$$

Typical conditions of $M_a \approx 29.0$, $M_p \approx 28$, $T_a \approx 288$ K and $T_1 = 2250$ K yield $\beta \approx 2.85$.

For a tilted jet, in which the hole axis is in the wind direction and at an angle θ_j to the horizontal, it has been shown by laboratory experiments that the flame length reduces as the jet is tilted into the wind, that is as θ_j. increases, because the air entrainment coefficient increases. A linear relation holds between L_B/D_s and θ_j. Then for the actual length L_B of the flame

$$\frac{L_B}{D_s} = 163 - 0.64\theta_j \qquad [16.18.21a]$$

or

$$L_B = 105.4D_s[1 - 6.07 \times 10^{-3}(\theta_j - 90)] \qquad [16.18.21b]$$

On the assumption that L_B scales similarly with θ_j for all wind speeds and directions, the general correlation for L_B is

$$L_B = L_{Bo}[0.51\exp(-0.4v) + 0.49][1 - 6.07 \times 10^{-3}(\theta_{jv} - 90)] \qquad [16.18.22]$$

where θ_j is the angle between the hole axis and the horizontal (°) and θ_{jv} is the angle between the hole axis and the wind vector in the plane containing the hole axis, the flame axis and the wind vector (°).

For the angle α between the axis of the orifice and that of the flame

$$\alpha = \frac{1}{\xi(L_{Bo})}\{8000R + \xi(L_{Bo})(\theta_{jv} - 90)[1 - \exp(-25.6R)]\}$$

$$R < 0.05 \qquad [16.18.23a]$$

$$\alpha = \frac{1}{\xi(L_{Bo})}\{1726(R - 0.026)^{1/2} + 134 + \xi(L_{Bo})(\theta_{jv} - 90)$$

$$\times [1 - \exp(-25.6R)] \quad R > 0.05 \qquad [16.18.23b]$$

where α is the angle between the hole axis and the flame axis (°).

For the lift-off distance b of the frustrum of the flame, by geometry

$$b = L_B\frac{\sin(\alpha - \alpha_b)}{\sin\alpha} \qquad [16.18.24a]$$

or

$$b = L_B\frac{\sin K\alpha}{\sin\alpha} \qquad [16.18.24b]$$

with

$$K = \frac{\alpha - \alpha_b}{\alpha} \qquad [16.18.25]$$

where b is the lift-off height (m) and α_b is the angle between the hole axis and the line joining the top of the flame to the centre of the hole (°).

K was correlated as follows:

$$K = 0.185\exp(-20R) + 0.015 \quad 0.005 < R < 3 \qquad [16.18.26]$$

For $\alpha = 0°$ or $180°$

$$b = KL_B \qquad [16.18.27]$$

For the length R_L of the frustrum, by geometry

$$R_L = (L_B^2 - b^2\sin^2\alpha)^{1/2} - b\cos\alpha \qquad [16.18.28]$$

For the width W_1 of the base of the frustrum the following correlation was obtained:

$$W_1 = D_s[13.5\exp(-6R) + 1.5] \times \left\{1 - \left[1 - \frac{1}{15}\left(\frac{\rho_a}{\rho_j}\right)^{1/2}\right]\exp(-70\xi(D_s)CR)\right\} \qquad [16.18.29]$$

with

$$C = 1000\exp(-100R) + 0.8 \qquad [16.18.30]$$

$$\xi(D_s) = \left(\frac{g}{D_s^2u_j^2}\right)^{1/3} D_s \qquad [16.18.31]$$

where W_1 is the width of the frustrum base (m).

For the width of the top of the frustrum W_2, the correlation obtained was

$$W_2 = L_B[0.18\exp(-1.5R) + 0.31][1 - 0.47\exp(-25R)] \quad [16.18.32]$$

where W_2 is the width of the frustrum top (m).

For the surface area A of the flame, including the two end discs, by geometry

$$A = \frac{\pi}{4}(W_1^2 + W_2^2) + \frac{\pi}{2}(W_1 + W_2)\left[R_L^2 + \left(\frac{W_2 - W_1}{2}\right)^2\right]^{1/2} \quad [16.18.33]$$

where A is the surface area of the flame (m^2).

The surface emissive power of the flame is then

$$E = \frac{F_r Q}{A} \quad [16.18.34]$$

where F_r is the fraction of heat radiated, E is the surface emissive power (kW/m^2) and Q is the net heat release rate (kW).

The fraction F_r of heat radiated was found to correlate with gas velocity u_j as follows:

$$F_r = 0.21\exp(-0.00323u_j) + 0.11 \quad [16.18.35]$$

The radiation incident on a target is then

$$I = \tau F E \quad [16.18.36]$$

where F is the view factor, I is the radiation incident on the target (kW/m^2) and τ is the atmospheric transmissivity.

A version of the Chamberlain model incorporated in the computer code SAFETI has been described by J Cook, Bahrami and Whitehouse (1990).

16.18.7 Johnson, Brightwell and Carsley model

A.D. Johnson, Brightwell and Carsley (1994) have described a model for a jet flame of natural gas issuing horizontally, which is an extension of the flare model of Chamberlain (1987), already described. The model was developed in conjunction with large-scale tests on natural gas flames.

As in the original model, the flame is represented as the frustrum of a cone with the maximum width at the end furthest from the origin. For the flame shape the treatment is as follows. The momentum flux of the expanded jet is

$$G = \frac{\pi \rho_j u_j^2 d_j^2}{4} \quad [16.18.37]$$

where d_j is the diameter of the expanded jet (m), G is the initial momentum flux of the expanded jet (N), u_j is the velocity of the expanded jet (m/s) and ρ_j is the density of the expanded jet (kg/m^3). The parameters d_j, u_j and ρ_j are as defined by Chamberlain.

A Richardson number $\xi(L)$ is defined as

$$\xi(L) = \left(\frac{\pi \rho_a g}{4G}\right)^{1/3} L \quad [16.18.38]$$

where g is the acceleration due to gravity (m/s^2), L is a characteristic length (m) and ρ_a is the density of air (kg/m^3).

The length scale L is the length over which the buoyancy force acts and is taken as the flame length L_{bo} for a vertical flame in still air. The value of L_{bo} is given by a correlation derived by Khalhatgi (1984). L_{bo} is obtained as the solution of the equations

$$\Psi = 0.2 + 0.024\xi(L_{bo}) \quad [16.18.39]$$

with

$$\Psi = \left(\frac{2.85D_s}{L_{bo}W}\right)^{2/3} \quad [16.18.40]$$

where D_s is the effective source diameter (m), L_{bo} is the flame length in still air (m), W is the mass fraction of the fuel in a stoichiometric mixture with air and Ψ is a parameter. The effective source diameter is the throat diameter of an imaginary nozzle from which air at ambient density issues with the same mass flow and momentum as the fuel:

$$D_s = d_j\left(\frac{\rho_j}{\rho_a}\right)^{1/2} \quad [16.18.41]$$

The authors indicate that range of validity of the relation for L_{bo} is $2 < \xi(L_{bo}) < 20$.

The flame shape is defined relative to the x, y and z co-ordinates, where x, y and z are the distances in the release direction, the vertical direction and the crosswind direction, respectively. The position of the flame is determined by the relative effects of the initial jet momentum flux and the wind momentum fluxes in the x, or release, direction and in the z direction, perpendicular to the flame. The balance of these momentum fluxes is characterized by the two parameters

$$\Omega_x = \left(\frac{\pi \rho_a}{4G}\right)^{1/2} L_{bo} u_a \quad [16.18.42]$$

$$\Omega_z = \left(\frac{\pi \rho_a}{4G}\right)^{1/2} L_{bo} w_a \quad [16.18.43]$$

where u_a is the wind speed in the release direction (m/s), w_a is the wind speed perpendicular to the release (m/s) and Ω_x and Ω_z are parameters.

The end of the flame frustrum is correlated by a term defining the end of the flame in still air multiplied by a term allowing for the effect of the wind. It was found experimentally that a croswind had little effect on the position of the flame in the x direction so that the influence of the parameter Ω_z could be neglected. Then for the Ω_x position of the flame X

$$\frac{X}{L_{bo}} = f(\xi)[1 + r(\xi)\Omega_x] \quad [16.18.44]$$

with

$$f(\xi) = 0.55 + (1 - 0.55)\exp(-0.168\xi) \qquad \xi < 5.11 \quad [16.18.45a]$$

$$f(\xi) = 0.55 + (1 - 0.55)\exp[-0.168\xi - 0.3(\xi - 5.11)^2] \qquad \xi > 5.11 \quad [16.18.45b]$$

$$r(\xi) = 0 \qquad \xi < 3 \quad [16.18.46a]$$

$$r(\xi) = 0.82\{1 - \exp[-0.5(\xi - 3.3)]\} \qquad \xi > 3 \quad [16.18.46b]$$

where f and r are parameters. A limit is placed on the x position by setting a maximum value of X/L_{bo} of 1.0. Similarly, for the y position of the flame Y

$$\frac{Y}{L_{bo}} = h(\xi)[1 - c(\xi)\Omega_x] \qquad [16.18.47]$$

with

$$h(\xi) = (1 + 1/\xi)^{-8.78} \qquad [16.18.48]$$

$$c(\xi) = 0.02\xi \qquad [16.18.49]$$

The y position is confined within the range $0 < Y/L_{bo} < 1.0$.

The maximum diameter of the flame, at the point furthest from the origin, is given by the correlation

$$\frac{W_2}{Lb_{xy}} = -0.004 + 0.0396\xi - \Omega_x(0.0094 + 9.5 \times 10^{-7}\xi^5) \qquad [16.18.50]$$

with

$$Lb_{xy} = (X^2 + Y^2)^{1/2} \qquad [16.18.51]$$

where W_2 is the maximum diameter of the flame (m) and Lb_{xy} is a parameter (m). For a realistic flame shape, W_2 must be greater than W_1 and less than Lb_{xy}.

The lift-off distance of the flame is

$$b = 0.141(G\rho_a)^{1/2} \qquad [16.18.52]$$

where b is the lift-off distance (m). The minimum diameter of the flame is

$$\frac{W_1}{b} = -0.18 + 0.081\xi \qquad [16.18.53]$$

where W_1 is the minimum diameter of the flame (m). The flame cannot become narrower than the forced convection limit and W_1/b has a minimum value of 0.12.

The z position of the flame is given by the correlation

$$\frac{Z}{X - b} = 0.178\Omega_z \qquad [16.18.54]$$

This completes the model for the flame shape. For the thermal radiation, the surface emissive power is given by

$$S = S_\infty[1 - \exp(-kL)] \qquad [16.18.55]$$

with

$$S_\infty = \frac{F_{s\infty}Q}{A} \qquad [16.18.56]$$

where A is the total surface area of the flame (m^2), $F_{s\infty}$ is the fraction of heat radiated for flames which emit black body radiation, k is a gray gas absorption coefficient (m^{-1}), L is a length representing the emitting path length (m), Q is the net heat release rate (kW), S is the surface emissive power (kW/m^2) and S_∞ is the black body surface emissive power (kW/m^2). The value of k was found to be 0.4 m^{-1}, whilst $F_{s\infty}$ was correlated as follows:

$$F_{s\infty} = 0.21\exp(-0.00323u_j) + 0.14 \qquad [16.18.57]$$

The thermal radiation on the target is then

$$q = (F_{sd}S_{sd} + F_{en}S_{en})\tau \qquad [16.18.58]$$

where F is the view factor, q is the thermal radiation incident on the target (kW/m^2) and τ is the atmospheric transmissivity. Subscripts en and sd denote the end and the side of the flame, respectively.

Figure 16.104 shows a set of comparisons between the results obtained with the model and those obtained from the experimental tests for four standard trial conditions B–E.

16.18.8 Cook *et al.* model

A model for a flare of natural gas has been given by D.K. Cook *et al.* (1987). This model also is relatively complex.

16.19 Jet Flames

There is a wide variety of situations in which a jet flame, or ejected flame, can occur in the process industries, either by design or by accident. The principal situations in which flames occur by design are in burners and flares. Flames on burners are not treated here. Those on flares have been considered in Section 16.18.

Ejection of flammable fluid from a vessel, pipe or pipe flange can give rise to a jet flame if the material ignites. An intermediate situation, and one which particularly concerns the designer, is where the jet flame results from ignition of flammable material vented from a pressure relief valve.

Scenarios involving jet flames are not easy to handle, since a large jet flame may have a substantial ‘reach’, sometimes up to 50 m or more.

Jet flames have been involved in a number of accidents. Perhaps the most dramatic were the large jet flames from the gas riser on the Piper Alpha oil platform, as described in Appendix 19. In other cases jet flames from pressure relief valves have caused adjacent vessels to overheat and burst, giving a boiling liquid expanding vapour explosion, or BLEVE. Such was the case at Mexico City, as described in Appendix 4.

16.19.1 Experimental studies

Much of the early experimental work relevant to jetflames was concerned with flares. An account of this work was given in Section 16.18. There is now, however, a growing interest in the jet flame in its own right.

Table 16.69 lists some studies on flares and on jet flames. Investigations of the combustion of large-scale jet releases of liquefied flammable gas have been undertaken by Shell, BP and British Gas, both separately and in co-operation.

The work done covers a variety of jet flames, including flames of natural gas and of LPG. Representative accounts of work using natural gas are those by Chamberlain (1987) and AD. Johnson, Brightwell and Carsley (1994) at Shell, and by D.K. Cook *et al.* (1987) at British Gas.

Accounts of work on jet flames of LPG at Shell and British Gas have been given by Hirst (1984) and Tam and

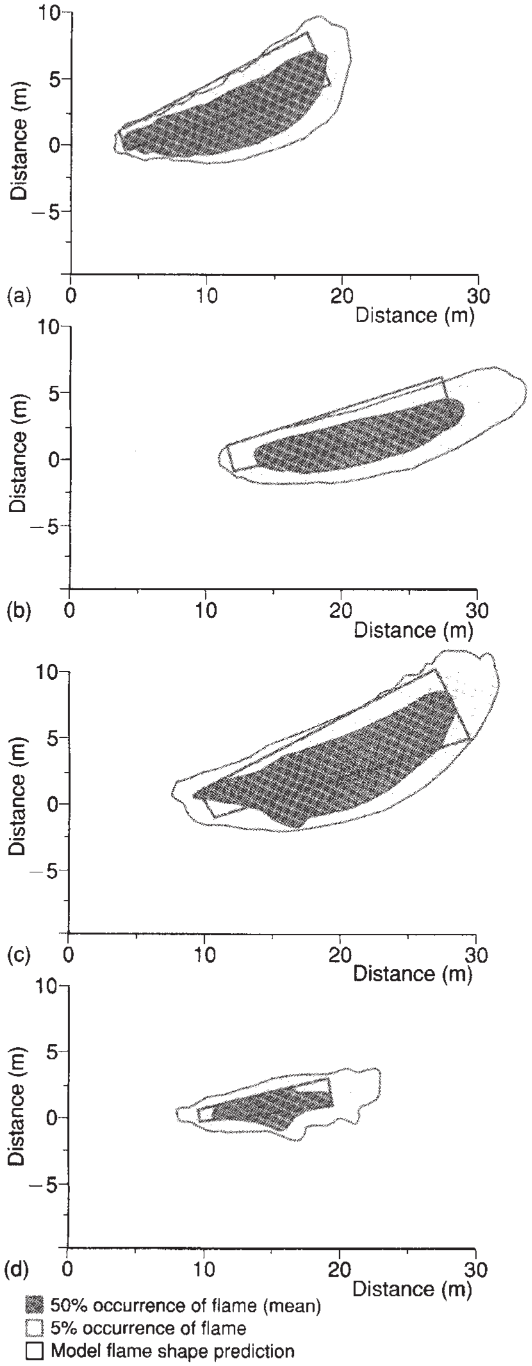

Figure 16.104 *Flare flames: flame dimensions for the model of Johnson, Brightwell and Carsley. Comparison between model predictions and experimental results (A.D. Johnson, Brightwell and Carsley, 1994): (a) Test 1040, Type B; (b) Test 1033, Type D; (c) Test 1083 Type C and (d) Test 1089, Type E*

Cowley (1989). The work on flames formed part of a study of emission and gas dispersion of jets as well as of combustion.

Hirst (1984) describes experiments using liquefied propane. Tests were carried out using orifices ranging from 9 to 52 mm in diameter and pressures from about 6 to 20 bar. Both vertical and horizontal releases were studied.

A series of tests were done with vertical releases. The liquid rose in a strongly divergent cone bending with the wind. The cone angle was typically 30° for the plume but up to 90° in the flash region. The releases usually reached a steady state before ignition. The visible clouds at ignition were large, extending up to 45 m vertically and 70 m downwind. In most cases a fireball formed and in several tests rose to 100 m; the most fully developed fireballs occurred at low wind speeds.

The overpressures generated by the flames were also measured. The maximum observed overpressures fell from some 3 mbar at 20 m from the release point to about 0.8 mbar at 100 m.

Other tests were done with horizontal releases. One of features measured in these trials was the distance reached by the flame. Figure 16.105 gives for a 5 mm diameter pipe the relation between the mass flow and the impingement distance of the flame.

One of the trials shows a 35 m long jet flame from a full bore release of 7.9 kg/s from a 50 mm pipe at a pressure of 13 barg. The combustion energy was 365 MW. The maximum surface emissive power was 250 kW/m^2 and occurred 25 m from the release point and just before the flame underwent transition from the momentum-dominated to the buoyancy-dominated condition.

However, for such full bore discharges the heat radiation within the flame was complex and steady heat fluxes were mainly in the range 50–220 kW/m^2 and depended on the discharge conditions and the target distance. The maximum temperature occurred at a distance of 4 m and had a value of 1570 K.

The problem of heat radiation from a flame on a pressure relief valve on a rail tank car onto the surface of the latter has been studied by Tunc and Venart (1984/85b). Experiments were conducted on ignited releases from pressure relief valves on tank cars.

16.19.2 Empirical features

A jet flame resulting from the ignition of a leak of flammable fluid at the leak aperture is a diffusion flame. The basic characteristics of such a flame have been outlined in Section 16.12.

At low velocities the flame is generally attached to the point of release, but at higher velocities it becomes detached, the distance between the orifice and the flame increasing with velocity so that it may become unstable and lift off, thus being extinguished. If, however, the flame impinges on an obstruction, this may serve to stabilize it.

As already stated, jet flames can have a considerable reach. The flame impingement distance can be up to 50 m or more. The reach is sometimes expressed in terms of the ratio of the flame length to the orifice diameter, and values of this l/d ratio in excess of 300 are quoted.

Generally, the length of a jet flame over the range of practical interest is approximately proportional to the square root of the mass flow. This is the implication of the API correlation for the flame length on a flare and of

the work on propane jet flames just described. It is also implied in a number of models.

The graph given in Figure 16.105 is fitted approximately by the relation

$$l_i \approx 6m^{0.5} \qquad 0 < m < 50 \qquad [16.19.1]$$

where l_i is the impingement distance (m) and m is the mass flow (kg/s).

The fraction of heat radiated by a jet flame is a function of the fuel, being less for hydrogen and methane than for propane. It tends to increase and reach a maximum as the orifice diameter increases. It usually lies in the range 0.15–0.3.

For diffusion flames in general the flame temperatures have been discussed by Gugan (1976). He quotes values of some 1600°C for laminar diffusion flames and 2000°C for turbulent diffusion flames, the heat release in the latter being an order of magnitude greater. The maximum flame temperature in a gas jet flame is of the order of 2000°C.

The maximum flame temperatures observed in the work on jet flames of liquefied propane were of the order of 1300°C. Further, in this work on liquefied propane the values of the surface emissive power up to 250 kW/m^2 were observed, but these are spot values and do not occur over the whole flame.

16.19.3 Modelling of jet flames

By comparison with fireballs and pool fires, with jet flames the number of possible scenarios to be considered is much greater. The case mainly treated is that of a vertical flame on an upward pointing jet, In calm conditions or in wind. Another case occurs where the jet points upwards not vertically but at an angle. In this case there may be a variety of wind directions, confluent with, opposed to or across the jet. A third case is the horizontal jet, for which again the wind direction may be confluent, opposed or across.

Different workers have assumed different geometries for the jet. These include a cone (e.g. Craven, 1972), a cylinder (e.g. Croce and Mudan, 1986) and a frustrum (e.g. Chamberlain, 1987). One consequence of this is that there is no generally applicable view factor and that the view factor to be used has to be developed for the particular geometry, except in so far as the point source method is applicable.

A model of a jet flame was formulated by Burke and Schumann (1928a,b) and was later taken up by Savage (1962). Another early model is that of Hawthorne, Weddell and Hottel (1949). Work on the modelling of jet flames has been done by Craven (1972), Bilger (1975, 1976, 1977, 1979, 1989), MITI (1976), H.A. Becker and Liang (1978, 1982), R. Becker (1980a,b), Kalghati (1981–1983, 1984), de Faveri, Fumarola and co-workers (Fumarola *et al.*, 1983; de Faveri *et al.*, 1985), Peters and co-workers (Peters and Williams,

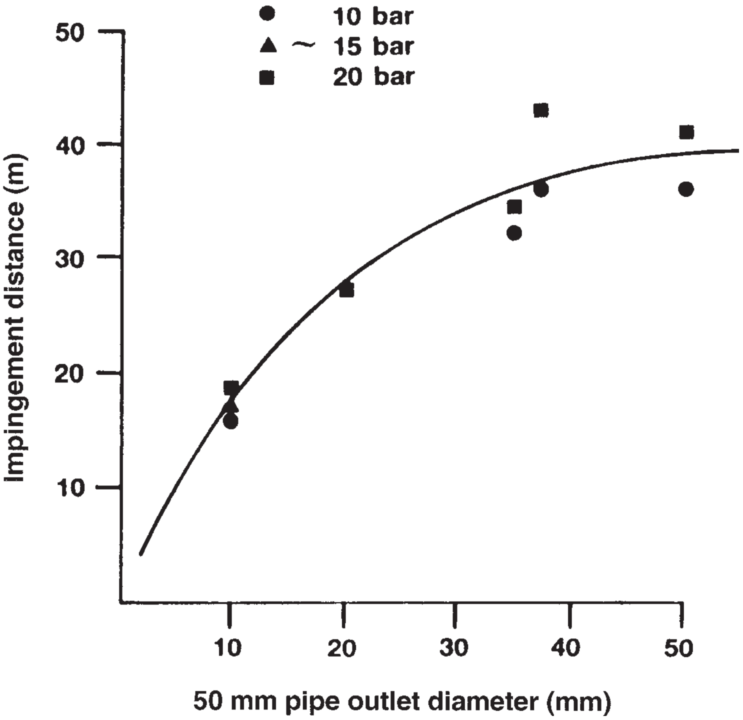

Figure 16.105 *Jet flames: flame impingement distance vs mass flow for propane (Tam and Cowley, 1989) (Courtesy of Gastech)*

1983; Peters and Göttgens, 1991), Hustad and Sonju (Sonju and Hustad, 1984; Hustad and Sonju, 1986), Croce and Mudan (1986) and Duijm (1994).

Work at Shell includes that by Chamberlain (1987) and A.D. Johnson, Brightwell and Carsley (1994).

Birch and co-workers at British Gas have conducted a series of studies on unignited and ignited jets (Birch *et al.*, 1978, 1984, 1988, 1989). Also at British Gas, D.K. Cook, Fairweather and co-workers have modelled natural gas flares (D.K. Cook, Fairweather, Hammonds and Hughes, 1987; D.K. Cook, Fairweather, Hankinson and O'Brien, 1987; D.K. Cook, 1991a,b; Fairweather *et al.*, 1991; Fairweather, Jones and Linstedt, 1992).

Models used by the HSE have been described by Clay *et al.* (1988), Grint (1989) and D.A. Carter (1991).

The set of models of fire events given by Considine and Grint (1985) includes one for a jet flame.

Many jet flame models derive from work on the modelling of flares, and most models are for jet flames of gas, particularly natural gas. There are also a few models for jet flames of a flashing liquid such as LPG.

Models for jet flames of LPG include those given by Clay *et al.* (1988), Grint (1989) and J. Cook, Bahrami and Whitehouse (1990).

Some of the principal jet flame models are now described.

16.19.4 Hawthorne, Weddell and Hottel model

One of the first models of a jet flame was that given by Hawthorne, Weddell and Hottel (1949). They envisage the flame as an inverted cone with the apex on the orifice. The equations for the length of the flame and for the diameter at the top of the cone have been given above as Equations 16.3.3 and 16.3.4, respectively.

16.19.5 Bzrustowski and Sommer model

The model of Brzustowski and Sommer (1973), which is given in API RP 521 as an alternative to the simplified API method for flare design and has been described in Section 16.18, is also used as a model for a jet flame.

16.19.6 Craven model

A model of a jet flame developed for the purpose of designing of emergency relief vents has been described by Craven (1972). He gives the following method of estimating the heat flux incident on a target near the flame.

The flame model considered is shown in Figure 16.106. The dimensions of the flame are estimated using the correlation of Hawthorne, Weddell and Hottel given in Equations 16.3.3 and 16.3.4. The flame temperature is assumed to be 2300 K, a value which is equal to or somewhat greater than adiabatic flame temperature for most hydrocarbons. The emissivity of the flame is taken as unity. The radiant heat flux E is then

$$E = \epsilon\sigma T^4 \qquad [16.19.2]$$

where E is the radiant heat flux (W/cm^2), T is the absolute temperature of the flame (K), ϵ is the emissivity of the flame, and σ is the Stefan–Boltzmann constant. The emissivity is assumed to be unity, so that for a flame temperature of 2300 K

$$E = 160\ \mathrm{W/cm^2} = 1600\ \mathrm{KW/m^2}$$

The heat flux and view factors for targets at points X, Y and Z in Figure 16.106 are considered. At point X, which is directly beneath the vent, the emissivity may be taken as unity. For a horizontal target at this point the flame is viewed as a disc and the view factor F_X (Howell, 1982–configuration B-11) is

$$F_X = \frac{r^2}{(l+h)^2 + r^2} \qquad [16.19.3]$$

where h is the height of the vent orifice (m), l is the length of the flame (m) and r is the radius of the flame at its tip (m).

For radiation at point Z the flame is treated as a rectangular radiator ABCD with an emissivity of unity. For

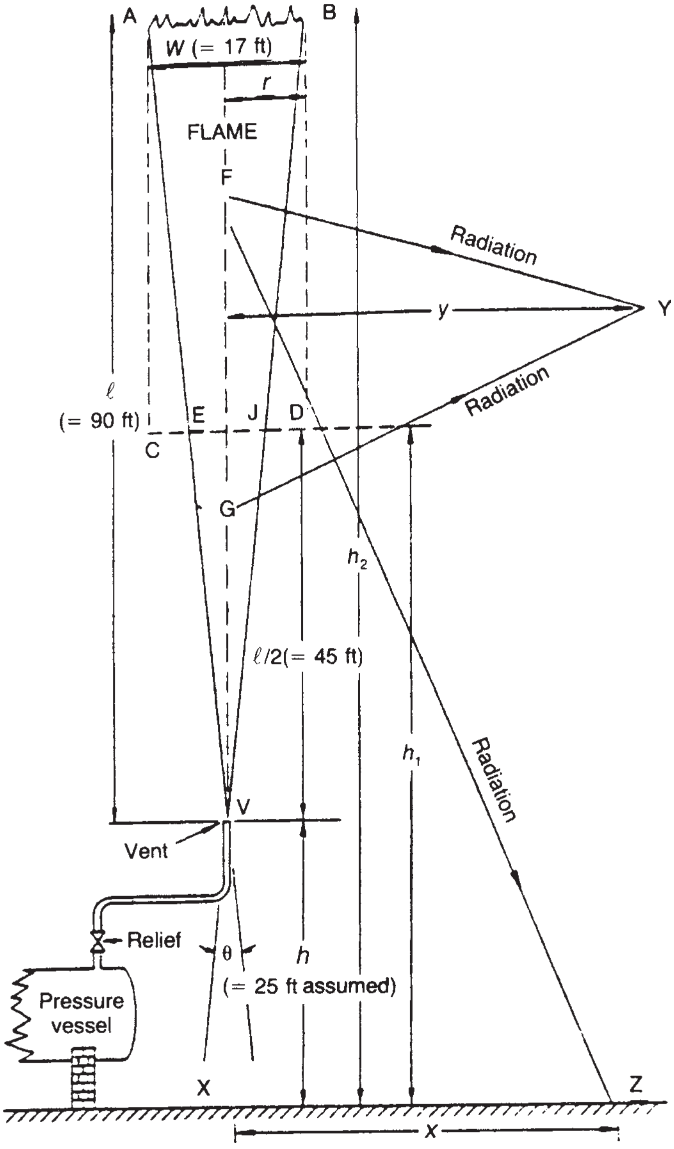

Figure 16.106 *Jet flames: flame dimensions for the Craven model (after Craven, 1972) (Courtesy of the Institution of Chemical Engineers)*

a horizontal target at this point the configuration factor F_Z is

$$F_Z = \frac{xr}{\pi}\left[\frac{1}{(h_1^2 + x^2)} - \frac{1}{(h_2^2 + x^2)}\right] \qquad [16.19.4]$$

with

$$h_1 = h + l/2 \qquad [16.19.5a]$$

$$h_2 = h + l \qquad [16.19.5b]$$

where h_1 is the distance from the ground to the bottom of the radiator ABCD (m), h_2 is the distance from the ground to the top of the radiator (m) and x is the distance between points X and Z (m). The value of the view factor F_Z passes through a maximum as x increases.

The radiation at point Y is more difficult to determine, but an estimate may be made as follows. At this point part of the radiation comes from the thin part of the flame. In this case the area of the radiator ABEJ is approximated by $^3/_4\, rl$ and the view factor F_Y is given very approximately by the expression

$$F_Y \approx \frac{rl}{\pi y^2} \qquad [16.19.6]$$

with

$$y \approx 10 D_{\max} \qquad [16.19.7]$$

where $D_{\max}$ is the maximum cone diameter (m) and y is the horizontal distance to the axis of the flame (m).

Craven points out that, whilst the above treatment applies to the highly turbulent flame occurring during the main discharge, a different situation occurs as this discharge subsides. In this stage there may exist for a short period a flame which is much less turbulent. Such a flame will tend to be larger but its temperature will be much less and the net effect is that the heat radiated is also less.

He also draws attention to the strong forces which can be exerted by a jet reaction when material under pressure is vented, and to the possibility that if the vent supports are inadequate, the vent pipe, and hence the flame, may be deflected from the vertical.

The method described is not intended to be used for flames on flare stacks, which are not highly turbulent and are therefore cooler.

Craven (1976) has compared estimates made by his method with observations given by R.O. Parker (1974) based on the ignition of an accidental discharge of natural gas. The results of the comparison of predicted and observed thermal radiation fluxes to targets side-on to the turbulent flame brush are given in Table 16.70.

The method given by Craven is essentially intended for design rather than for hazard assessment. In particular, the value assumed for the flame temperature is at the upper end of the range that is likely to occur in practice.

[b] Predicted using the method of Craven (1972), as described in the text.
[c] Observed data given by R.O. Parker (1974).

16.19.7 Hustad and Sonju model

Another jet flame model is that of Hustad and Sonju (Sonju and Hustad, 1984; Hustad and Sonju, 1986). Following earlier work by Suris, Flankin and Shoring (1977), Hustad and Sonju correlate the flame dimension in terms of the Froude number Fr. Their equations are

$$\frac{H}{d} = A\ \mathrm{Fr}^m \qquad [16.19.8]$$

$$\frac{D}{d} = B\,\mathrm{Fr}^m \qquad [16.19.9]$$

with

$$\mathrm{Fr} = \frac{u^2}{gd} \qquad [16.19.10]$$

where d is the diameter of the orifice (m), D is the diameter of the flame (m), g is the acceleration due to gravity (m/s^2), H is the height of the flame (m), u is the gas velocity at the nozzle exit (m/s), A and B are constants and m is an index.

For vertical flames they obtained values of A of 21 for methane and 27 for propane, and values of B of 2.5 for methane and 4 for propane. For both gases the value of m in both equations was 0.2 for $\mathrm{Fr} < 10^5$, but zero for $\mathrm{Fr} > 10^5$. Thus for both gases the value of the ratio H/D was constant, being 8.4 for methane and 6.75 for propane.

For horizontal flames of propane Equations 16.19.8 and 16.19.9 again applied. For Equation 16.19.8 the values of the constant just given were again applicable, but for Equation 16.19.9 the values of B and m were 10 and 0.156, respectively.

The height H^* over which the flame radiates heat is given as

$$H^* = H - h \qquad [16.19.11]$$

with

$$\frac{h}{d} = C\left(\frac{d}{u}\right)^{-1} \qquad [16.19.12]$$

where h is the lift-off height (m), H^* is the flame radiation height (m) and C is a constant. The value of the constant C is 3.6×10^{-3} s^{-1}.

For the fraction of heat radiated, Hustad and Sonju give

$$F = 4.74Q^{-0.2} + 11.6Q^{0.4} \qquad 1 < Q < 7 \qquad [16.19.13]$$

where F is the fraction of heat radiated and Q is the heat release rate (MW).

Thus, for example, for propane at heat release rates of 1 and 7 MW the fractions of heat radiated are 0.163 and 0.285, respectively.

16.19.8 Chamberlain model and Johnson, Brightwell and Carsley model

The flare models of Chamberlain (1987) and A.D. Johnson, Brightwell and Carsley, described in Section 16.18, also have application as models for a jet flame in an accident. The latter model is for a horizontal flame, which is the orientation of most interest in that context.

16.19.9 Cook, Bahrami and Whitehouse model

J. Cook, Bahrami and Whitehouse (1990) have described the jet flame models incorporated in the computer code SAFETI. There are two such models.

The first model is described as based on the API RP 521 jet flame model. The relations given are

$$L = 0.00326[\dot{m}(-\Delta H_c)]^{0.478} \qquad [16.19.14]$$

$$R_s = 0.29s[\log_{10}(L/s)]^{0.5} \qquad [16.19.15]$$

where $(-\Delta H_c)$ is the heat of combustion (J/kg), L is the length of the flame (m), $\dot{m}$ is the mass flow (kg/s), R_s is the radius of the flame at distance s (m) along the centre line (m).

It is assumed that the jet is emitted either vertically upwards or horizontally downwind. For a vertical jet which may be bent over by the wind, the trajectory is constructed using the API prescription according to the equation

$$\frac{dz}{dx} = \frac{1.6\pi D_j u_j}{u_w}\left(\frac{1}{s} - \frac{1}{L}\right) \qquad [16.19.16]$$

where D_j is the diameter of the jet (m), u_j is the velocity of the jet (m/s), u_w is the wind velocity (m/s) and x and z are the distances in the horizontal and vertical directions (m). Then the trajectory of the centre line of the jet flame is

$$x(s) = \int_0^s \frac{ds'}{\left[1 + (dz/dx)^2\right]^{0.5}} \qquad [16.19.17]$$

$$z(s) = \int_0^s \frac{ds'}{\left[1 + (dx/dz)^2\right]^{0.5}} \qquad [16.19.18]$$

The other jet flame model used is the Chamberlain model.

16.19.10 Carter model

A model for the thermal radiation incident on a target from a jet flame on a gas pipeline has been given by D.A. Carter (1991).

The flame assumed is as shown in Figure 16.107. Its dimensions are based on its state 30 s after release. Carter states that the model of the flame itself is based on that of Chamerlain, but otherwise gives no details.

The flame is treated as a multiple source radiator. For each source in the flame the relation for the thermal radiation is

$$q = \frac{F_r(-\Delta H_c)\dot{m}\tau}{4\pi x^2} \qquad [16.19.19]$$

with

$$\tau = 1 - 0.0565 \ln x \qquad [16.19.20]$$

where F_r is the fraction of heat radiated, $(-\Delta H_c)$ is the heat of combustion (kJ/kg), $\dot{m}$ is the mass flow (kg/s), q is the heat incident on the target (kW/m^2), x is the distance from the source to the target (m) and τ is the atmospheric transmissivity.

The flame model is embodied in the computer code SHELF and the heat radiation model in the code MAJESTIC.

As an illustration of the model, consider the example given by Carter. The problem is the determination of the heat radiation contours for a release of ethylene from a 9 in. pipeline at 100 bar with a mass flow of 43.7 kg/s. The flame length is 39 m and the flame tilt from vertical 11.5°. The heat of combustion is 4.771×10^4 kJ/kg and the fraction of heat radiated is 0.1284. Then from Equation 16.19.19 the contours of incident heat are as shown in Figure 16.108.

16.19.11 MITI model

Turning now to models for jet flames of flashing liquids, an equation for the length of a diffusion flame on the surface of an oil storage tank as a function of the Froude number has been given by Werthenbach (1971a,b, 1973). This equation has been adapted by the MITI (1976) for the jet flame formed if liquefied flammable gas blows a bursting disc and then ignites:

$$q = 0.0006785L^{2.5} \qquad [16.19.21]$$

where L is the flame length (m) and q is the fuel flow (kg/s). The use of this equation to correlate the length of ejected flames from fire engulfed vessels is discussed below.

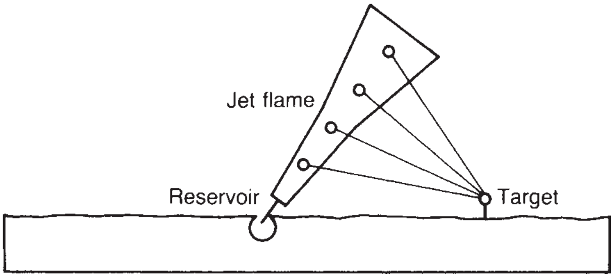

Figure 16.107 Jet flames: flame dimensions for the Carter model of gas pipeline release (D.A. Carter, 1991) (Courtesy of Butterworth-Heinemann)

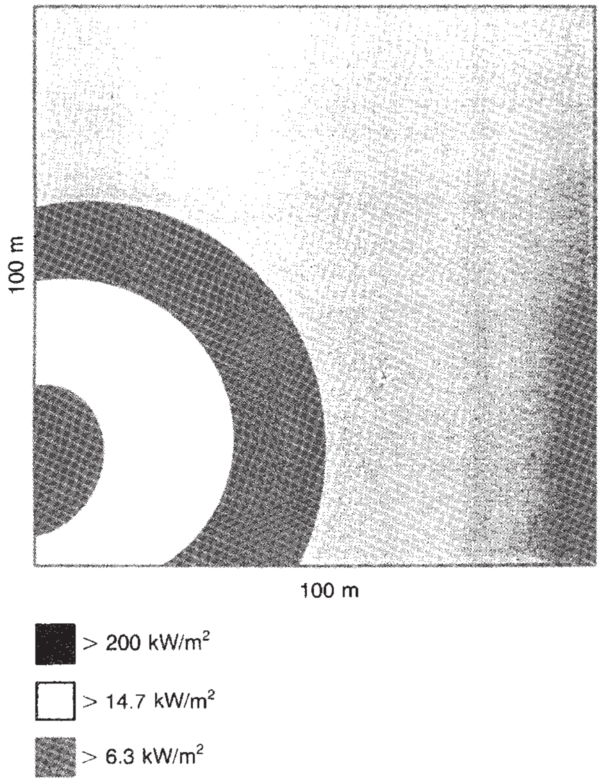

Figure 16.108 *Jet flames: heat radiation contours for illustrative example of flame from gas pipeline release (D.A. Carter, 1991). A > 200 kW/m^2; B > 14.7 kW/m^2 and C > 6.3 kW/m^2 (Courtesy of Butterworth-Heinemann)*

16.19.12 Considine and Grint model

Considine and Grint (1985) have derived a model for a jet flame based on the work of the MITI (1976) on liquid ethylene.The flame is assumed to be conical. The model equations are

$$L = 9.1\dot{m}^{0.5} \qquad [16.19.22]$$

$$W = 0.25L \qquad [16.19.23]$$

where L is the length of the flame (m), $\dot{m}$ is the mass flow (kg/s), and W is the half-width of the flame tip (m).

This model also includes relations for the hazard range of the flame. These are given in Section 16.39.

16.19.13 Clay *et al.* model

Clay *et al.* (1988) describe a set of models used by the HSE for hazard assessment, one of which is for a jet flame of LPG.

The flame length is given as

$$F = \frac{(H_c m)^{0.444}}{161.66} \qquad [16.19.24]$$

where F is the flame length (m), H_c is the heat of combustion (J/kg) and m is the mass flow (kg/s).

The flame is modelled as a point source radiator with heat radiated from a point located 4/5 of the flame length from the origin. For the thermal radiation the relation used is

$$q = \frac{fH_c m\tau \times 10^{-3}}{4\pi x^2} \qquad [16.19.25]$$

with

$$\tau = 1 - 0.0565 \ln x \qquad [16.19.26]$$

where f is the fraction of heat radiated, q is the thermal radiation received by the target (kW/m^2), x is the distance between the source and the target (m) and τ is the atmospheric transmissivity.

Graphs for the flame length and thermal radiation from a jet flame of LPG are given by Grint (1989) and appear to give results similar to those obtained with this model.

16.19.14 Modified Cook, Bahrami and Whitehouse model

J. Cook, Bahrami and Whitehouse (1990) state that for jet flames from a liquid or from a two-phase liquid–vapour mixture Chamberlain's model can be adapted by the following modification of the effective source diameter:

$$D_s = D_j \frac{(\rho_j \rho_v)^{1/2}}{\rho_a} \qquad [16.19.27]$$

and the lift-off distance b modified as follows:

$$b = 0.015L \qquad [16.19.28]$$

where ρ_v is the density of the vapour (kg/m^3).

16.19.15 Tunc and Venart model

The problem of heat radiation from a flame on a pressure relief valve on a rail tank car onto the surface of the latter has been studied by Tunc and Venart (1984/85b). Vertical and tilted flames are considered. The flame is modelled as a radiating surface rather than a point source. The view factor for a tilted flame is given.

16.19.16 View factors

In some applications it is sufficient to treat the jet flame as a point source radiator. In other cases it may be necessary to use a more accurate view factor. For a view factor based on the point source method use may be made of Equations 16.13.101–16.13.103.

View factors for some of the jet flame models just described have been given by Crocker and Napier (1988a). For the model by Hawthorne, Weddel and Hottel (1949) of a vertical flame, Crocker and Napier refer to the work of Tunc and Venart (1984/85b), who treat the flame as conical, and quote for the view factor F in this case the following integral equations given by Becker (1980a):

$$F = \frac{2}{\pi}\int_{\mathrm{h}}^{h+L} \frac{[x\sin\psi + (z\tan\alpha - r_{\mathrm{f}})\psi]r_{\mathrm{f}}z}{(x^2+z^2)^2}\,\mathrm{d}z \qquad [16.19.29]$$

Horizontal target

$$F = \frac{2}{\pi}\int_{\mathrm{h}}^{h+L} \frac{(x - r_{\mathrm{f}})r_{\mathrm{f}}[x\sin\psi + (z\tan\alpha - r_{\mathrm{f}})\psi]}{(x^2+z^2)^2}\,\mathrm{d}z$$

Vertical target [16.19.30]

where h is the height of the jet above the ground (including any lift-off), L is the visible length of the flame, $r_{\mathrm{f}}\,(z)$ is the radius of the flame at height z, x is the distance between the axis of the jet and the target, z is the height of the flame differential element, α is the half-angle of the flame and $\psi(z)$ is the angular position of the flame differential element.

In the model of Chamberlain (1987) for a flare, the jet flame is treated as a frustrum with the widest end furthest from the jet exit, as shown in Figure 16.103. For this case Crocker and Napier give the following expressions by Croce and Mudan (1986), in which the flame is treated as equivalent to a cylinder with diameter D_{e} and length L:

$$D_{\mathrm{e}} = 2\frac{(W_1 + W_2)^{1/2}}{L}[L^2 + (W_2 - W_1)]^{1/4} \qquad [16.19.31]$$

$$L = \frac{L_{\mathrm{BV}}\sin\alpha_{\mathrm{B}}}{\sin(90 - \alpha_{\mathrm{B}})\sin(180 - \theta)} \qquad [16.19.32]$$

where the notation is as defined in Subsection 16.18.6 and Figure 16.103, except that L_{BV} is the height of the centre of the flame tip above the level of the jet exit (m) and α_{B} is the angle between the vertical and the line joining the jet exit and the centre of the flame tip (°). In general, the angle α_{B} is not equal to the angle α_{B} as defined in Figure 16.103, although the two become the same for a vertical jet. The view factor for this equivalent tilted cylinder is then obtained using the standard view factors for a tilted cylinder, as described in Section 16.17.

Crocker and Napier also give the results of a numerical investigation of the values of the radiation intensity on a target for a propane jet flame burning at a vent, as obtained for vertical and tilted flames using for the vertical flame the model of Hawthorne, Weddell and Hottel and the Becker relations, and for the tilted flame a point source treatment based on the model of Brzustowksi and Sommer, a multiple point source treatment based on the model of de Faveri *et al.* and the solid flame model of Chamberlain with the Croce and Mudan view factor. They select the latter as the preferred model for a tilted flame.

A treatment of the view factor for a jet flame is also given in the IP *LPG Storage Code*. To the extent that a jet flame may be characterized as a cylinder, view factors for cylinders may be used. The *Code* gives view factors for vertical and tilted cylinders with target levels above and below.

16.19.17 Application of models

The model of Hawthorne, Weddell and Hottel was used in some early work. For example, Gugan (1976), in a discussion of the release at Flixborough, expressed the view that whilst this model had not been verified for large-scale situations, there was no fundamental reason why it should not apply, and stated that use of the model to correlate incidents had not revealed any defect.

The model of Considine and Grint of SRD has been widely used by the HSE and others in hazard assessment work. The model is given in the CCPS *QRA Guidelines* (1989/5).

The Chamberlain model has been used by Shell for the study of possible impingement of jet flames from gas risers on the accommodation modules of oil production platforms, as described by Chamberlain (1989) at the Piper Alpha Inquiry.

The IP *LPG Storage Code* recommends for a jet flame of LPG the use of the Brzustowski and Sommer point source model provided that: (a) the target is at least one flame length away; (b) the fraction of heat radiated is taken as 0.38 for exit velocities up to Mach 0.5 and 0.22 up to Mach 0.9; (c) allowance is made for attenuation due to atmospheric transmittance and (d) the code calculation methods are used. The flame length is taken as twice the distance from the flame centre to the point of discharge.

For the case where the target is less than one flame length away, the *Code* refers to the treatment of Chamberlain, whilst stating that this is not universally accepted.

16.19.18 Enclosed jet flames

The work just described relates to jet flames in the open. In some instances, a jet flame may occur within an enclosure. This case is of particular relevance to ignited releases in offshore modules.

Work on this aspect has been described by Chamberlain (1994). The experiments were conducted in an enclosure 8 m long × 3.54 m wide × 3.91 m high. The enclosure contained a cylindrical target 0.27 m in diameter, and thermocouples, radiometers and total heat flux gauges were located on the target and the enclosure walls. Propane was released both as a vapour, in the subsonic and sonic flow regimes, and as a liquid at a flow which averaged 0.21–0.3 kg/s. Both vertical and horizontal nozzle orientations were used. Some trials were conducted with full end wall opening and others with partial wall opening (2.5 m × 2 m); one trial condition involved a partially open roof. Measurements were also made of the composition, particularly the carbon monoxide concentration, of the combustion products and of the size of and thermal radiation from the external flame from the enclosure.

The situation investigated is strongly similar to the compartment fires which have been much studied in work on fires in buildings, as described in Section 16.36. In the ventilation-controlled conditions which occur in a compartment the hot combustion products flow out through the top of the aperture and cold air flows in through the bottom, with a relatively well-defined boundary between the two. This has led to the three zone model of a compartment fire, the three zones being the fire plume itself and the hot and cold gas zones. The air flow in such a fire is normally modelled in terms of the ventilation factor $AH^{1/2}$, where A is the area of the ventilation opening (m^2) and H is its height (m).

However, a jet flame in an enclosure differs from the pool fire case in at least two important respects. One is the much greater degree of mixing and the other the absence of 'flashover'.

Some of the findings from these tests were as follows. For ventilation-controlled fires with vertical apertures it took about 10 min to reach steady-state conditions. The boundary between the hot and cold layers occurred about halfway up the opening. The gas temperature in the upper layer was remarkably uniform and could reach about 1200°C.

In addition to the heat effects on the wall and the contents of the enclosure, other hazards are the thermal radiation from the external flame and the generation of smoke and carbon monoxide.

In some tests using propane gas from a vertical nozzle the heat flux at the impingement area on the roof reached over 300 KW/m^2, rising to this value as radiation from the walls came into play.

For the external flame the maximum vertical and horizontal extents measured were 6 and 3 m , respectively, for a trial using liquid propane, though two trials using propane gas gave comparable values of 5 and 3 m, respectively; there was no external flame in the two trials with full wall opening.

It is the flame stoichiometry which governs the production of soot and carbon monoxide. This stoichiometry is a function of the fuel flow, the jet momentum and the vent opening. The experiments showed that the parameter $0.5AH^{1/2}$ tends to give an overestimate of the air flow. The author advises against its use for the determination of flame stoichiometry.

Jet flames which were fuel rich gave much higher yields of soot and of carbon monoxide and larger external flames.

When ventilation-controlled, roof ventilated jet flames were found to be unstable and to self-extinguish. With this geometry a stable two-way flow of air and combustion products is not established.

16.20 Engulfing Fires

The engulfment of vessels in fire may occur in various ways and the problem has been studied from several different angles. Important distinctions relate to the container, which may be a fixed tank or vessel or pipework or a transport container, and to the fire, which may be a pool fire or a directed flame.

There have been a number of experiments on rail tank cars and on fixed storage vessels engulfed in fire, and various models have been developed for heat transfer to such vessels, for the response of the temperatures and pressures in the vessel, for pressure relief of the vessel and for bursting of the vessel. Some studies of engulfing fires are given in Table 16.71.

16.20.1 Heat absorbed

Relations for the heat absorbed by a vessel from a pool fire are given in API RP 520: 1976 *Recommended Practice for Design and Installation of Pressure Relieving Systems in Refineries* and API Std 2000: 1982 *Venting Atmospheric and Low-pressure Storage Tanks*. It is convenient to consider first the relationships given in these publications and then the subsequent changes.

Theoretical model of temperatures and pressures in a vessel containing liquid engulfed by fire	D.L.M. Hunt and Ramskill (1985)

The two documents mentioned give for the heat absorbed by the wetted surface area expressions of the engulfing general form

$$Q = kA^n \qquad [16.20.1]$$

where A is the wetted surface area, Q is the heat absorbed, k is a constant and n is an index.

For the estimation of the heat absorbed for purposes of determining relief requirements, API RP 520 gives the equation

$$Q = 21{,}000\ FA^{0.82} \qquad [16.20.2]$$

where A is the wetted area (ft^2), F is an environment factor and Q is the heat absorbed (BTU/h).

API RP 520 contains an appendix (Appendix A) in which the origin of Equation 16.20.2 is explained. It is based on tests carried out in 1925 by Standard Oil of California. The tests were conducted on a small tank and were intended to give guidance on relief sizing for tank trucks. The tests indicated the maximum heat absorption rate to be expected in the worst case. There were also available data on cases where tanks had survived fire exposures. The available data were plotted by Stroop on log–log paper as a curve. This curve was intended to give guidance for small tanks and, by extrapolation, for tanks with wetted areas up to 10,000 ft^2. It was subsequently observed by Maker that the data could be represented by a straight line and he proposed the equation

$$q = 48{,}000\ A^{-1/3} \qquad [16.20.3]$$

where q is the heat absorbed per unit area (BTU/h ft^2) and A is the wetted area (ft^2). Equation 16.20.3 became known as the Stroop–Maker formula and was applied not only to atmospheric storage tanks but also to pressure vessels.

Another set of equations developed during the Second World War are the formulae of the Petroleum Administration for War (PAW). These are

$$q = 16{,}000\ A^{-0.18} \qquad [16.20.4]$$

$$Q = 16{,}000\ A^{0.82} \qquad [16.20.5]$$

The Stroop–Maker and PAW formula have been widely used in the petroleum industry.

API RP 520 gives a plot comparing the PAW and API formulae given here as Equations 16.20.2 and 16.20.5, respectively, with various additional data points obtained from tests carried out during the period 1925–1950. Some of the tests represent the worst conditions likely to occur, since they were delayed until calm conditions prevailed and plentiful fuel supplies were used.

API Std 2000 quotes Equation 16.20.2 for use in determining the venting requirements of atmospheric and low Pressure storage tanks for wetted areas greater than 2800 ft^2. It also gives tables for determining the venting requirements for wetted areas less than this. It is explained in an appendix (Appendix B) that the tables are based on the following equations:

$$Q = 20{,}000\ A \qquad 20 < A < 200 \qquad [16.20.6a]$$

$$Q = 199{,}300\ A^{0.566} \qquad 200 < A < 1000 \qquad [16.20.6b]$$

$$Q = 963{,}400\ A^{0.338} \qquad 1000 < A < 2800 \qquad [16.20.6c]$$

The method used in earlier versions of API Std 2000 was to assume a constant value of heat absorbed ($q = 6000$ BTU/h ft^2), but tests conducted in 1961 on a horizontal tank led to a revision and development of the equations just quoted.

A discussion of the heat absorbed by a vessel in an engulfing fire has been given by Craven (1976). He suggests that if a well-developed fire radiates heat at a given rate, then it could be argued that an object engulfed in a fire should receive heat at the same rate, since the view factor is unity. A large fire can radiate heat at a rate of some 17 W/cm^2 (170 kW/m^2). In tests on small tanks the heat input rates recorded are, on average, about 11 W/cm^2 (110 kW/m^2), while for large tanks they rarely exceed 7 W/cm^2 (70 kW/m^2). The exponents in Equations 16.20.1, as given in Table 16.72, reflect this falling off in heat absorption with size. Craven argues, however, that there is no theoretical justification for an exponent less than unity and that in certain circumstances a vessel might receive a heat input nearer 17 W/cm^2 (170 kW/m^2). For the latter case he gives the equation

$$Q = 54{,}000\ A \qquad [16.20.7]$$

where A is the wetted area (ft^2) and Q is the heat absorbed (BTU/h).

Figure 16.109 (Crawley and Scott, 1984) shows a comparison of the PAW and API formulae and some of the data points given in API RP 520.

Table 16.72 *Parameters for use in the equations given in API RP 520 and API Std 2000 for the heat absorbed in fire engulfment*

	Wetted area, A		*Heat absorbed, Q*		*Conditions*
	(ft^2)	(m^2)	(BTU/h)	(kW)	
API RP 520: 1990			21,000 $A^{0.82}$	43.1 $A^{0.82}$	–[a]
			34,500 $A^{0.82}$	70.8 $A^{0.82}$	–[b]

[b] Drainage and fire fighting equipment inadequate

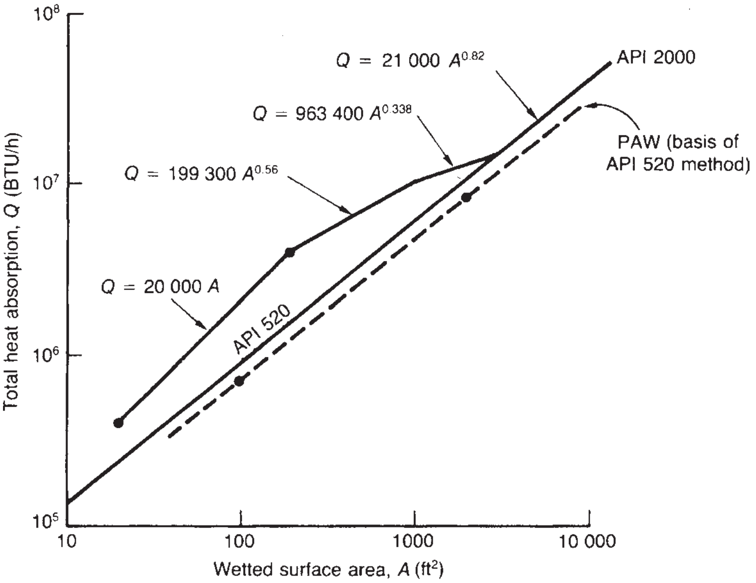

Figure 16.109 *Comparison of the equations given by the API for the heat absorbed by a tank or vessel in a fire (Crawley and Scott, 1984) (Courtesy of the Institution of Chemical Engineers)*

The history of the API RP 520 treatment of heat absorption is discussed by Heller (1983).

API RP 520: Part 1: 1990 gives in Appendix *D* two equations for the heat absorbed, which differ in that they are based on the adequacy of drainage and fire protection. The first is Equation 16.20.2 and the second the equation

$$Q = 34{,}500\ FA^{0.82} \qquad [16.20.8]$$

Equation 16.20.2 is to be applied where adequate drainage and fire-fighting equipment exist and Equation 16.20.8 where they do not.

The API recommendations are therefore as follows. API RP 520: 1990 and API Std 2000: 1992 recommend the use of Equation 16.20.1 with the constants shown in Table 16.72.

It should be borne in mind that the API RP 520 equations are given for the purpose of plant design rather than hazard assessment.

Further information on the heat absorbed is given below in relation to particular studies of engulfing fires.

16.20.2 General studies of engulfing fires

A series of theoretical studies of the effect of engulfing fires on vessels and pipework with and without insulation has been carried out by Borgnes, Solberg and coworkers, as reported by Solberg and Borgnes (1983). The work was done using the Det norske Veritas (DnV)computer program NV613 for the determination of temperature profiles.

The heat absorbed in an engulfing fire is not well defined, but at the flame surface a heat flux of about 150 kW/m^2 seems to be a reasonable value. Inside the flame the heat flux would be higher; how much higher is uncertain, but perhaps by some 50–100 kW/m^2. There is also a convective heat flux. For pool fires a heat flux of 30–40 kW/m^2 is a conservative estimate, but for jet fires it may be appreciably higher. The approach taken is therefore as follows. Heat transfer is assumed to be by radiation only, with the object engulfed in the flame so that the view factor is unity. The flame temperature of the engulfing fire is assumed to be 1525 K with the flame emissivity and target absorbtivity both taken as unity. The justification for the latter is that in such a fire the metal would soon be covered with a deposit of carbon. For an object at an initial temperature of 400 K the initial heat flux under these conditions is 310 kW/m^2.

The temperature at which steel suffers serious loss of strength, or the critical steel temperature, is taken as 675 K.

The base case is a considered 2 m diameter vessel with 20 mm wall thickness and 50 mm mineral wool insulation, containing gaseous propane at an initial temperature of 400 K and at pressures of 5, 20 and 80 bar. Figure 16.110(a) shows the wall temperatures attained for different gas pressures after different time periods. For an uninsulated vessel the critical steel temperature is reached within a few minutes. For an insulated vessel at 5 bar pressure the time to critical steel temperature is less than 1.5 h, while for one at 80 bar pressure the steel reaches a temperature of 610 K after 2 h.

Figure 16.110(b) shows, for a 0.2 m diameter uninsulated pipe, the times to different wall temperatures/or stagnant and flowing methane gas at 5 and 80 bar pressure. Figure 16.110(c) shows, for uninsulated and insulated pipe of the same diameter, the wall temperature response for stagnant and flowing liquid methane at an initial temperature of 110 K.

Figure 16.110(d) shows the wall temperature and gas pressure responses for 2 and 10 m uninsulated horizontal vessels partly filled with liquid propane, with fill ratios of 0.625 and 0.88. Figure 16.110(e) shows the corresponding responses for insulated vessels. For the latter case the temperature profile in the vessel wall is shown in Figure 16.110(f). This very steep temperature gradient may give rise to severe stresses in the vessel shell.

The authors also describe work on other aspects, such as the effect of defects in the insulation and unevenness in water sprays.

16.20.3 Vessels filled with gas

A theoretical study of the effect of an engulfing fire on a vessel filled with methane has been made by Nylund (1984).

The vessel considered was 13 m long × 3 m diameter with a wall thickness of 53 mm, a working temperature of 300 k and a pressure of 8.2 MPa.

Pool and jet fires were investigated. The flame temperature for both fires was assumed to be 1500 k. The convective heat transfer coefficient was taken as 28 W/m^2 K for the pool fire and as 250 W/m^2 K for the jet fire. A model is given for vessel rupture as a function of vessel temperature and pressure and wall thickness.

Some of the results obtained by Nylund are shown in Figue 16.111. Figure 16.111(a) shows the time response of the gas temperature, the gas pressure and the rupture pressure for a jet fire, for a jet with an effective diameter of 1 m. The rupture pressure does not fall below the gas pressure. Figure 16.111(b) shows the response for a jet fire with a jet having an effective diameter of 4 m. In this case the rupture pressure does fall below the gas pressure, so the vessel would rupture. Rupture is predicted for jet fires with jets having an effective diameter of 2, 3 and 4 m for which the pressure crossovers occur at about 7.5, 7 and 5 min respectively. Figure 16.111(c) shows the response for a pool fire. In this case not only does the rupture pressure fall, but the gas pressure rises appreciably so that rupture occurs in somewhat less than 5 min.

Nylund also discusses pressure relief and depressurization. In both types of fire rupture can occur within 5 min. For neither type does a pressure relief valve provide real protection. In the case of the jet fire the rupture occurs at gas pressures well below the relief valve set pressure. In the pool fire case the gas pressure does reach the set pressure, but the relief valve capacity is insufficient to vent the pressure quickly enough.

Depressurization is capable of providing protection. Figure 16.111(d) illustrates a successful depressurization.

16.20.4 Vessels part filled with liquid

There have been several experimental investigations of the response of vessels containing liquefied flammable gas to an engulfing fire.

A test on fire engulfment of a 64 te LPG rail tank car has been described by C. Anderson *et al.* (1974) and Charles (1974). Measurements were made of the heat flux from the fire, of the vessel wall temperatures in the liquid and vapour spaces and the relief valve flare. The relief valve opened at 1.96 MPa and remained open. The vessel ruptured after some 24.5 min, propelling 63 fragments, some for considerable distances. The pressure at failure was 24.1 bar and the wall temperature near the point where failure occurred had a maximum value of 650°C. The temperatures of and heat fluxes from the pool fire and the relief valve torch are given in Table 16.73.

A series of tests on vessels for rail tank cars have been carried out at 1/5 scale by Appleyard (1980). One objective of these tests was to investigate the effectiveness of the internal thermal radiation protection Explosive.

These and other tests have been reviewed by Tunc and Venart (1984/85b) and by Moodie, Billinge and Cutler (1985).

Models for radiant heat transfer to a horizontal cylindrical vessel from (1) an engulfing fire and (2) a relief valve flare have been given by Tunc and Venart (1984/85a,b).

Large-scale tests on the effect of fire around a liquid ethylene storage vessel have been carried out as part of the experiments by the MITI (1976) described earlier.

In one test, a storage vessel with vacuum perlite insulation fitted, with a 25 cm diameter bursting disc and containing 718.5 kg of liquid ethylene was subjected to a flame from LPG burners for 15 min with the water sprays on and then for 15 min with the sprays off. The total quantity of LPG consumed in the fire was 80 kg and the total heat released was estimated as 960,000 kcal. The pressure in the vapour space in the vessel remained at about 1.0 kg/cm^2 g throughout the test.

In another test the insulating vacuum of the vessel was broken and part of the perlite at the base of the vessel was removed. The vessel was subjected to a pool fire of kerosene which engulfed it. The water spray was not used on the vessel. The total quantity of heat released by the kerosene fire was estimated as 34,496,000 kcal. The bursting disc blew when the vapour pressure reached 8.3 kg/cm^2 g, which occurred 34 min after ignition.

When the disc blew, some 620 kg of ethylene was ejected as a vapour–liquid mixture within about 6.5 s. The material ignited and gave a large flame which lasted about 8–9 s and

Table 16.73 Temperatures and heat fluxes in a full scale fire engulfment test on a rail tank car (Tunc and Venart, 1984/85b; after Charles, 1974)(Courtesy of the Fire Safety Journal)

Time (min)	*Recorded heat flux* (kW/m^2)	*Temperature* (°C)		*Heat flux* (kW/m^2)	
		Fire	*Torch*	*Fire*	*Torch*
5.0–11.5	90.12	871	1120	60.28	171.8
11.5–15.0	68.7	816	1040	49.4	134.28
15.0–24.5	29.65	802	1090	46.94	159.22
Maximum reading (6.5 min)	104.8	871	1180	60.28	203.4

was about 100 m long. The actual length of the flame agreed well with the value of 105 m calculated from Equation 16.19.21 assuming that 620 kg was released over 8 s.

Part of the flame formed a fireball. The diameter and duration of the fireball were calculated from the NASA formula (Equations 16.16.5 and 16.16.7). The total mass of the combustion reactants was taken to include the air required Jor combustion, so that 28 kg of ethylene require 96 kg of oxygen, making a total mass of 124 kg. The observed fireball had a diameter of 40 m and persisted for about 3 s. According to Equations 16.16.5 and 16.16.7 this corresponds to about 324 kg of ethylene. Thus on the basis of this calculation about half the mass of ethylene ejected was involved in the fireball.

Two series of tests on horizontal cylindrical vessels partly filled with liquid and engulfed in a pit fire have been carried out by the HSE. In the first series, described by A.F. Roberts, Cutler and Billinge (1983), 5001 vessels were used. A preliminary set of tests was done with vessels containing water; the main tests were then done with LPG.

In the tests using water the vapour space heated up rapidly and caused boiling at the water surface at 4 min. The bulk water began to boil after 8 min. Between 4 and 8 min the boiling reduced the temperature of the vapour but not that of the wall in the vapour space. After 8 min it reduced both these temperatures.

The heat balance on the wall was expressed as

$$\rho c d \frac{\mathrm{d}T_1}{\mathrm{d}T} = Q - \epsilon \sigma T_1^4 - \sigma \mathrm{F} T_1^4 \qquad [16.20.9]$$

where the second and third terms on the right-hand side represent the heat radiated externally and that radiated internally, respectively. The equation is solved to give

$$\frac{4Qt}{\rho c d T_{\mathrm{A}}} = \ln\left(\frac{T_A + T_1}{T_{\mathrm{A}} - T_1}\right) - \ln\left(\frac{T_{\mathrm{A}} + T_0}{T_{\mathrm{A}} - T_0}\right)$$

$$+ 2\tan^{-1}\left(\frac{T_1}{T_{\mathrm{A}}}\right) - 2\tan^{-1}\left(\frac{T_0}{T_{\mathrm{A}}}\right) \qquad [16.20.10]$$

with

$$T_A = \left[\frac{Q}{\sigma(\epsilon + F)}\right]^{1/4} \qquad [16.20.11]$$

where c is the specific heat of the wall metal, d is the thickness of the metal wall, F is a factor (explained below), Q is the heat absorbed per unit area, T_{A} is the asymptotic value of T_1, T_0 is the initial value of the wall temperature, T_1 is the value of the wall temperature at time t, ϵ is the emissivity of the external surface of the wall, ρ is the density of the metal and σ is the Stefan–Boltzmann constant. The factor F includes the emissivity of the internal surface of the wall, the absorptivity of the water surface and the view factor from the wall to the water surface.

Equation 16.20.10 was used to obtain estimates of the heat absorbed Q and of the factor F from the wall temperature data. The heat absorbed was estimated to have an average value of 134 kW/m^2 and the factor F a value of 0.055, which is consistent with a wall emissivity of unity, a water surface absorptivity of 0.09 and the view factor of $2/\pi$. The estimated average flame temperature was 1100°C.

The calculated equilibrium conditions for the unwetted upper part of the vessel were a wall temperature of 950°C, a total heat transfer from the fire of 134 kW/m^2, re-radiation from the vessel to the atmosphere of 127 kW/m^2 and internal radiation to the liquid layer 7 kw/m^2. For the wetted lower part of the vessel the total heat transfer was estimated as 124 kW/m^2, giving an overall average heat flux of 130 kW/m^2.

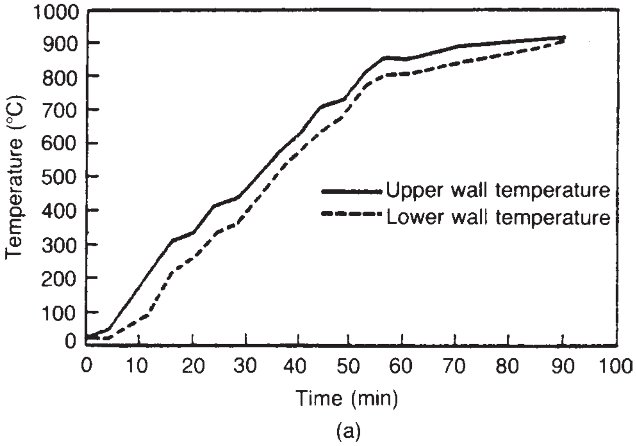
The main set of ten trials were then conducted using propane, one with an uninsulated vessel and nine with insulated vessels. A feature of these trials was the behaviour of the pressure relief valves. The valves were set to open at 1.7 MPa, but in fact opened at pressures in the range 0.7–1.8 MPa, due probably either to weakening of the spring or damage to the valve seat from the effects of the fire.

In the water tests the boiling regime was nucleate boiling. In the propane tests the regime was film boiling in most cases, although nucleate boiling did occur. Figure 16.112(a) illustrates film boiling in which the wall temperature in the liquid space is close to that in the vapour space, while Figure 16.112(b) shows nucleate boiling when the liquid space wall temperature is much lower. The occurrence of film boiling, and the associated poor heat transfer, therefore renders the walls vulnerable to thermal weakening.

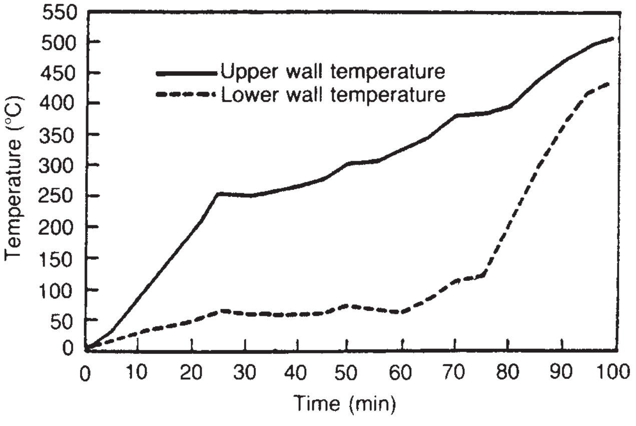
In the second series of fire engulfment tests by the HSE, described by Moodie, Billinge and Cutler (1985) the tanks used were 1/4 and 1 the uninsulated vessels part filled with propane. Five tests were carried out, two with 1/4 te vessels and three with 1 te vessels. In one of the former tests the pressure relief valve failed, so that there were four successful tests. Plate 13 shows a test in which the pressure relief valve is operating, giving a large jet flame.

The vessels were instrumented for the measurement of temperatures in the tank wall, the vapour space and the liquid, as shown in Figure 16.113.

In these larger-scale tests the fire was deficient in oxygen and gave a yellow, smoky flame. The flame temperatures



(a)



(b)

Figure 16.112 *Temperatures in a 500 l vessel part filled with propane engulfed in fire (A.F. Roberts, Cutlerand Billinge, 1983): (a) typical film boiling; (b) typical nucleate boiling (Courtesy of the Institution of Chemical Engineers)*

were 900–950°C with a maximum of 1000°C. The maximum wall temperatures recorded were in the range 600–800°C, which is consistent with a flame emissivity of 0.56.

The experimental conditions and heat fluxes are summarized in Table 16.74.

Thus in the successful 1/4 te tank test the average heat flux before venting into the propane was estimated as 73 kW/m^2 and that into the tank wall as 24 kW/m^2 giving a total of 97 kW/m^2. During venting the heat flux into the propane was 80 kW/m^2.

The four successful tests, one with the 1/4 te tank and three with the 1 te tank, showed a similar pattern. The wall temperature of the vapour space rose almost linearly, while the wall temperature of the liquid space rose to a plateau, levelled out and then rose again. When the pressure relief valve opened giving a nearly constant pressure the liquid wall temperature settled just above the corresponding boiling point, until the wall became exposed due to evaporation of the liquid. Figure 16.114(a) shows for the successful 1/4 te test the temperatures of the walls in the liquid an vapour spaces and Figure 16.114(b) shows the temperatures of the vapour and liquid.

The behaviour of the wall temperature in the liquid space in these tests points to nucleate rather than film boiling, and estimates of the heat flux indicate that the high heat fluxes necessary for film boiling did not occur.

In all the successful tests the internal pressure rose to the relief valve set pressure within 3–5 min. The relief valves cycled at least twice, then remained open venting the pressure down eventually to atmospheric pressure. This behaviour was attributed to weakening of the springs or damage to the seats due to the fire. Although the vessel walls would be weakened by the high temperatures experienced, at no time did the internal pressure have a value which would have been likely to cause rupture.

One of the tests on the 1/4 te tank with 40% fill was unsuccessful in that the relief valve, after opening correctly, failed to do so subsequently. The vessel ruptured at an internal pressure of 35 bar and maximum wall temperature of 600°C.

Test	*Tank size* (te)			
	1/4	1/4	1	1
Degree of fill (%)	40	80	40	20
Mass of liquid (kg)	100	870	420	160
Volume of liquid (m^3)	185	1635	789	308
Tank pressure (bar)	5.5	6.1	4.1	4.1
Ambient temperature (°C)	5	14	−3	−3
Surface areas (m^2):				
Total	3.8	10.4	10.4	10.4
Wetted	1.68	6.28	4.32	3.02
Average heat flux (kW/m^2):				
To propane before venting	73	84	59	33
To walls before venting	24	34	16	28
To propane during early stages of venting	85	50	54	76

Metallurgical examination revealed no indication of failure due to cracks and was consistent with failure by hoop stress in the wall. The authors suggest that the burst pressure may therefore be calculated from thick-walled cylinder theory and give the equation

$$P_b = \frac{2}{3^{1/2}} \sigma_y A \ln K \qquad [16.20.12]$$

with

$$A = 2 - \sigma_u/\sigma_y \qquad 0 < T < 700 \qquad [16.20.13a]$$

$$A = 1 \qquad T > 700 \qquad [16.20.13b]$$

where K is the ratio of the outside to the inside diameter, P_b is the burst pressure, T is the metal temperature (°C), σ_u is the ultimate tensile strength and σ_y is the yield strength, both as measured at temperature T.

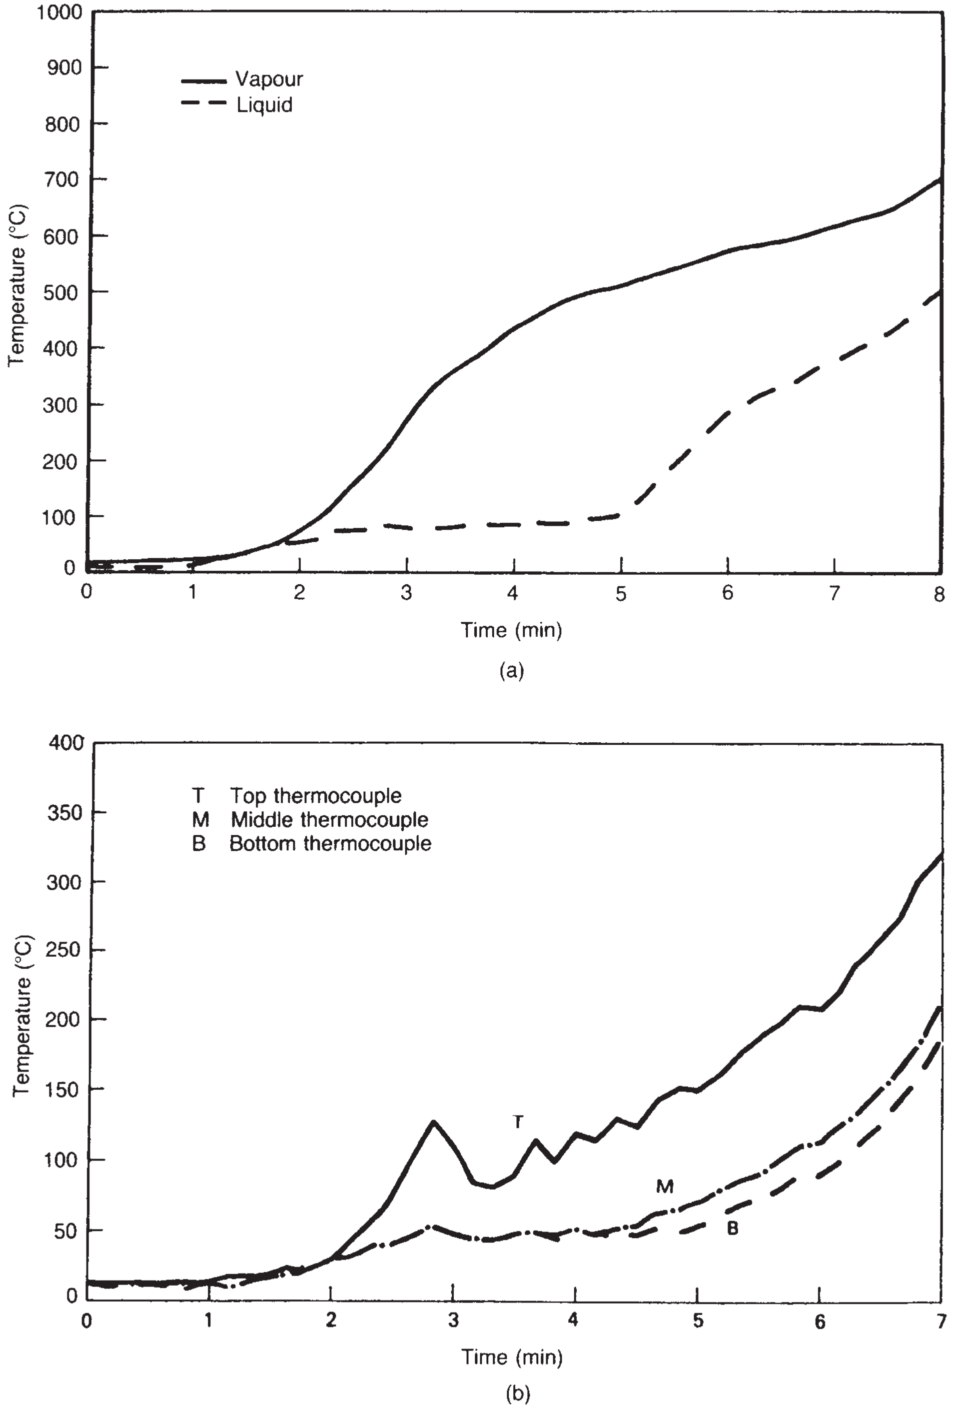

Figure 16.114 *Temperatures in the $^{1}/_{4}$ te vessel part filled with propane engulfed in fire (Moodie, Billinge and Cutler, 1985): (a) temperatures of walls in liquid and vapour spaces; (b) temperatures of vapour and liquid (Courtesy of the Institution of Chemical Engineers)*

If the wall temperature in this test is taken as 600°C, the burst pressure calculated by Equation 16.20.12 is 38 bar, which is within 8% of the observed value. Moreover, application of Equation 16.20.12 to data given by C. Anderson *et al.* (1974) and Droste *et al.* (1984) predicts all the burst pressures with an error of less than 18%. The authors also discuss the implications of the work for the pressure relief of vessels engulfed in fire.

In association with these tests a theoretical model for the behaviour of a vessel engulfed in fire has been developed by D.L.M. Hunt and Ramskill (1985). Figure 16.115 shows the heat flows taken into account in the model.

Some predictions given by the model for one of the 5001 vessels in the first HSE series of tests are compared with the observed values in Figure 16.116. Figure 16.111(a) shows the wall temperatures of the vapour and liquid spaces and Figures 16.116(b) and (c) the temperatures of the vapour and liquid, respectively.

16.20.5 Jet flame attack

There is relatively little available data on the effect on equipment of jet flame attack, as opposed to pool fire engulfment, but the EC currently has in hand a major

programme of work on this, an account of which is given by Duijm (1994). The objectives of the programme are (1) the modelling of unobstructed jet fires, (2) the modelling of obstructed jet fires, (3) the modelling of the thermal response of pressure vessels, (4) the assessment of mitigation techniques and (5) the modelling of the failure modes of the pressure vessels.

For unobstructed single-phase jet flames the work involves the development of the models incorporated in the UMPFIRE and TORCIA codes, as described by Crespo *et al.* (1991) and Bennett *et al.* (1991), with extension of the treatment to two-phase jet flames. For obstructed jet flames a distinction is made between small targets engulfed by the flame and large targets. For the latter the heat flux distribution can be very non-uniform and can thus create thermal stresses. The heat fluxes shown in the figures given by Duijm vary between 40 and 300 $\mathrm{kW/m^2}$. Techniques such as CFD (Hernandez and Crespo, 1992) and wind tunnel tests (Verheij and Duijm, 1991) are used to model the heat transfer. The principal mitigation techniques investigated are insulation and water sprays.

The cooling of vessels subject to an impinging jet flame is considered in Section 16.27.

16.21 Effects of Fire: Damage

Fire causes damage to property and injury to people. The statistics of fire damage and injury have been considered in Chapter 2. The modelling of fire damage is treated in this section and that of fire injury in the following one.

Broadly, fire may be treated terms of ignition, steady- and unsteady-state combustion, an extinction, and of flame spread, both over surfaces and within buildings. An account of these aspects is given in *An Introduction of Fire Dynamics* (Drysdale, 1985).

In this section the treatment is confined to (1) the ignition of liquids, (2) the ignition of wood and (3) the spread of flame.

16.21.1 Ignition of liquids

The susceptibility of a flammable liquid to ignition is related to the flashpoint. For high flashpoint liquids, the firepoint is also relevant. The flashpoint and firepoint of a liquid, and the methods of determination, have been discussed in Section 16.2. The firepoint is the temperature at which the liquid not just ignites but also supports a flame and it is therefore a higher temperature than the flashpoint. Essentially, the flashpoint may be obtained by experiment using closed cup or open cup methods, or by calculation as the temperature at which the vapour pressure reaches the lower flammability limit. Data on the flashpoint are available for a large number of substances. The firepoint is determined experimentally. Information on the firepoint of liquids is relatively sparse.

It was found in the work of A.F. Roberts and Quince (1973) that for a flame to be sustained on the surface of the liquid, it is necessary for the vapour concentration to be above the stoichiometric value. An apparent exception is alcohols for which the flashpoint and firepoint measured using spark ignition are the same. The maintenance of the flame on a liquid surface has been interpreted by Rasbash (1975b) in terms of the flame heat balance.

Traditionally, a liquid has been classed as highly flammable if it has a low flashpoint. Essentially the criterion value used in a particular country reflects the summer temperatures in that country. In the United Kingdom, the value taken has been a temperature of less than 32°C as measured by the Abel closed cup test. For a low flashpoint liquid the hazard is that a flammable mixture will form above the liquid surface and will be ignited.

If the temperature of the liquid is high enough a vapour cloud may form. The evaporation and dispersion of such a cloud has been dealt with in Chapter 15. Vapour cloud fires have been considered in Section 16.14.

For a high flashpoint liquid to be ignited it must be heated above its firepoint. This may occur due to the play of a flame on the surface of the liquid. It has been shown by Sirignano and Glassman (1970) that if such flame impingement occurs, a surface tension effect occurs and convection currents are set up which have the effect of cooling the volume of liquid which is being heated. The liquid pool will eventually ignite but, as shown by Burgoyne and Roberts (1968a), only after the transfer of a substantial amount of heat.

Ignition of a high flashpoint liquid occurs much more readily, however, if there exists at the surface of the liquid a wick. This may take the form of a porous material such as a cloth. The liquid layer held in such a wick is too thin for the heat to dissipate and there is a rapid increase in the local temperature. The effect has been studied by Burgoyne, Roberts and Quinton (1968).

16.21.2 Ignition of solids

In the ignition of combustible solids it is usual to distinguish between (1) spontaneous, or unpiloted, ignition and (2) piloted ignition. With spontaneous ignition, also termed unpiloted ignition or autoignition, ignition occurs when the material has been heated up to the point where not only does it evolve vapours of volatile material but it is not enough to ignite these vapours. With piloted ignition, by contrast, ignition of these vapours is by the pilot flame.

A further distinction may be made between the case where the pilot flame actually impinges on the surface of the solid and that where it does not. Simms (1962) refers to these situations as (1) piloted ignition (in the more restricted sense) and (2) surface ignition. This terminology is adopted here.

In this section consideration is restricted to the ignition of wood. This is the solid combustible material principally studied and it is also that of prime interest on process plants.

16.21.3 Ignition of wood

A classic study of the ignition of wood by thermal radiation is that described by Lawson and Simms (1952a,b), who subjected samples of dry wood to thermal radiation from a heated panel, with and without a pilot flame playing half an inch from the surface of the sample.

They first obtained for various kinds of wood critical values I_o of the thermal radiation intensity I below which ignition does not occur even at long exposure times. The woods used included oak, mahogany, red cedar and whitewood. For the minimum thermal radiation intensity for spontaneous ignition I_s they obtained the range of values $0.57-0.66\ \mathrm{cal/cm^2\,s}$ with an average of about $0.62\ \mathrm{cal/cm^2\,s}$, and for the minimum thermal radiation intensity for piloted ignition I_p they obtained the range $0.30-0.36\ \mathrm{cal/cm^2\,s}$ with an average of about $0.35\ \mathrm{cal/cm^2\,s}$. They also studied fibre insulation board, for which the critical values were 0.57 and $0.15\ \mathrm{cal/cm^2\,s}$ for spontaneous and for piloted ignition, respectively.

For thermal radiation intensities above these threshold values they obtained the following relations. For piloted ignition*

$$(I - I_p)t_i^{2/3} = A \qquad [16.21.1]$$

with

$$A = 0.025 \times 10^6(k\rho s + 68 \times 10^{-6}) \qquad [16.21.2]$$

where A is a parameter (cal^2/cm^4(°C)^2 s), I is the thermal radiation intensity (cal/cm^2 s), I_p is the minimum thermal radiation intensity for piloted ignition (cal/cm^2 s), k is the thermal conductivity of the wood (cal/cm^2 s (°C/cm)), s is the specific heat of the wood (cal/g°C), t_i is the ignition time (s) and ρ is the density of the wood (g/cm^3).

For spontaneous ignition they obtained*

$$(I - I_s)t_i^{4/5} = B \qquad [16.21.3]$$

with

$$B = 0.05 \times 10^6(k\rho s + 35 \times 10^{-6}) \qquad [16.21.4]$$

where B is a parameter (cal^2/cm^4(°C)^2/s) and I_s is the minimum thermal radiation intensity for spontaneous ignition (cal/cm^2 s).

On the assumption that surface cooling occurs, there should be an effect of the thermal inertia $k\rho s$ (cal^2/cm^4 (°C)^2 s). This is the case, in that the parameters A and B are found to be linear functions of this quantity. Values of ρ, s and k for a number of materials are given in texts on heat transfer such as that by Carslaw and Jaeger (1959).

Thus for oak the relations between thermal radiation intensity and exposure times for ignition were approximately as follows:

Ignition time, t_i (s)	*Thermal radiation intensity* (cal/cm^2 s)	
	Piloted ignition, I_p	*Spontaneous ignition,* I_s
5	1.45	
10	1.10	1.40
25	0.77	1.05
50	0.65	0.86
100	0.52	

From this work a minimum thermal radiation intensity for ignition of wood of 0.3 cal/cm^2 s (12 kW/m^2) has been used for building design. This figure was given, for example, in the Scottish Building Regulations 1971.

Further work by Simms and co-workers (Simms, 1960, 1961, 1962, 1963; Simms and Law, 1967) has shown that it is possible to determine for a given wood a minimum surface temperature for ignition.

Simms and co-workers have also developed a number of models for ignition of a thin slab and of a semi-infinite solid by radiant heat. One standard heat transfer relation applicable to a semi-infinite solid is quoted by Drysdale (1985) as follows:

$$\frac{\theta_s}{\theta_\infty} = 1 - \exp(\beta^2)\ \mathrm{erfc}\ (\beta) \qquad [16.21.5]$$

with

$$\theta_s = T_s - T_o \qquad [16.21.6]$$

$$\theta_\infty = T_\infty - T_o \qquad [16.21.7]$$

$$\beta = \frac{ht^{1/2}}{(k\rho c)^{1/2}} \qquad [16.21.8]$$

where h is a heat transfer coefficient for convection (cal/cm^2 s°C), t is the time (s), T is the surface temperature for ignition (K), T_o is the initial surface temperature (K), T_∞ is the surface temperature for ignition at infinite time (K), β is a parameter, θ_s is the surface temperature difference for ignition (°C) and θ_∞ is the surface temperature difference for ignition at infinite time (°C).

The parameter β is known as the cooling modulus. It may be written in the alternative form

$$\beta = \frac{h(\alpha_h t)^{1/2}}{k} \qquad [16.21.9]$$

where α_h is the thermal diffusivity (cm^2/s).

It may also be expressed in terms of the dimensionless groups

$$\beta = \mathrm{BiFo}^{1/2} \qquad [16.21.10]$$

with

$$\mathrm{Bi} = \left(\frac{hL}{k}\right) \qquad [16.21.11]$$

$$\mathrm{Fo} = \left(\frac{\alpha_h t}{L^2}\right) \qquad [16.21.12]$$

where L is a linear dimension, Bi is the Biot number and Fo is the Fourier number.

It has been shown by Simms (1963) that Equation 16.21.5 may be reformulated as follows. The surface temperature difference θ_∞ is related to the thermal radiation intensity I:

$$h\theta_\infty = \alpha I \qquad [16.21.13]$$

where α is the absorptivity.

Then from Equations 16.21.5 and 16.21.13

$$\theta_s = \frac{\alpha I}{h}[1 - \exp(\beta^2)\ \mathrm{erfc}\ (\beta)] \qquad [16.21.14]$$

which Simms recasts as

$$\gamma = \beta[1 - \exp(\beta^2)\ \mathrm{erfc}\ (\beta)]^{-1} \qquad [16.21.15]$$

with

$$\gamma = \frac{\alpha It}{\rho c(\alpha_h t)^{1/2}\theta_s} \qquad [16.21.16]$$

where γ is a parameter known as the energy modulus.

---

* In the first edition of the book SI versions of Equations [16.21.1] and [16.21.3] given by Eisenberg, Lynch and Breeding (1975) were quoted which are incorrect, evidently due to an error in the conversion. The latter work gives incorrect dimensions for the thermal conductivity k, as do the original authors, which may be the explanation.

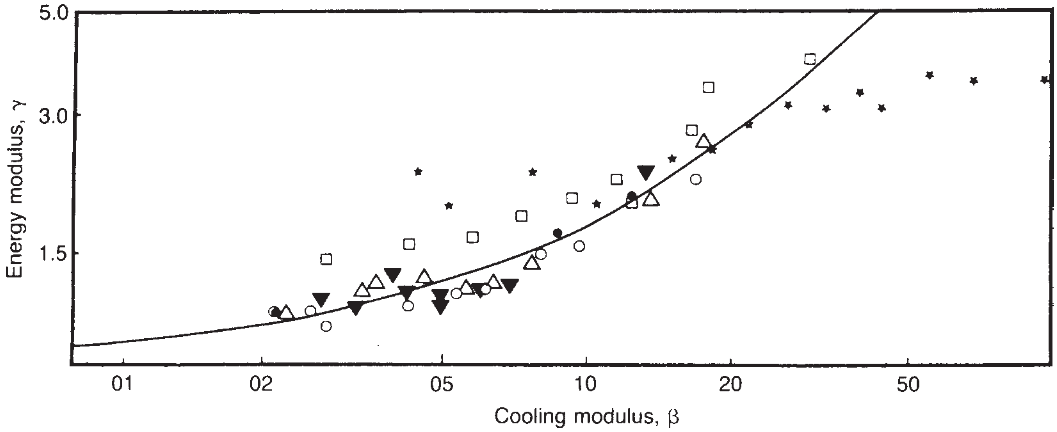

Figure 16.117 *Ignition of wood by thermal radiation: energy vs cooling modulus correlation (Simms, 1963):* $\theta_s = 30°C$*; h = 33 W/m² K; (∗) fibre insulation board; (□)cedar; (△) freijo; (○) mahogany; (●) oak (▼) iriko. The cure is that given by Equation 16.21.15. (Courtesy of Combustion and Flame)*

Simms obtained for various woods the relation between the energy modulus γ and the cooling modulus β shown in Figure 16.117.

Another form of the model given by Simms and Law (1967) is

$$\frac{It}{\rho c(kt)^{1/2}\theta_s} = \frac{\beta}{1 - \exp(\beta^2)\ \mathrm{erfc}\ (\beta)} \qquad [16.21.17]$$

These authors term the heat transfer coefficient, given above by the symbol h, the Newtonian cooling coefficient, but the two are identical. They also give values for the coefficient for various temperature differences.

The work of Simms and others has shown that for a given wood it is also possible to correlate results in terms of the minimum ignition temperatures for spontaneous ignition, pilot ignition, and surface ignition. These temperatures are discussed by Simms (1962) and Simms and Law (1967). For piloted ignition without flame contact the results obtained tend to depend on the precise positioning of the flame, though they are reproducible for a given configuration.

Further, for spontaneous ignition, woods exhibit a common minimum ignition temperature of about 545°C. This does not apply, however, at very low rates of heating such that the volatile matter becomes exhausted without ever igniting. Likewise, there is a common minimum ignition temperature for piloted ignition of about 380°C. Taking an initial temperature of 20°C, these two minimum ignition temperatures correspond respectively to minimum ignition temperature differences θ_s of about 525°C and 360°C.

The relation between the minimum thermal radiation intensity I_o and the minimum temperature difference θ_s for ignition is

$$I_o = h\theta_s \qquad [16.21.18]$$

Thus, for example, for piloted ignition Simms and Law give a value of h of 8.6×10^{-4} cal/cm² s °C. Then for $\theta_s = 360°C$, $I_o = 0.31$ cal/cm² s.

The results described were obtained in carefully controlled experiments using dry wood samples with specified characteristics. It is known that there are effects of thermal inertia, water content, wood grain, etc., and surface absorptivity.

A material with low thermal inertia ignites more readily than one with high inertia. This effect is taken into account in the correlations given above.

The effect of water content has been studied by Simms and Law (1967). Water content influences ignition in several ways. It affects the thermal inertia of the wood through its effects on the individual properties, namely density, specific heat and thermal conductivity. In addition, it affects the overall heat transfer in two ways: heat transfer by molecular diffusion of water; and vaporization of water, which cools the hot zone, and condensation, which heats the cooler zones.

The water content of the wood increases the minimum ignition energy, the minimum thermal radiation intensity and the ignition time for both spontaneous ignition and piloted ignition without contact. But for the latter it becomes significant only at water contents of 40% or more. A water content of 60% doubles the minimum thermal intensity for piloted ignition.

The properties of the wood itself affect thermal radiation ignition. These include the cut end, the direction of the grain and any knots. One effect of grain is on thermal conductivity. Another is on the flow of volatile matter.

The absorptivity of the wood increases as charring occurs.

With regard to the thermal radiation incident on the wood, it has been shown by Kashiwagi (1979a) that there can be a significant attenuation due to the volatile matter issuing from it.

Further work on ignition of wood has been described by Wesson, Welker and Sliepcevich (1971). They use a correlation of the form

$$t_i = k_1 \rho^{n_1} (\alpha I)^{n_2} \mathrm{erf}[L/2(\alpha_h t)^{1/2}]^{n_3} \qquad [16.21.19]$$

where L is the thickness of the slab (cm), k_1 is a constant and n_1–n_3 are indices. For wood $\alpha_h \approx 1.5 \times 10^{-3}$ cm²/s and for the wood samples used $L \approx 2$ cm. Using these values in Equation 16.21.19 the term $\mathrm{erf}[L/2(\alpha_h t_i)^{1/2}]$ is approximately unity for $t < 700$ s. From experiments on a number of woods the authors obtained values of the constant in Equation 16.21.19 to yield

$$t_i = 35\rho^{0.9}(\alpha I)^{-2.8} \qquad [16.21.20]$$

A comparison of the minimum ignition temperature for heat transfer by radiation and convection has been made by Kanury (1972a), who quotes the following approximate values:

Heat transfer mode	*Minimum ignition temperature* (°C)	
	Piloted ignition	*Spontaneous ignition*
Radiation	300–410	600
Convection	450	490

16.21.4 Flame spread

The growth of fire is frequently governed, particularly in the early stages, by flame spread over the surface of solids or liquids. Flame spread itself is considered at this point. The spread of fire through buildings is discussed in Section 16.36.

Accounts of flame spread include those given by P.H. Thomas, Simms and Wraight (1964, 1965), Burgoyne, Roberts and Quinton (1968), de Ris (1969), MacKinven, Hensel and Glassman (1970), Sirignano and Glassman (1970), Magee and McAlevy (1971), W.J. Parker (1972), Fernandez-Pello and Williams (1974), R. Friedman (1977). F.A. Williams (1977), Quintiere (1981), Suzuki and Hirano (1982), Ray and Glassman (1983), Drysdale (1985) and Ishida (1986, 1988).

The two situations considered here are flame spread across (1) a liquid surface and (2) a solid surface. In both cases the spreading flame has two effects: it serves as a source of heat and it causes pilot ignition.

In work on flame spread across a combustible liquid surface a distinction is made between a liquid which is below the fire point and one which is above it. If the liquid is below the fire point, it has first to be heated up. As described above, work by Sirignano and Glassman (1970) has demonstrated the role of surface tension effects in the circulation flows set up in the bulk liquid. Further work includes that by MacKinven, Hensel and Glassman (1970) on the effect of pool depth and width.

If the liquid is above its fire point, the flame spread is governed by flame propagation through the flammable mixture above the liquid surface. It has been found by Burgoyne and Roberts (1968a) that for a stoichiometric mixture the apparent rate of spread reaches a limiting value of some 4–5 times the fundamental burning velocity.

Work on flame spread over ground soaked with fuel has been described by Ishida (1986, 1988).

Flame spread over solid surfaces is a function of (1) the orientation and geometry of the surface, (2) the direction of propagation, (3) the thickness of the combustible material, (4) the properties of the material and (5) the environment factors.

The behaviour of a flame on a vertical surface differs from that of one on a horizontal surface. The direction of propagation also makes a radical difference. Flame spread is most rapid when propagation is upwards on a vertical surface. These differences are largely accounted for by differences in the extent to which the flame preheats the solid.

The rate of upward flame spread on a vertical surface tends to increase exponentially. It can be characterized by the time taken for the rate of spread to double, or the doubling time, as described by Alpert and Ward (1984).

For thin layers of combustible solid, the rate of flame spread has been shown by experiment and theory to be inversely proportional to the thickness of the bed. Relevant work has been described by Magee and McAlevy (1971) and Fernandez-Pello and Williams (1974).

The rate of flame spread is also a function of the thermal properties of the material. The precise relations depend on the thickness of the surface. A critical thickness exists which is

$$\tau_{cr} = (\alpha_h L/V)^{1/2} \qquad [16.21.21]$$

where L is the 'heating length', V is the rate of flame spread, α_h is the thermal diffusivity of the material and τ_{cr} is the critical thickness. The heating length is the length of solid over which the material is heated to its fire point. It can be shown that for thin surfaces $(\tau < \tau_{cr}) V \propto (\rho c \tau)^{-1}$ and for thick surfaces $(\tau > \tau_{cr}) V \propto (k\rho c)^{-1}$, where c is the specific heat, k is the thermal conductivity, ρ is the density of the material and τ is the thickness. Further, since the thermal conductivity k is approximately proportional to the density, in this latter case $V \propto \rho^{-2}$. Thus the rate of flame spread over the surface of a low density material can be very rapid.

The geometry of the surface also affects flame spread. There have been a number of studies of features such as width and edge effects.

Flame spread is also influenced by environmental factors, including the initial temperature of the fuel, the air velocity over the surface, the imposed thermal radiation and an oxygen enriched atmosphere.

Thermal radiation can cause a marked enhancement of the rate of flame spread, as evidenced by the work of Alvares (1975), Kashiwagi (1976), Fernandez-Pello (1977 a,b), Hirano and Tazawa (1978) and Quintiere (1981) and others.

The effect of air velocity on flame spread depends on the direction of air flow. If the air flow is in the same direction as the flame spread, an increase in air velocity tends to increase the rate of spread, whilst if it is in the opposing direction the effect depends on the magnitude of the air velocity. A low air velocity tends to enhance the rate of flame spread but a high one tends to reduce it. Whichever of the two directions the air flow has, there will come a point at which a very high velocity results in flame extinction, or blow-off.

The spread of flame across surfaces has been modelled by a number of workers. F.A. Williams (1977) gives the so-called 'fundamental equation of fire spread'

$$\rho V \Delta H = \dot{q} \qquad [16.21.22]$$

where ΔH is the enthalpy change per unit mass in raising the material to its fire point, $\dot{q}$ is the rate of heat transfer across the surface, V is the rate of flame spread and ρ is the density of the fuel.

The rather different problem of flame spread through open fuel beds has been studied by P.H. Thomas, Simms and Wraight (1964, 1965), who conducted a classic set of experiments on wooden cribs. Their results have been applied by other workers to a variety of fire situations.

In practical cases some factors which are of particular importance in determining flame spread over a solid surface are the thickness and composition of the surface, the imposed thermal radiation and the air movement over the surface.

16.21.5 Thermal radiation limits

Thermal radiation limits are quoted in a number of codes and standards and in numerous papers. Many limits are given for the purposes of plant design and layout. Some are relevant to hazard assessment. Generally, such sets of limits include both limits related to damage and others related to injury. It is convenient, therefore, to defer consideration of such limits to the next section.

16.22 Effects of Fire: Injury

There is a requirement in hazard assessment for relationships which permit heat radiation intensity to be translated into the equivalent burn injury. Correlations for both fatal and non-fatal burn injury have been derived in the Vulnerability model by Eisenberg, Lynch and Breeding (1975). A detailed review and additional information have been given by Hymes (1983 SRD R275). Further correlations are given in the *Green Book* (CPD, 1992b).

16.22.1 Sources of thermal radiation

The effect of thermal radiation on man depends very much on the source of radiation and it is therefore necessary to specify this. One source of thermal radiation which is of long-standing interest is a flare and some of the earliest thermal radiation limits relate to flares.

Another source of thermal radiation which has received increasing attention is a fireball, typically as part of a BLEVE. A fireball is well defined relative to most other types of fire to which people may be exposed and it is one of the fire hazards most likely to give rise to a large number of serious injuries.

16.22.2 Experimental studies

Experimental work on injury from thermal radiation has been done on humans and on animals. The use of human subjects is limited to the lower levels of pain and injury.

Henriques (1947) carried out experiments in reddening and blistering in man exposed to thermal radiation. Buettner (1951b) performed experimental work on man in which skin temperature and pain threshold were measured. Experiments on man were also conducted by Stoll and Greene (1959) to investigate skin temperature and thresholds of pain and blistering.

Experimental work on rats exposed to thermal radiation by NML, Brooklyn, and on rats exposed to direct flame contact by NADC, Johnsville, quoted by Stoll and Chianta (1971), provides a basis for comparing burn injury by these two modes.

Hinshaw (1957) at the University of Rochester investigated the thermal radiation intensities required to produce second and third degree burns in pigs. Experiments on swine burn have also been performed by Hardee and Lee (1977/78).

Tests on the response of fabrics to thermal radiation have been done by Wulff and co-workers (Wulff, 1973; Wulff *et al.*, 1973; Wulff and Durbetaki, 1974), and work on heat transfer from burning clothing to the wearer has been done by Williams *et al.* (n.d.) at MIT and by Arnold *et al.* (1973) at the Gillette Research Institute.

16.22.3 Skin properties

Human skin consists of two layers, the epidermis and the dermis. It ranges in thickness from some 5 mm on the back to some 0.5 mm on the eyelids. The area of skin on the average man is some 1.8 m^2. The distribution of skin surface area is considered in Section 16.22.10.

16.22.4 Pathology of burns

Accounts of burns and burn treatment are given in *Burns and Their Treatment* (I.K. Muir and Barclay, 1974), *Burns: a Team Approach* (Artz, Moncrief and Pruit, 1979), *Clinical Burn Therapy* (Hummel, 1982), *Physiological Responses to Burn Injury* (J.W.L. Davies), *Burn Mortality* (W. Clark and Fromm, 1987), *Plastic Surgery* (Goldin, 1987) and *Plastic Surgery* (McCarthy, 1990). Treatments of burn injuries of particular relevance here are those by Glasstone (1962) and Hymes (1983 SRD R275).

The effects of incident heat radiation are, in order of increasing severity:

Burn type	*Criterion*
First degree	Persistent redness
Second degree:	
Moderate	Some blistering
Deep	Full blistering
Third degree	Charring

A first degree burn involves the epidermis. There is reddening but no blistering. A second degree burn may be superficial or deep. The former affects the epidermis and part of the dermis and involves some blistering, but with damage to the surface layers only. The latter penetrates further into the dermis and damages it more severely. A third degree burn destroys both the epidermis and the dermis.

The terms second and third degree burn have largely given way to characterization in terms of the depth of burn, reference being made to full depth and other burns.

16.22.5 Skin temperature

Burn injury correlates closely with skin temperature. Pain is experienced at a temperature of 44°C and above this temperature injury occurs.

Relations for the unsteady-state temperature profile of the skin suddenly exposed to a source of heat radiation have been given by Buettner (1951a) and by Stoll and Chianta (1971). The simplest of these is the equation given by Buettner for a non-penetrating constant source of thermal radiation.

$$T_s - T_o = \frac{2Qt^{1/2}}{(\pi k \rho c)^{1/2}} \qquad [16.22.1]$$

where for the skin c is the specific heat, k is the thermal conductivity, Q is the net heat absorbed, t is the time, T_o is the initial temperature throughout, T_s is the surface temperature and ρ is the density.

The thermal response is governed by the thermal inertia ($k\rho c$). Measurements of the thermal inertia were made by Stoll and Greene (1959), who found that it varied strongly with the thermal radiation intensity.

Stoll and co-workers (Stoll and Greene, 1959; Stoll and Chianta, 1971) have studied the temperature at the basal layer of skin, which is about 80 μm (0.08 mm) below the surface. They found that damage occurs at temperatures above 44°C.

The temperature profile of skin at 80 μm subjected to thermal radiation sufficient to cause blistering given by these workers is shown in Figure 16.118(a). They give a model for the degree of tissue damage W due to heat radiation. Part of the damage occurs during the cooling period after the heat source is removed.

The rate of injury above 44°C increases very rapidly indeed with temperature. The relation given by Stoll and Chianta is shown in Figure 16.118(b). There is an approximate trebling of the rate of injury for each 1°C temperature rise. Thus the injury rate at 50°C is some 100 times that at 44−55°C.

Stoll and Chianta describe work on burn in rats. The responses of rats to thermal radiation and to flame contact have been studied by NML, Brooklyn, and by NADC, Johnsville, respectively. Figure 16.118(c) gives a comparison of the two sets of results which shows that the responses are virtually identical. These results indicate that the dose−response relation is similar for thermal radiation and for flame contact. The results are usually regarded as applicable to man also.

16.22.6 Injury factor

Inquiry due to exposure to a short but strong pulse of thermal radiation may be correlated in several ways. The most convenient is to take the injury factor as the thermal dose which is the product of the thermal radiation intensity and time. The level of thermal radiation for a particular effect is often correlated in terms of the thermal dose.

It is found, however, that this somewhat understates the effect of very high intensities of thermal radiation and that better correlation is obtained if these are more highly weighted. The empirical correlation for the injury factor which best fits the data is

$$tI^n = \text{Constant} \qquad [16.22.2]$$

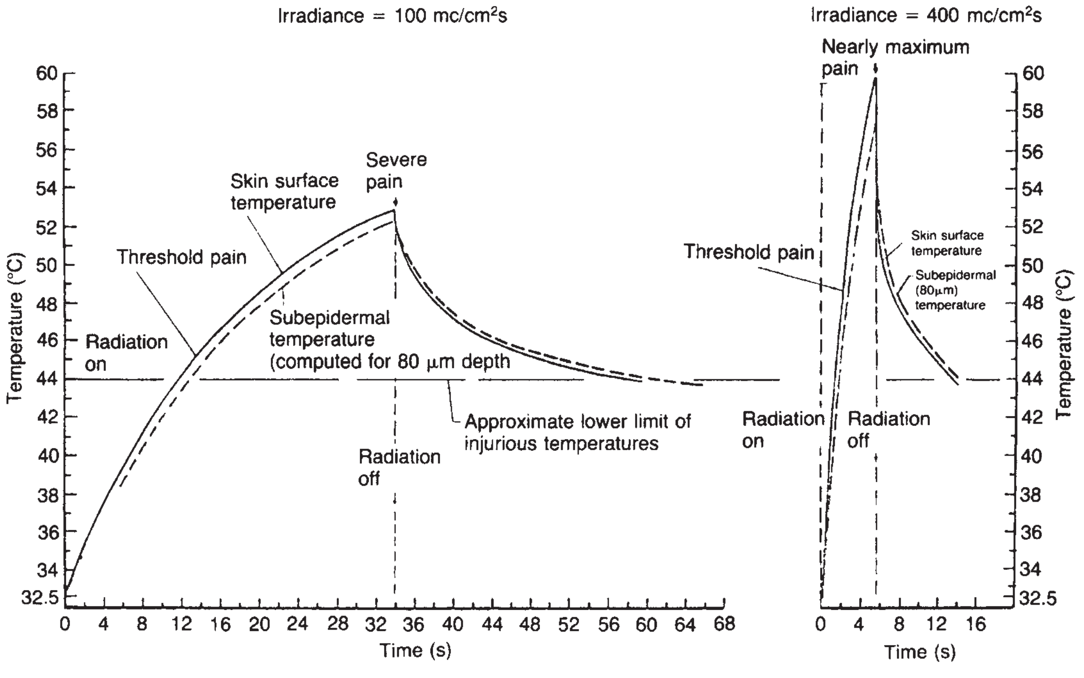
where I is the intensity of thermal radiation (W/m^2), t is the time (s) and n is an index.

As described below, Equation 16.22.2 has been given by Eisenberg, Lynch and Breeding (1975) for the correlation of data on burn fatalities with a value of the index $n = 4/3 = 1.33$. For non-fatal burn injuries these authors use the slightly different exponent $n = 1.15$. It has been proposed by Hymes that the data for fatal and non-fatal injury are adequately correlated using a value of $n = 1.33$ for both.

The term $tI^{4/3}$ is referred to here as the thermal load L to distinguish it from the thermal dose $D = tI$. It is conventional to express the thermal radiation intensity in kW/m^2 but to use in probit equations an intensity expressed in W/m^2. Since this latter practice gives rise to thermal loads which are large numbers, it is convenient to define also an alternative thermal load L'. These quantities are thus defined as follows:

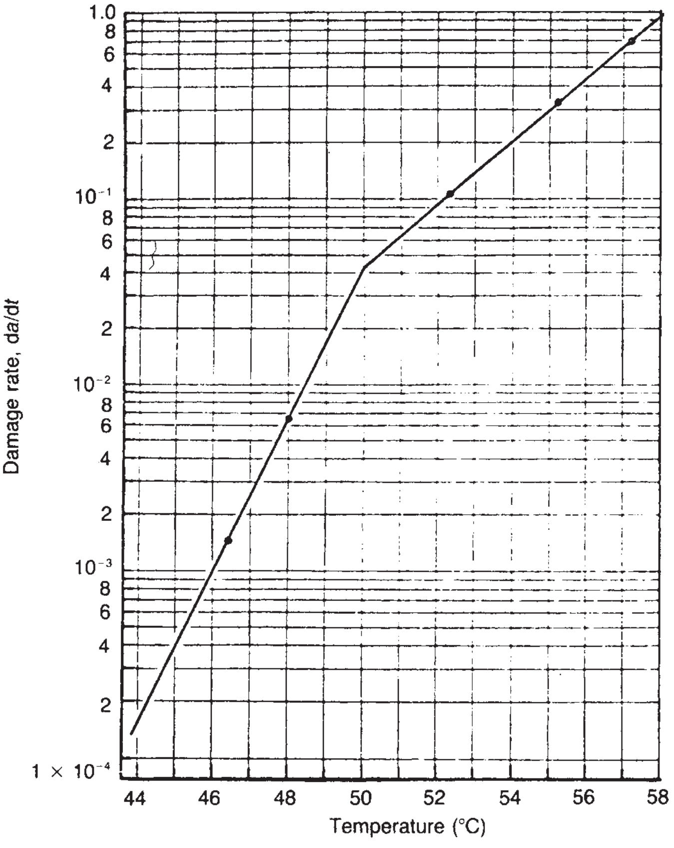
$$D = tI \qquad [16.22.3]$$

$$L = tI^{4/3} \qquad [16.22.4]$$

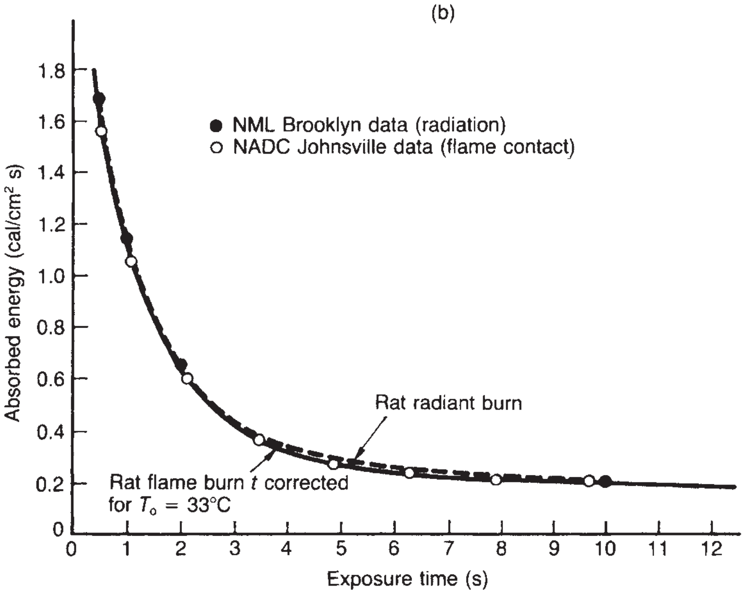


(a)

Figure 16.118 Effect of heat on skin (Stoll and Chianta, 1971): (a) heating and cooling of skin exposed to heat radiation



(b)



(c)

Figure 16.118 continued *(b) rate of damage to skin exposed to heat radiation; and (c) burn injury to rats exposed to heat radiation and to flame contact (Courtesy of the New York Academy of Sciences)* where D is the thermal dose (kJ/m^2), I is the thermal radiation intensity (kW/m^2), L is the thermal load (s (kW/m^2)$^{4/3}$) and t is the exposure time (s). Further

$$L' = tI^{4/3}/10^4 \qquad [16.22.5]$$

where I is the thermal radiation intensity (W/m^2) and L' is the thermal load ((s (W/m^2)$^{4/3}$)/10^4).

16.22.7 Pain and blister thresholds

A number of workers have correlated thresholds of pain and blistering. Table 16.75 shows some limits for pain and injury given in the literature, in terms of thermal radiation intensity in Section A and of thermal dose in Section B.

Table 16.76, Section A, shows the results obtained for the time to the threshold of pain in man by Buettner (1961b), and by Stoll and Green (1959). Figure 16.119(a) (Mudan, 1984c) is a plot of data reported by these and other workers.

The threshold of pain may also be expressed in terms of the thermal load. Values given by Hymes based on the work of Stoll and Greene are shown in Table 16.76, Section C. Hymes gives as the approximate threshold of pain a value of 92 s (W/m^2)$^{4/3}$/10^4.

Results for the time to the threshold of blistering in man by Stoll and Greene are shown in Table 16.76, Section B, whilst a plot by Mudan of these and other data is given in Figure 16.119(b).

16.22.8 Second and third degree burns

Several workers have investigated the degree of exposure of pigs to levels of thermal radiation which cause second and third degree burns. In work by Hinshaw (1957) at the University of Rochester, pigs were subjected to thermal radiation exposures of 210, 420 and 670 kJ/m^2 for periods of 0.5, 1, 3, 5, 10 and 30s.

At high thermal radiation intensities the heat is sufficient to vaporize the tissue fluids, an effect known as ablation. The burn injury occurring in these circumstances is termed a 'steam bleb'. Histological examination in these experiments showed that the thermal radiation was sufficiently intense in some tests to cause steam 'bleb' formation and mitigation of the tissue damage.

The data have been analysed by Hymes who has derived the results given in Table 16.77 correlated in terms of the heat injury factor. From these data Hymes estimates the threshold for steam bleb formation as a thermal load of some 4000–4500 s (W/m^2)$^{4/3}$/10^4. This is a very high level of thermal radiation which, according to the relations for fatality given below, would be lethal in some 90% of cases. It is therefore thermal radiation intensity below the level of steam bleb formation which is of prime interest.

The depth of skin burn in Hinshaw's experiments at thermal radiation intensities below those which cause steam bleb has been correlated by Hymes, as shown in Figure 16.120(a). He takes the burn depths for the threshold of second degree burns and the onset of third degree burns

Table 16.75 *Some limits for pain and injury from thermal radiation*

A Thermal radiation intensity

Thermal radiation intensity (kW/m^2)		*Reference*
1.5	Threshold of pain	Atallah and Allan (1971)
2.1	Level at which pain is felt after 1 min	
1	Level just tolerable to a clothed man	HSE (1978b)
8	Level which causes death within minutes	
4.7	Threshold of pain. Average time to experience pain, 14.5 s	Crocker and Napier (1986)

B Thermal dose

Thermal dose (kJ/m^2)		*Reference*[a]
40	Second degree burns	Williamson and Mann (1981)[a]
125	Third degree burns	
65	Threshold of pain	Rijnmond Public Authority (1982)

	88	10.0
	90	8.0
	91	5.5
	103	3.0

[a] Time to threshold of pain.

[b] Time to unbearable pain.

as 0.1 and 2 mm, respectively. The corresponding thermal loads are approximately 1200 and 2600 s (W/m^2)$^{4/3}$/10^4, respectively.

Swine burn experiments have also been done by Hardee and Lee (1977/78), who have derived from their results considerably lower values for the levels of heat radiation intensity for given degrees of injury. According to Hymes, the reinterpretation of this work does not support these lower values.

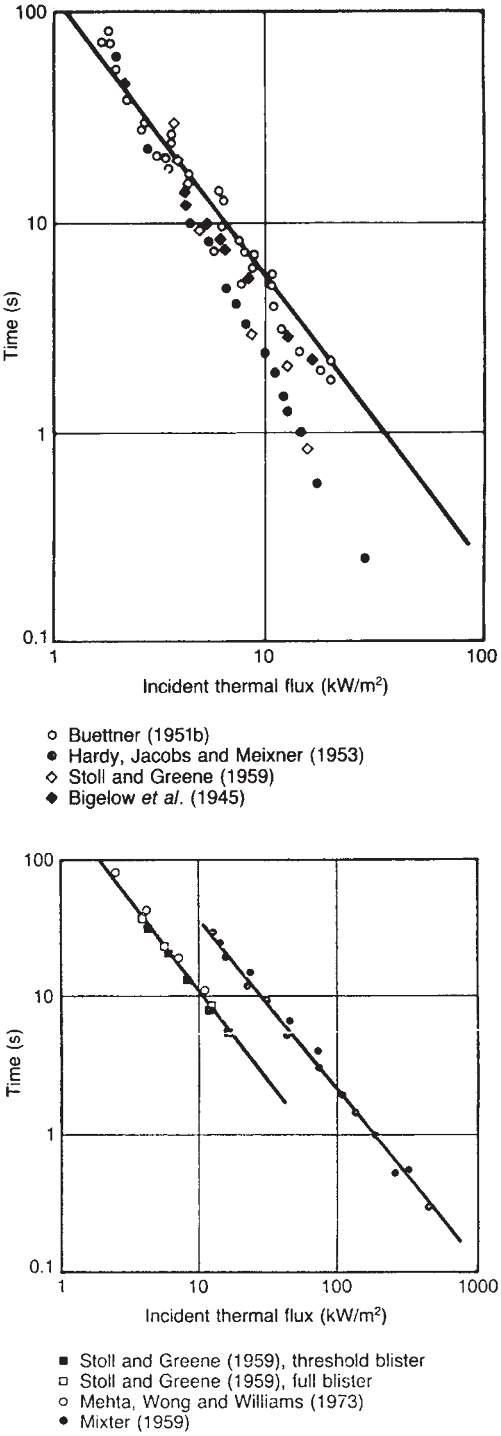

Figure 16.119 *Time to threshold effects of heat radiation (Mudan, 1984c): (a) threshold of pain; and (b) threshold of blistering (Courtesy of Progress in Energy and Combustion Science)*

Table 16.77 *Second and third degree burn injury to pigs exposed to thermal radiation (after Hymes, 1983 SRD R275) (Courtesy of the UKAEA Safety and Reliability Directorate)*

Thermal dose (kJ/m^2)	*Time* (s)	*Thermal load* (s (W/m^2)$^{4/3}$/10^4)	*Thermal damage* (mm)	*Steam bleb*

	5	3430	1.6	No
	10	2720	1.6	No
	30	1890	1.1	No

As described above, work has been done at MIT and at the Gillette Research Institute on the heat transferred from burning clothing to the wearer.

Figure 16.120(b) shows the relation between depth of skin burn and thermal load from these sources as given by Hymes.

Another source of information on second and third degree burns is data on burn victims from the nuclear weapons dropped on Japan, which are given by Glasstone (1962).

16.22.9 Human response to fire events

Human response to a fire event depends on (1) the nature of the event and (2) the awareness of the person.

The event primarily considered in relation to burn injury is a fireball. Another sudden event may be a rapid growth in the size of a flare. Other types of event such as a pool fire are generally considered to occur more gradually and to allow more time for escape, though this may not always be so. It is the fireball hazard which is primarily considered by Hymes and Marshall, and also here.

Accounts of burn injury such as those by Hymes and in the *Green Book* quote a human response time of 5 s. The application of this reaction time to a fireball scenario is that the person faces the fireball for 5 s and then turns his back and seeks to escape.

In an analysis of human exposure to a BLEVE, in the context of a discussion of the disaster at San Carlos, Hymes considers two situations. In Situation 1 with the lift-off time less than the reaction time, the first phase involves frontal exposure for the 5 s reaction time. The person then turns his back and seeks to escape. During this escape the fireball passes through three further phases: further growth at ground level, shrinkage just prior to lift-off, and rise. In Situation 2, the lift-off time equals the reaction time, so that there is no phase of further growth at ground level; otherwise the scenario is similar, with the period of frontal exposure again being 5 s.

In practice, human behaviour tends to be more complex. Hymes gives an account of the BLEVE at the Lowell Gas Company at Tewkesbury, Massachusetts, in 1972. One comment quoted contains two relevant points. The firefighters seem to have had 'momentary warning' of the impending BLEVE. Since the front of their clothing was not burned but the back was, they appear to have turned their backs very promptly, but since their faces were burned, it is believed that they tended to look round to see what was happening.

16.22.10 Protection by clothing

The degree of protection offered by clothing depends on the fraction of the body which is so protected. Data on the fraction of the body area represented by the different parts of the body are given in the *Green Book*. An extract from this tabulation, giving the fraction of body area (%) for the parts of the body most likely to be exposed, is as follows:

Fraction of body area (%)

Part of body	*Age group* (years)					
	1	1–4	5–9	10–14	15	*Adult*
Head	19	17	13	11	9	7
Neck	2	2	2	2	2	2
Hands (each)	2.5	2.5	2.5	2.5	2.5	2.5
Lower arms (each)	3	3	3	3	3	3
Upper arms (each)	4	4	4	4	4	4
Lower legs (each)	5	5	5.5	6	6.5	7
Upper legs (each)	5.5	6.5	8	8.5	9	9.5

The *Green Book* takes for the Dutch population a maximum value of the body surface exposed of 20% in normal conditions.

From the above data the following estimates of the fractions of body area (%) exposed for an adult may be obtained:

	Fraction of body area (%)		
	Front	*Back*	*Total*
Head	4	3	7
Neck	1	1	2
Hands	2.5	2.5	5
Lower arms	3	3	6
Total	10.5	9.5	20

If the thermal radiation is so intense as to ignite the clothing, a different situation pertains. This is considered in Subsection 16.22.13. A detailed discussion of the protection afforded by clothing is given by Hymes.

16.22.11 Protection by buildings

The degree of protection afforded by a building to a person within it depends on the location of that person. In many cases this will be such that the building affords complete protection. Persons in buildings are liable to be exposed, however, to thermal radiation through glass windows. A person aware of an event outside may well move to view it through a window.

Figure 16.121 from Hymes shows the transmissivity of window glass for thermal radiation from sources up to 1200°C.

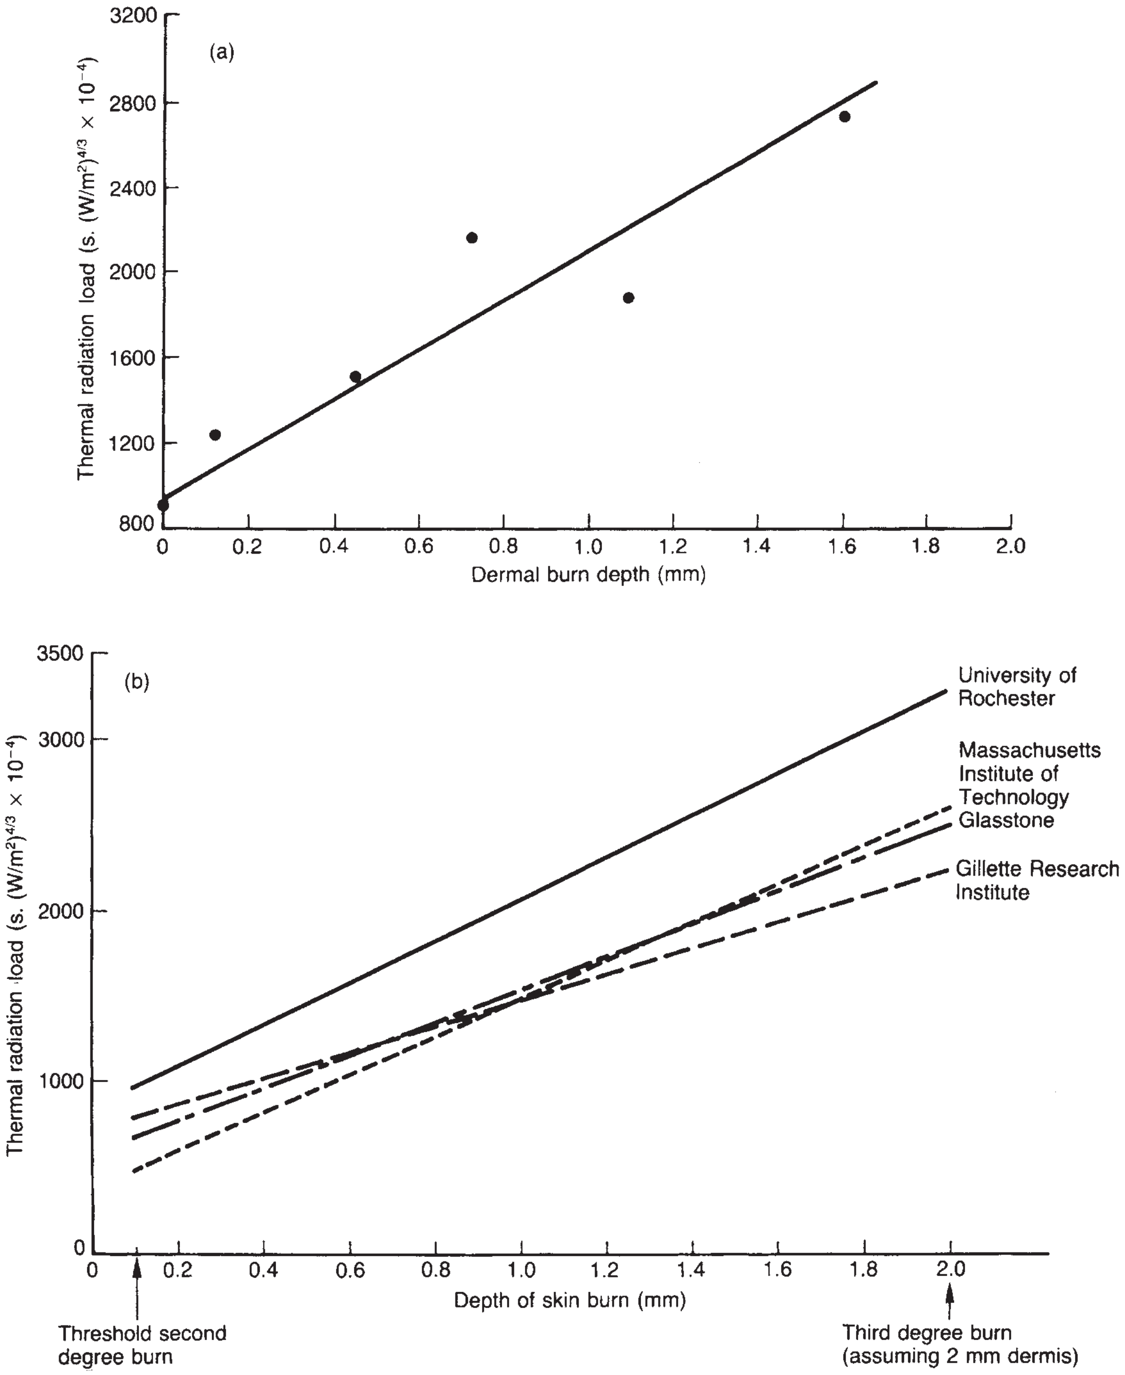

Figure 16.120 *Depth of skin burn due to heat radiation (Hymes, 1983 SRD R275): (a) sub-'steam bleb' burns in pigs obtained at University of Rochester by Hinshaw; and (b) comparison with results of other workers (Courtesy of the UKAEA Safety and Reliability Directorate)*

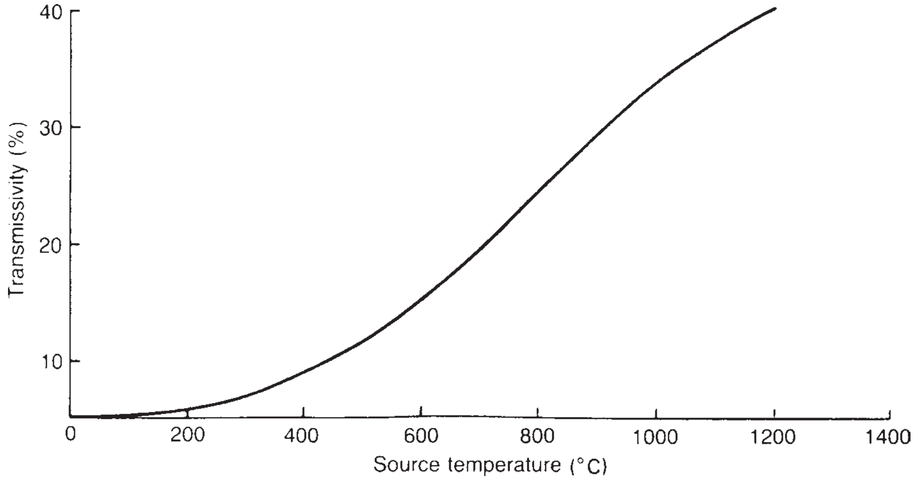

Figure 16.121 *Transmissivity of ordinary window glass for heat radiation (Hymes, 1983 SRD R275) (Courtesy of the UKAEA Safety and Reliability Directorate)*

16.22.12 Effective radiation intensity

In estimating burn injury it is important to utilize an appropriate value of the thermal radiation. The effective intensity is determined by the atmospheric transmissivity and the geometry of the body as presented to the radiation source. The attenuation due to the atmosphere has been discussed in Section 16.13 and is not considered further here.

The importance of the geometry of the body has been emphasized by V.C. Marshall (1987). There is a tendency in hazard assessments to treat the whole of the exposed area of the body as subject to the radiation nominally incident at the particular point. If the body is treated as a thin object, the ratio of the surface to the projected area is approximately 2. If it is treated as a long cylinder, the ratio is π. For a sphere the ratio is 4. The three-dimensional nature of the body is therefore significant. The thermal radiation incident on the exposed area is appreciably less than that calculated as falling on the projected area.

A related aspect is that with a three-dimensional body the angle of incidence of the radiation varies from 90° to close to zero. Typically, the view factor used takes account of the angle of incidence in two dimensions, but not three.

16.22.13 Ignition of clothing

The protection afforded by clothing is limited by the fact that at thermal radiation intensities within the range of interest here it is prone to ignite. A distinction needs to be made between everyday clothing and fire fighters' suits; the latter are naturally designed to resist ignition. It is primarily everyday clothing which is considered here.

For clothing subject to thermal radiation, there is also a distinction to be made between spontaneous and piloted ignition. A similar distinction is made for ignition of wood by thermal radiation, as described in the previous section. Whilst spontaneous ignition may be regarded as the base case, Hymes suggests that in certain scenarios, notably a BLEVE, the probability of piloted ignition, for example, by burning paper or leaves, is quite high.

As already stated, work on ignition of fabrics has been carried out by Wulff and co-workers. From this work Hymes has given relations for the determination of the times to unpiloted and to piloted ignition together with tables of parameters for common fabrics.

For spontaneous ignition times are correlated by Hymes using the relation

$$tI^n = \text{Constant} \qquad [16.22.6]$$

where I is the thermal radiation intensity (W/m^2), t is the time (s) and n is index. The values quoted for n lie in the range 1.16–3.22.

Using this equation, Hymes gives for one fabric subject to a thermal radiation intensity of 198 kW/m^2 the following estimate of the induction time for ignition.

$$t = \frac{2.87 \times 10^{18}}{(198,000)^{3.44}} = 1.7 \text{ s}$$

For piloted ignition the approach is slightly different. In this case the time is taken as that required to heat the fabric from its initial temperature to its piloted ignition temperature:

$$t_\text{p} = \frac{SC(T_\text{p} - T_\text{o})}{aW} \qquad [16.22.7]$$

where a is the absorptivity of the fabric, C its specific heat (J/g°C) and S its density (g/cm^2),t_p is the time to piloted ignition (s), T_o is the initial temperature of the fabric (°C), T_p is the piloted ignition emperature (°C)and W is the incident heat radiation (W/cm^2). It should be noted that the density is defined in terms of the mass per unit thickness. Values of the piloted ignition temperawre and other properties of the fabric are tabulated by Hymes.

He gives as an example a fabric subjected to a thermal radiation intensity of 198 KW/m^2, hence $W = 19.8$ W/cm^2, with the properties $a = 0.19$, $C = 1.35$ J/g°C; $S = 0.024$ g/cm^2, and at conditions $T_o = 14$°C and $T_p = 334$°C, yielding $t_p = 2.75$ s.

Hymes states that for thermal radiation intensities greater than 75 kW/m^2 most clothing will undergo spontaneous ignition within about 5 s. Under conditions such as a BLEVE, piloted ignition is probable and the time to ignition will tend to be even shorter.

The *Green Book* refers to the work of Hymes and proposes for the ignition of clothing the following threshold relation

$$tI^2 = D_s \qquad [16.22.8]$$

where D_s is the clothing ignition load (s(KW/m^2)^2), I is the thermal radiation intensity (kW/m^2) and t is the time (s). It states that the value of D_s lies approximately in the range 2.5×10^4 and 4.5×10^4 s (kW/m^2)^2.

Ignition of clothing has two main effects. One is that it distracts the wearer. He May well stop running and try to douse the flames, with effects not only on the speed of escape but also on the orientation of the body.

The other effect is to cause injury from burning clothing. For the heat released by the burning of clothing, Hymes quotes the following figures for typical clothing such as cotton. The heat of combustion lies in the range 5–20 kJ/g Which translates to 1–4 J/mm^2 of fabric. When the clothing burns there is transfer of some 15–50% of the heat of combustion. The thermal does received would then be of the order of 105–356 kJ/m^2. He also refers to the medical adage that 'one square centimetre of burnt skin'.

Mortality from burning clothing is discussed in the next subsection.

16.22.14 Mortality from burns

Information of the mortality in persons admitted to hospital with burn injuries has been given in a series of papers spanning some 40 years by Bull, Lawrence and co-workers, the first being that of J.P. Bull and Squire (1949) and the most recent that of J.C. Lawrence (1991), the intermediate publications being those of J.P. Bull and Fisher (1954) and J.P. Bull (1971).

Table 16.78 from J.C. Lawrence (1991) shows the mortality among persons admitted with burns or scalds as a function of fraction of the body exposed and of age group. The total number of cases in the 7-year survey period was 3044.

Analysis of the data given by Lawrence indicates the following breakdown of causes of burn injury in the admissions trated:

	Proportion (%)	
	Admissions	*Fatalities*
Building fires	3	16
Flammable liquids	10	21
Space heating	8	19
Electrical fire/flashover	~20	
Chemicals	~20	
Explosions, molten metal	~25	
Hot objects, chemicals and molten fats	14	low
Other		
Total	100	

Table 16.78 *Mortality in cases admitted to hospital with burn and scald injuries as a function of body area exposed and age group (J.C. Lawrence, 1991) (Courtesy of the Fire Safety Journal)*

Body area burned (%)	*Age* (years)

The proportion of burn victims who die without ever being admitted is not stated, but it is probably small. An appreciable fraction of such cases is likely to be victims of building fires who have died from both smoke and burns. Table 16.78 takes account of vulnerable groups, the elderly being particularly at risk from this mode of injury.

Burn injury is an area where there have been great improvements in medical treatment over the years. One aspect of this mentioned by Craven (1976) is the improvement in survival rates since 1965 due to silver nitrate prophylaxis.

Lawrence states that over the 40-year period up to 1991 deaths attributable to burns and scalds have halved. Since the situation reported by Bull in 1971, mortality has decreased by 19%. The data given in the table therefore take account of the effects of modem medical treatment.

Work is available by Arnold *et at.* (1973) on the degree of incapacitation as a function of the fraction of body area burned. Graphs from this work are given by Hymes.

With regard to fatal injury from ignited clothing, in a survey of five American hospitals by Schlapowsky (1967) of 179 people admitted to hospital suffering from burns from clothing, almost 40% had second degree burns or worse, requiring extensive surgery and skin grafts; 16% had third degree burns.

In his survey, Lawrence states that there were 248 cases of ignition of ordinary clothing, excluding those involving flammable liquids, of whom 46 died, giving a mortality of 18.5%.

16.22.15 Eisenberg, Lynch and Breeding models

An early set of relations for thern1al injury were those given in the Vulnerability model by Eisenberg, Lynch and Breeding (1975). For fatal injury, these authors utilize an adaptation of data given by C.S. White (1971) for the thermal injuries caused by nuclear weapons dropped on Japan. The data of the latter author for thermal radiation are based on the weapon yield. Using a formula given by Glasstone (1962) for the relationship between weapon yield and pulse duration, Eisenberg, Lynch and Breeding convert the original data to thermal radiation intensities over a defined pulse. The figures obtained are summarized in Section A of Table 16.79.

From analysis of these data the authors obtain the data shown in the first four columns of Section B of Table 16.79. Further analysis indicated that the form of the causative factor, in this case a thermal load, should be the $I^{4/3}$, which is confirmed by the relative constancy of the three sets of figures for 1, 50 and 99% mortality in the last column of Section B. The profit equation derived by these authors is then

$$Y = -14.9 + 2.56\ln\left(tI^{4/3} \times 10^{-4}\right) \qquad [16.22.9]$$

where I is the thermal radiation intensity (W/m2), t is the time of exposure (s) and Y is the profit.

Since Equation 16.22.9 is based on burn injuries to people going about their normal affairs, it applies to persons who are clothed.

The same equation is applied by these authors to burn injury both from flash fires and pool fires. In their model system the values of thermal radiation intensity and of time are for flash fires the effective values and for pool fires the actual values.

Eisenberg, Lynch and Breeding also give the following relation for the threshold of burns, or first degree burns, obtained from the values in Table 16.79:

$$tI^{1.15} = 550 \times 10^3 \qquad [16.22.10]$$

16.22.16 Hymes models

The review of burn injury given by Hymes, which has already been extensively quoted, does not include any new model as such. For fatal injury Hymes utilizes Equation 16.22.9 of Eisenberg, Lynch and Breeding. He also gives a number of thermal injury effects which ar1fa.bk summarized in Table 16.80.

The work of Hymes covers most of the relevant aspects of burn injury, including clothing ignition, thresholds of pain and blistering, and burn fatalities.

Some of the heat radiation limits and dos−response relations given by Hymes are shown in Figure 16.122, and others are given in the tables in Subsection 16.22.20.

16.22.17 *Green Book* models

A set of relations for thermal injury are given in the *Green Book*. For fatal injury, use is made of an adaptation of Equation 16.22.9 by Eisenberg, Lynch and Breeding. The modification is based on the fact that thermal radiation from nuclear weapons is in the UV range, whereas that from hydrocarbons is in the IR range.

Two relations are given, one for persons unprotected by clothing and one for those so protected. These are:

$$Y = -36.38 + 2.65\ln\left(tI^{4/3}\right) \quad \text{Unprotected} \qquad [16.22.11]$$

$$Y = -37.23 + 2.56\ln\left(tI^{4/3}\right) \quad \text{Protected} \qquad [16.22.12]$$

where I is the thermal radiation intensity (W/m^2) and t is the time of exposure (s).

The *Green Book* also gives relations for non-fatal injury. For first degree burns

$$Y = -39.83 + 3.02\ln\left(tI^{4/3}\right) \qquad [16.22.13]$$

and for second degree burns

$$Y = -43.14 + 3.02\ln(tI^{4/3}) \qquad [16.22.14]$$

16.22.18 Lees model

Another model for injury by thermal radiation has been developed by Lees (1994a). The model is essentially a set of relationships which may be combined in various ways depending on the scenario modelled and which have been utilized by the author to produce a relation for fatal injury from a sudden heat release such as a fireball, subject to defined assumptions.

The causative factor is taken as the thermal load $L' = tI^{4/3}$ ([s(W/m^2)$^{4/3}$]/10^4).

For the severity of the burn injury use is made of the relation given in Figure 16.120(a) of Hymes between thermal load and burn depth δ, which is equivalent to

$$\delta = 8.85 \times 10^{-4}(L' - 920) \qquad [16.22.15]$$

For the relationship between burn injury and mortality the data of J.C. Lawrence (1991) given in Table 16.78 are utilized.

The fraction of the body exposed depends on the scenario considered. The base case is taken as an adult wearing light clothing such that the head, neck, hands and lower arms are exposed. From the data given in Subsection 16.22.10, it can

Table 16.79 *Estimated relations between thermal radiation intensity and burn injury (after Eisenberg, Lynch and Breeding, 1975)*

A Nuclear weapons: effects and thermal injury

Thermal radiation intensity (cal/cm^2 s)			
Weapon yield	20 kt	1 Mt	20 Mt
Pulse duration	1.43	10.1	45.2
Thermal injury			
First degree burn	1.75	0.297	0.0886
Second degree burn	3.14	0.643	0.221
Lightly clothed (summer)			
Few, if any, injuries	1.75	0.297	0.0886
Significant injury threshold	2.80	0.594	0.210
Lethality			
Threshold	3.50	0.792	0.243
Near 50%	6.30	1.385	0.442
Near 0%	14.0	3.07	0.952

B Thermal radiation intensity and mortality

Mortality %	*Duration* (s)	*Thermal radiation intensity*		*Thermal load,* $tI^{4/3}$ (s (W/m^2)$^{4/3}$)
		(cal/cm^2 s)	(W/m^2)	
1	1.43	3.50	146×10^3	1099×10^4
1	10.1	0.792	33.1×10^3	1073×10^4
1	45.2	0.243	10.2×10^3	1000×10^4
50	1.43	6.30	263.6×10^3	2471×10^4
50	10.1	1.385	57.95×10^3	2264×10^4
50	45.2	0.442	18.5×10^3	2210×10^4
99	1.43	14.0	586×10^3	7008×10^4
99	10.1	3.07	128×10^3	6546×10^4
99	45.2	0.952	39.8×10^3	6149×10^4

be seen that the fraction exposed is about 10.5% at the front and 9.5% at the back. The total bare skin, or nominal exposed, area is taken as 20%. The corresponding grouping in Table 16.78 is an exposed fraction of 18–22%.

The population considered is that in the age range 10–69 years (12 groups). Then for 18–22% exposure the average mortality P_{ma} given burn injury is

$$P_{\mathrm{ma}} = \frac{(0.1 \times 3) + 0.3 + 0.5}{12} = 0.09$$

Table 16.80 obviously applies to a wide range of burn depths. Since it is desirable to be able to reflect the severity of burns: a particular burn depth δ_{a} is selected as that corresponding to the average mortality P_{ma} of 0.09 just quoted.

It is reasonable to assume that most burns treated are the less severe end of the range of burn depths. For the case just considered the burn depth corresponding to the average mortality $P_{\mathrm{ma}} = 0.09$ is taken as $\delta_{\mathrm{a}} = 0.25$ mm, which from Equation 16.22.15 corresponds to a thermal load $L'_{\mathrm{a}} = 1200\ (\mathrm{W/m^2})^{4/3}\ \mathrm{s}/10^{-4}$. This thermal load corresponds to the value for second degree burns given in Table 16.80. The thermal load at which the burn depth and the mortality are zero is given by Equation 16.22.15 as 920 s $(\mathrm{W/m^2})^{4/3}/10^4$. Then, by linear interpolation between these two points of burn depth vs thermal load, full depth burn with $\delta = 2.0$ occurs at a thermal load L'_{a} of 3200 s $(\mathrm{W/m^2})^{4/3}/10^4$. Similarly, linear extrapolation gives at this thermal load a mortality P_{m} of 0.64. By further linear extrapolation, $P_{\mathrm{m}} = 1.0$ occurs at a thermal load L' of 4500 s $(\mathrm{W/m^2})^{4/3}/10^4$ and an extrapolated, or notional, 'burn depth' δ of 3.17.

Table 16.80 *Some limits and dose–response relations for heat radiation (after Hymes, 1983 SRD R275) (Courtesy of the UKAEA Safety and Reliability Directorate)*

Thermal load (s(W/m^2)$^{4/3}$/10^4)	*Effect*
210–700[a]	Threshold of blistering
1200[b]	Second degree burn
2600[c]	Third degree burn
1060[d]	1% mortality
2300[d]	50% mortality
1100–4000	Piloted ignition of clothing
3000–10,000	Unpiloted ignition clothing

[a] There is evidence for a region of constant injury between these limits.

[b] Second degree burns with a burn depth of 0.1 mm. This value is approximately the same as that for 50% mortality.Burn depth increase linearly up to a thermal load value of 2600.

[c] Third degree burns with a burn depth of 2 mm. This value is approximately the same as that for 50% mortality.

[d] Values based on the profit equation of Eisenberg, Lynch and Breeding (1975).

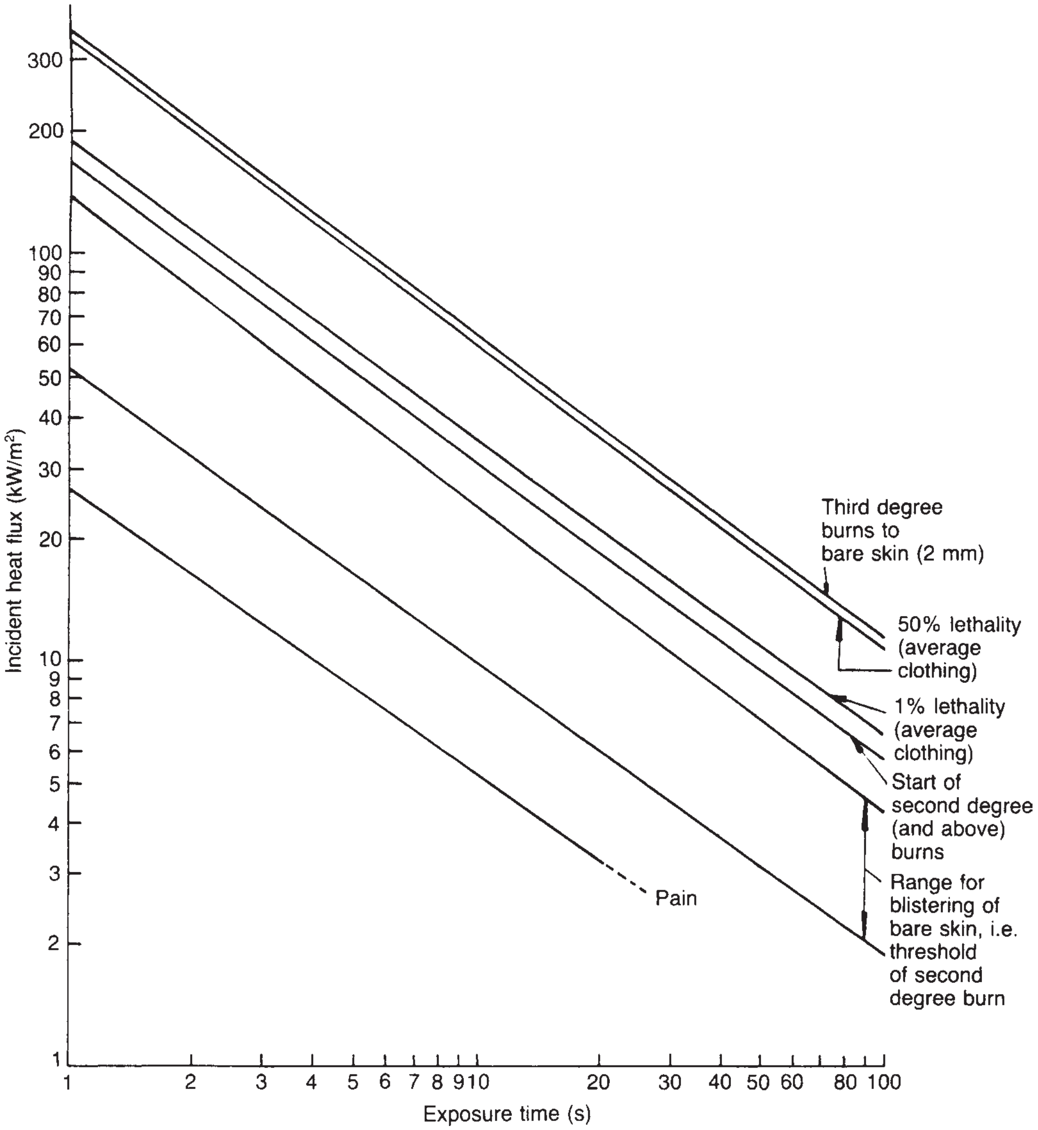

Figure 16.122 *Time to various levels of burn discomfort and injury due to heat radiation (Hymes, 1983.SRD R275) (Courtesy of the UKAEA Safety and Reliability Directorate)*

The relations between thermal load, burn depth and mortality in this model are then:

Thermal load, L' (s (W/m^2)$^{4/3}$/10^4)	*Burn depth,* δ (mm)	*Mortality,* P_m
920	0	0
1200	0.25 (=δ_a)	0.09 (=P_a)
3200	2.0	0.64
4500	3.17 (notional)	1.0

The variation of the mortality P_m with burn δ depth may expressed in terms of the average burn depth δ_a using the relations

$$\delta_1 = \frac{\delta - \delta_l}{\delta_a - \delta_l} \quad \delta < \delta_a \qquad [16.22.16]$$

$$\delta_2 = \frac{\delta - \delta_a}{\delta_u - \delta_a} \quad \delta > \delta_a \qquad [16.22.17]$$

where δ is the burn depth (mm) and subscripts a, l, u, 1 and 2 denote average, lower, upper, first coefficient and second coefficient, respectively. The mortality P_m is then obtained as

$$P_m = \delta_1 P_{ma} \qquad \delta < \delta_a \qquad [16.22.18]$$

$$P_m = P_{ma} + \delta_2(1 - P_{ma}) \qquad \delta > \delta_a \qquad [16.22.19]$$

The thermal radiation intensity used is the value incident on the person after atmospheric attenuation.

The exposure of the person to this radiation depends his behaviour. One model of response is that he faces event for the response time of 5 s and then turns his back and runs away. However, as described in Subsection 16.22.9, there is evidence, on the one hand, of shorter response times but, on the other, of a tendency to turn round to look at the event. From the data given above the fraction of the body exposed when facing the event is greater than that exposed when the back is turned to it, but the difference is not great. The base case adopted is, therefore, that, at least until any clothing ignition, the front and back are equally exposed.

At this stage there are a number of corrections which might be applied. One is for the three-dimensional effect discussed in Subsection 16.22.12. Another is for the angle of incidence of the radiant heat on the body surface. In the base case a single factor ϕ of 0.5 is used, which takes account of the fact that only about half the bare skin is exposed to the thermal radiation at a given time. This factor is applied to the time t in the thermal load expression, which thus becomes $\phi t I^{4/3}$ so that a given thermal load applied to half the exposed surface over a given time interval t is treated as equivalent to half that load applied to the whole exposed surface over the same time interval.

For clothing ignition correlations have been developed using different 'thermal loads'. One of those used by Hymes is the regular thermal load $tI^{4/3}$ and it is this which is utilized. With respect to the load at which clothing ignition occurs, the value adopted corresponds to the middle value of the range of 'load' given in the *Green Book*. Thus from Equation 16.22.8

$$tI^2 = 3.5 \times 10^4 \text{ s(kW/m}^2)^2$$

which for a 5 s pulse gives an intensity $I = 84$ kW/m^2 and a thermal load

$$L' = tI^{4/3} \approx 1800 \text{ s(W/m}^2)^{4/3}/10^4$$

Clothing ignition is taken in the model as resulting in the doubling of the effective exposed area. Following such ignition, therefore, this area is taken as the nominal exposed area. Thus from this point the factor ϕ has a value of unity.

Table 16.81 shows for this model the burn depth and the mortality as a function of the thermal load. The profit equation for fatal injury obtained from these data is

$$Y = -10.7 + 1.99 \ln L' \qquad [16.22.20]$$

where L' is the thermal load ([s (W/m^2)$^{4/3}$]/10^4).

This profit equation is based on the mortality values given in Table 16.81, except the last value of 1.0. A described above, in the model a thermal load of 4500 is taken as corresponding to a mortality of unity. Therefore the probit equation is used only up to a mortality of 70%, and the following relations are used thereafter:

Table 16.81 *Lees model for burn injury from a sudden fire event such as a fireball (Lees, 1994a): mortality as a function of thermal load (Courtesy of the Institution of Chemical Engineers)*

Thermal load, L' ([s (W/m^2)$^{4/3}$]/10^4])	*Burn depth,* δ (mm)	*Mortality,* P_m (%)	*Mortality (Eisenberg)* (%)
1000	0.07	0.025	0.015
1200	0.25	0.09	0.04
1400	0.42	0.14	0.09
1600	0.60	0.20	0.16
1800	0.78	0.26	0.24
2000	0.96	0.31	0.33
2500	1.4	0.45	0.55
3000	1.84	0.59	0.73
3200	2.00	0.64	0.78
4500	3.17 (notional)	1.0	0.95

$$P_m = 0.70 + 0.0003(L' - 3500) \qquad L' < 4500 \qquad [16.22.21a]$$

$$P_m = 1.0 \qquad L' > 4500 \qquad [16.22.21b]$$

Also shown in Table 16.81 for comparison are the mortalities predicted by Equation 16.22.9 of Eisenberg, Lynch and Breeding. Apart from those at very high thermal loads, the values are not greatly different. The difference between the method of these authors and that of Lees lies in the treatment of the effective exposed area.

In Section 16.15 an account has been given of the 16 fireball model by V.G. Marshall (1987). Table 16.82 illustrates the application of Lees' model to the case of the 20 te fireball considered by this author. For this fireball the spherical radius is 75 m, the hemispherical radius 95 m, the duration 10.3 s and the crude thermal radiation intensity $2.17 \times 10^9/x^2$ W/m^2, where x is the distance from the centre of the fireball to the target (m). In the calculation underlying the data in Table 16.82, use was made of the atmospheric attenuation factors given by Marshall and the fireball duration time was rounded to 10 s. Also shown in the table are the predictions of mortality from the Eisenberg probit applied to the unadjusted thermal loads for the full duration time of 10 s. In his discussion of the rotational factor, Marshall suggests that whereas the Eisenberg probit gives for a such a fireball a distance of 170 m to 50% mortality, experience of incidents indicates this is much too far, and he tentatively suggests that the distance of about 90 m given by assuming rotation through 360° is closer to reality. From the table, Lees' model gives a distance of 125 m.

Lees states that his model, whilst not intended to be conservative and whilst less so than the Eisenberg relation, may nevertheless still be so.

16.22.19 Prugh model

A model for burn injury from exposure to a fireball has been given by Prugh (1994). He presents a summary of data on burn injury, which for fatality draws on the work of Eisenberg, Lynch and Breeding (1975), Lees (1980b), A.F. Roberts (1982) and the Society of Fire Protection Engineers (1988 NFPA/22). From these data he derives the

Table 16.82 *Lees model for burn injury from a sudden fire event such as a fireball (Lees; 1994a): illustrative example of mortality from a 20 te LPG fireball (Courtesy of the Institution of Chemical Engineers)*

A Physical conditions

Distance (m)	*Thermal radiation intensity* (kW/m^2)		*Thermal load factor, L′/t* ((W/m^2)$^{4/3}$/10^4)	*Time to ignition, t* (s)	*Thermal load* (s (W/m^2)$^{4/3}$/10^4)		
	Crude, I	*Attenuated, I_e*			*Before ignition*	*After ignition*	*Total, L′*
75[a]	390						
95[b]	240	173	964	3.73	1800	6044	7844
105	197	142	738	4.89	1800	3771	5571
115	164	118	577	6.24	1800	2169	3969

135	119	83	361	9.97	1800	54	1854
145	103	72	298	N	(1490)	N/A	1490

B Thermal injury

Distance (m)	*Clothing ignition*	*Mortality* P_m (%)	*Mortality* (Eisenberg) (%)
75[a]	Y	1.0	1.0
95[b]	Y	1.0	1.0
105	Y	1.0	1.0
115	Y	0.84	0.99
125	Y	0.49	0.95
135	Y	0.23	0.86
145	N	0.12	0.72

[a] Radius of spherical fireball.

[b] Radius of hemispherical fireball.

following correlation for the probability P of fatality:

$$P = \{1 + [1 - \exp\{-5.3[\ln(E/53)]^2\}]^{0.5}\} \times [1 - 2(E/53)] \qquad [16.22.22]$$

where E is the thermal dose (J/m^2). He presents a graphical comparison of this equation with the two *Green Book* relationships for unprotected and protected exposure, which shows that the mortalities predicted by his correlation are appreciably lower.

With regard to the extent of the burns and to medical treatment, Prugh gives a graph of mortality vs fraction of the body with third degree burns, based on the data of J.W. Davies (1982), but states that such treatment is presumably already taken into account in the basic mortality data which he uses.

Combining the fireball model and the injury relationships, Prugh derives for a propane fireball a graphical correlation for mortality, which is a function of the mass of fuel and the distance of the person exposed. He also gives equations, which are considered in Section 16.39.

16.22.20 Thermal radiation limit

There are a number of empirical limits of thermal radiation which have traditionally been used in plant design. Other limits are quoted in work on hazard assessment. Some of these limits are quoted in Table 16.83.

16.23 Fire Protection of Process Plant

In general, fire prevention and protection measures constitute either (1) passive prevention and protection or (2) active protection.

Reference has already been made to some principal publications on fire in relation to process plants, but it is appropriate to refer here to *Practical Fire Protection* (Underwood, 1971–) and *Underwood's Practical Fire Protection* (Hirst; 1989), *Fire Protection Manual for Hydrocarbon Processing Plants* (Vervalin, 1964a, 1973a), *Storage and Handling of Petroleum Liquids: Practice and Law* (J.R. Hughes, 1970), to the NFPA codes and to BS 5908: 1990 *Code of Practice for Fire Precautions in the Chemical and Allied Industries*.

16.23.1 Passive fire protection

Passive prevention and protection comprises measures which are taken in order to prevent a fire occurring and to limit its spread. Measures of active protection comprise fixed and mobile fire fighting systems and emergency arrangements.

As a broad generalization, passive fire protection has the great advantage that it is very much less dependent on the intervention of protective devices or of humans, both of which are liable to fail, and is therefore that much less vulnerable to management failings.

One of the principal passive fire protection measures is fireproofing. In general this has the advantages just mentioned. But it also brings with it the risk that corrosion may occur under the fireproof coating and may be difficult to detect. Another problem with fireproofing is the fact that it may not withstand the action of the powerful water jets used in fire fighting.

Insofar as management has some control over both these features – the avoidance of corrosion and of loss of coating by water jets – they illustrate the fact that even the use of

Table 16.83 Some limits for thermal radiation

A Design guidance: IP *LPG Storage Code* 1987

See Table 22.8

B Design guidance: API RP 510: 1990

Thermal radiation intensity (kW/m^2)	*Limit*
15.6	Intensity on structures where operators are unlikely to be performing and where shelter is available
9.5	Intensity at design flare release at locations to which people have access and where exposure would be limited to a few seconds for escape
6.3	Intensity in areas where emergency actions lasting up to 1 min may be required without shielding but with protective clothing
4.7	Intensity in areas where emergency actions lasting up to several minutes may be required without shielding but with protective clothing
1.6	Intensity at design flare release at locations where people are continuously exposed

C Design guidance: Kletz (1980h)

Thermal radiation intensity (kW/m^2)	*Limit*
38	Intensity on storage tanks
12.5	Intensity on wood or plastics[a]
5	Intensity on people performing emergency operations

D Design and assessment guidance – BS 5980: 1990[b]

Thermal radiation intensity (kW/m^2)	*Limit*
37.5	Intensity at which damage is caused to process equipment
25	Intensity at which non-piloted ignition of wood occurs
12.5	Intensity at which piloted ignition of wood occurs
4.5	Intensity sufficient to cause pain to personnel unable to reach cover in 20 s, though blistering of skin (first degree burns) unlikely
1.6	Intensity insufficient to cause discomfort for long exposures

E Design and assessment guidance: Mecklenburgh (1985)

Thermal radiation intensity (kW/m^2)	*Limit*
14	Intensity which normal buildings should be designed to withstand
10–12	Intensity at which vegetation ignites
6	Intensity tolerable to escaping personnel
3	Intensity tolerable in infrequent emergency situations of up to 30 min duration
1.5	Intensity safe for stationery personnel and members of the public

F Assessment guidance: Dinenno (1982)

Thermal radiation intensity (kW/m^2)	*Limit*
30	Spontaneous ignition of wood
15	Piloted ignition of wood
20	Ignition of No. 2 fuel oil in 40 s[c]
10	Ignition of No. 2 fuel oil in 120 s[c]
18–20	Cable insulation degrades[d]
12	Plastic melts[e]
37.5	Equipment damage[f]
9	Equipment damage[f]

[a] Kletz comments that the implication of this limits that large storage tanks need to be located at least 200 m from public roads.

[b] BS 5908: 1990 also gives a thermal dose of 600–1800 kJ/m^2 from a fireball as a criterion for the starting of secondary fires.

[c] EPRI (1981a).

[d] EPRI (1979b).

[e] Gelderblom (1980).

[f] Di Nenno comments that there is significant variation in the thresholds for equipment damage. He gives the source of the value of 37.5 kW/m^2 as Gelderblom (1980), and treats the value of 9.5 kW/m^2 given by Tan (1967a), in relation to flare system design, as conservative.

passive fire protection measures does not avoid the need for good management.

The optimum solution to the fire protection problem is normally a combination of passive and active measures. Often passive fire protection can limit fire spread and can 'buy time' in which the firefighting resources can be mobilized.

16.23.2 Active fire protection

Active fire protection measures are also provided in the basic plant design, but are effective only when activated in response to a fire. Elements of active fire protection are:

(1) fire warning systems;
(2) fire detection systems;
(3) firefighting agents;
(4) fire water supply system;
(5) fixed firefighting systems;
(6) mobile firefighting systems.

Item (1) of these measures is described in Chapter 24 and item (4) in Chapter 10, while the other items are dealt with below.

16.23.3 Fire detection and alarm

The initiation of active fire protection measures, whether fixed systems or mobile firefighting systems, depends on the fire detection and alarm arrangements.

Accounts of fire detection and alarm are given by Fry and Eveleigh (1975 BRE CP 32/75) and P. Nash and Young (1975 BRE CP 29/75). Treatments of water sprinkler and water spray systems also frequently deal with detection systems.

Relevant codes and standards are the NFPA 72 series, particularly NFPA 72E: 1990 *Automatic Fire Detectors*, BS 5445: 1977 – *Components of Automatic Fire Detection Systems*, BS 5839: 1988 – *Fire Detection and Alarm Systems for Buildings* and, until recently, BS 6020: 1981 – *Instruments for the Detection of Combustible Gases*, now superseded by the series BS EN 50054–50058 which has the general title *Electrical Apparatus for the Detection and Measurement of Combustible Gases*.

When a fire occurs, two things which are of prime importance are to ensure the safety of personnel and the prompt initiation of action to deal with the fire. The most effective way of ensuring rapid action is generally the use of an automatic system. But in situations where personnel may be present the arrangements need to ensure that they are not put at risk by the action of the automatic system.

There are several different types of system for the detection of leakage and/or fire. They may be classified according to whether they detect (1) leakage, (2) flame, (3) heat or (4) smoke. These systems and the devices used are listed in Table 16.84.

Table 16.84 *Some detection systems for fire protection*

Basis of detection	*Detector*
All modes	Humans
Leakage	Flammable gas detector
Flame	Infrared detector
	Ultraviolet detector
Heat	Temperature measuring instrument
	Quartz bulb detector
	Gun cotton bridge and wire
	Fusible link and wire
	Temperature sensitive resistor
	Air line
Smoke	Smoke detector

In general, it is preferable to detect a leakage in its initial stages and before it ignites. On the other hand, some types of fire, such as lagging fires, are not preceded by readily detectable leakage.

The alternative is to detect the fire itself. This is done most rapidly by flame detection. Detection of the heat and smoke from the fire is possible only after it has developed to some extent.

Some important characteristics of detection systems are:

(1) area covered;
(2) response time;
(3) reliability
  (a) fail-to-danger faults,
  (b) fail-safe faults (spurious alarms);
(4) cost.

The area covered by a detection device is important, because a small coverage leads to a complex and expensive system. The reliability is also important both in respect of fail-to-danger faults and of fail-safe faults which cause spurious alarms.

Detection of abnormal conditions, including leakage and fire, is a basic function of the process operator. He is capable of detecting such conditions by all the modes described and gives wide coverage with high reliability and low cost. His great disadvantage is that he may not respond rapidly enough, not only in making the initial detection but also in initiating firefighting action.

Instrument detection systems are therefore widely used. In many cases they are part of a fully automatic system which triggers protective devices such as steam curtains, or releases firefighting agents. In other cases, however, the function of the detection system is limited to providing an alarm signal to the operator, which he then has to interpret. There are several reasons for not always making the system fully automatic. One is that detection systems are liable to give spurious alarms; another is that it is not always easy to define in advance precisely what is required. It is often difficult, for example, in an automatic water spray system to avoid wasting water in cooling plant where this is not really necessary. This is important, because the quantities of water required for water sprays are large.

The most widely used type of system is the combustible gas detection method. Descriptions are given by several authors (e.g. Bossart, 1974; Dailey; 1976; Johnson, 1976). There are two main types of combustible gas detection. One consists of a number of devices which sample the atmosphere at different points and pass the sample back to a common analyser. Typical sample pipe velocities are 3 m/s and sampling rates 10–30 s per point.

There are a variety of instruments available for combustible gas analysis, based on the measurement of the heat produced by a catalytic reaction, radiant energy, absorption, ionization phenomena, electrochemical effects, colorimetric effects and gas chromatography. Details are given by Dailey.

A single instrument system is, in general, most appropriate where the analyser itself is very complex and expensive and where some time delay is acceptable. These characteristics appear to make it more suitable for detecting toxic gases which pose a long-term hazard, but less so for detecting flammable gases, where the analytical instruments are comparatively simple but fast response is important. Common analyser systems have in fact been subject to severe criticism by some users (e.g. Kletz, 1976i) as being excessively slow in response and liable to faults such as blockage.

The other system, which is preferred by such users, utilizes an individual catalytic diffusion type detector at each detection point. Generally, a combustible gas detector is installed and calibrated for one particular hydrocarbon gas, but will respond to others. The instrument scale is usually calibrated as 0–100% of the lower explosive limit (LEL). The output of a detector calibrated on propane will read some 20% high on methane and some 20% low on propylene.

Catalytic detectors are susceptible to poisoning. In particular, silicone grease and silicone rubber sealants have been found harmful. Combustible gas detector instruments should be regularly serviced. Portable detectors should be checked before use.

There tends to be some trade-off between the speed of response and the number of spurious signals obtained. It is suggested by Johanson that the specification for response time is generally too tight and that an allowance of a few seconds delay reduces the number of false alarms.

There are various approaches to laying out the detection points. Generally, it is desirable to have detectors around the periphery. Other detectors are then sited according to principles such as uniform coverage, location at leak sources, location between leak and ignition sources.

The optimum height of the sample point depends on the density of the gas. Johanson suggests installation at $1\frac{1}{2}$ and 6–8 ft heavy and light gases, respectively. It is also necessary to take into account depressions, roofed areas and other pockets.

A combustible gas leakage detection system may be used to provide alarm signals in the control room or to initiate protective action by water sprays or by a steam curtain.

Detection of a flame is done by infrared or ultraviolet detecting instruments. The response time of the former is generally about 10 s, while with the latter it is almost zero. The reliability of these relatively complex instruments is a problem, particularly, although not exclusively, because they tend to give frequent false alarms, but there has been considerable improvement in this aspect. The instruments are also comparatively expensive. Again a flame detection system may be used to give alarm signals or to trigger water sprays.

There are a number of devices which detect heat. They include temperature measuring instruments, quartz bulbs, and devices which explode, melt or change characteristics when exposed to fire. The latter include guncotton bridges and wire, fusible links and wire, air lines which melt through and resistors which change resistance. Measuring instruments can be used to furnish alarm signals or to set off water sprays, but the other devices are generally used for the latter purpose. Thus a simple detection system might be based on an air line which can be melted through by a fire so that the air pressure in the line falls, allowing the drench valve on apply the water spray system to open.

A quartz bulb detector figured prominently in the Flixborough inquiry (R.J. Parker, 1975, pp. 20–26, especially paragraphs 137, 156, 157 and 160, and figure 8). According to the 8 in. pipe hypothesis, a fire occurred at a non-return valve in a lagging box. There was believed to be a quartz bulb some 12 in. above the top of the valve and some 18 in. to the east which was set to actuate a water spray system at a temperature of 68°C or above. It was a matter of dispute whether there could have been a fire at the lagging box without activation of this detector. Proponents of the 8 in. pipe hypothesis argued that either there was no quartz bulb or that it did not operate. Calculations were done which were said to show that heat radiation from the assumed flame would not be enough to trigger the detector and that heat radiation from the pipework would be necessary to do this. The assessors considered, however, that if the hypothesis were correct the sensor would have been triggered by other flames and radiating surfaces present. In any event, the water spray system apparently did not operate. These points are of some importance, because they bear on the effectiveness of detector systems. Further discussion of the matter is given by J.I. Cox (1976b).

Another method of detecting fire is by smoke detectors. These are widely used in buildings, but appear likely to be less effective for fires on open plant.

16.23.4 Emergency material transfer

It is necessary to have arrangements so that in the event of fire it is possible to transfer flammable material away from the parts of the plant affected. Provision of a relief header leading to a vent stack or flare stack allows vapour to be vented safely from pressure vessels. The removal of liquid from a pressure vessel may be catered for by facilities for blowdown to a suitable receiver. Similarly, pumps may be installed on atmospheric storage tanks to allow liquid to be transferred out.

16.23.5 Dow Fire and Explosion Index

The Dow Fire and Explosion Index given in the Dow *Guide* has been described in Chapter 8, where the method of calculating the index was outlined. The purpose of the index is to assist in the selection of preventive and protective features.

The following set of preventive and protective features are listed in the Fourth Edition of the *Guide* (Dow Chemical Company, 1976): (1) basic preventive and protective features and (2) recommended minimum preventive and protective features. The latter features are not given as such in the later editions, but the Fifth Edition introduces loss control credits, which cover similar ground, and also an engineer's checklist. Table 16.85 lists the basic preventive and protective features given in the Seventh Edition (Dow Chemical Company, 1994) and Table 16.86 lists the headings of the recommended minimum preventive and protective features in the Fourth Edition.

The features shown in Table 16.85 should always be provided, irrespective of the degree of hazard. If they are not, the hazard will be greater than that calculated by the index. Many of them apply in any plant, regardless of whether it contains flammable materials.

It should be noted that the codes and electrical area classification mentioned in Table 16.85 are those applicable in the United States.

Table 16.86 lists headings of the features which should always be considered where a fire or explosion hazard exists. The detailed measures under these headings are described in the *Guide*. The features are intended to reduce the magnitude and/or the probability of the loss. The need for a particular feature depends on the nature of the hazard.

The Dow Fire and Explosion Index is widely used as an aid to the selection of fire preventive and protective features, and is therefore a relatively well-proven method. Nevertheless, it is a generalized method and, if used, it should be supplemented by specific hazard identification and assessment studies which may reveal the need for other preventive and protective features.

16.24 Passive Fire Protection

The previous section has given an account of the general nature and purpose of passive fire protection. In this section specific passive fire protection measures are considered.

Table 16.85 *Dow Guide: Basic Preventive and Protective Features(Seventh Edition) (Dow Chemical Company, 1994; reproduced with permission)*

A Adequate water supply for fire protection, This is determined by multiplying the water demand by the length of time for which the worst possible fire can be expected to last. The supply deemed adequate will vary with different authorities and may range from enough for a 2-h fire to enough for one lasting 8 h
B Structural design of vessels, piping, structural steel, etc.
C Overpressure relief devices
D Corrosion resistance and/or allowances
E Segregation of reactive materials in process lines and equipment
F Electrical equipment grounding
G Safe location of auxiliary electrical gear (transformers, breakers, etc.)
H Normal protection against utility loss (alternate electrical feeder, spare instrument air compressor, etc.)
I Compliance with various applicable codes (ASME, ASTM, ANSI, Building Codes, Fire Codes, etc.)
J Fail-safe instrumentation
K Access to area for emergency vehicles and exits for personal evacuation
L Drainage to handle probable spills safely, plus firefighting water from hose nozzles and sprinkler heads and/or chemicals
M Insulation of hot surfaces that heat to within 80% of the autoignition temperature of any flammable in the area
N Adherence to the National Electrical Code, The Code should be followed except where variances have been requested/approved
O Limitation of glass devices and expansion joints in flammable and hazardous service, Such devices are not permitted unless absolutely essential. Where used, they must be registered and approved by the production manager and installed in accordance with Dow standards and specifications
P Building and equipment layout. Separation of high-hazard area must be recognized especially as it relates to both property and interruption of business. Separation of tanks must be at least in accordance with NFPA 30
Q Protection of pipe racks and instrument cable trays as well as their supports from exposure to fire
R Provision of accessible battery limit block valves
S Cooling tower loss prevention and protection
T Protection of fired equipment against accidental explosion and resultant fire
U Electrical classification. Division 2 electrical equipment will be required for outside flammable liquid handling where congestion is minimal and natural ventilation, is unobstructed, Division 1 equipment is required only for special chemicals and/ or special building or process handling conditions or where ventilation is inadequate
V Process control rooms shall be isolated by 1 fire walls from process control laboratories and/or electrical switchgear and transformers
W A process review shall determine a need for reactive
X A hazard and operability (hazop) review is recommended in high hazard areas

Table 16.86 *Dow Guide: Minimum Preventive and Protective Features (Fourth Edition) (Dow Chemical Company, 1976) – these features are listed in the Guide which gives a detailed description of them*

1 Fireproofing
2 Water spray protection of equipment and area
3 Foan or filming agents
4 Monitor guns
5 Dump, blowdown or spill contrl
6 Combustible gas monitors
7 Diking for storage tanks
8 Buried tanks
9 Foam on tanks
10 Remote manual Control
11 Special instrumentation
12 Fire Walls and barrier walls/cubicles
13 Building ventilation
14 Dust explosion control
15 Open explosin structure
16 Emergency relief venting for buildings

Measures of fire prevention and passive fire protection are built into the basic plant layout and design. They include such aspects as:

(1) elimination of fires
    (a) leaks and spillages,
    (b) sources of ignition;
(2) emergency material transfer
    (a) pressure relief and flaring,
    (b) blowdown,
    (c) dumping;
(3) fire spread limitation;
(4) fire protective insulation
    (a) fire resistant thermal insulation,
    (b) fire insulation;
(5) storage tank layout.

Of these measures, items (1) and (2) have been dealt with already in this chapter and item (5) is considered in Chapters 10 and 22. The Other items are described below.

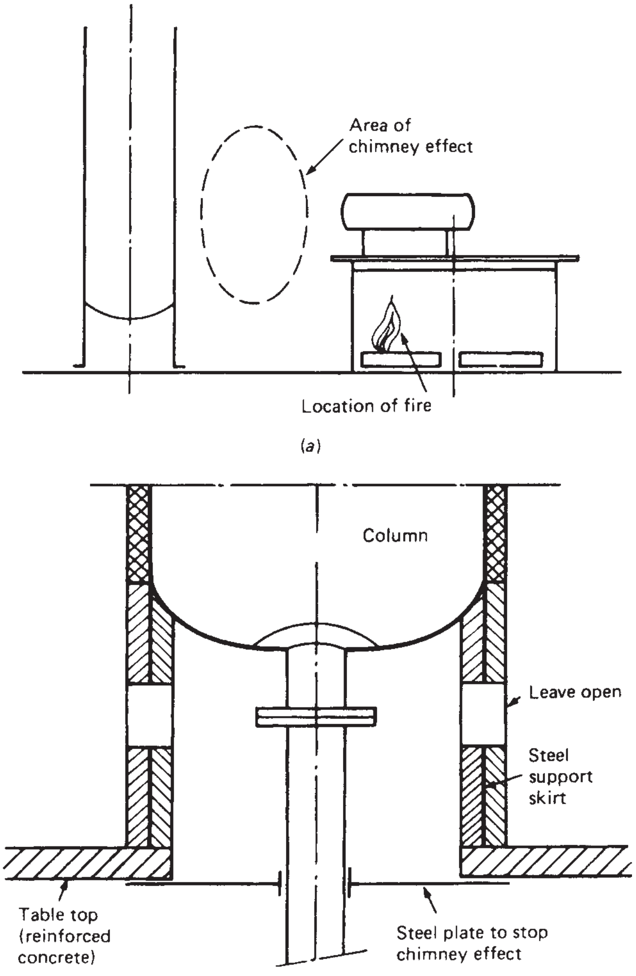
16.24.1 Fire spread limitation

There are certain plant configurations which assist fire spread, By avoiding or modifying these configurations, fire spread may be limited.

Two examples given by Klootwijk (1976) are shown in Figure 16.123. In a fire a chimney effect can develop in the space between a table top and a tall equipment or structure as illustrated in Figure 16.123(a). Such an effect tends to increase damage and to extend it to a higher level. Where a potential chimney cannot be avoided, it may be appropriate to install a water spray system to control fire in the area.

A chimney effect can also occur between a table top and the bottom of a large column. In this case the opening should be closed off with a support skirt, as shown in Figure 16.123(b).

Another way in which fire can spread is by the flow of a burning liquid. The plant layout with regard to this aspect should be carefully considered, It is normal practice to put bunds around storage tanks. But there may be other situations which can give rise to liquid flow, Drains, sewers



(a)

(b)

***Figure 16.123** Fire spread and its limitation (Klootwijk, 1976): (a) chimney effect between table top and a tall structure; (b) elimination of the chimney effect between a table top and the bottom of a column by use of a steel support skirt*

and pipe trenches are features which are particularly liable to aggravate this hazard.

16.24.2 Fire resistant thermal insulation

Many items of equipment are fitted with thermal insulation. This is to be distinguished from fire insulation proper. Nevertheless, provided it is of the right type, thermal insulation can provide a degree of fire protection. Much process plant is thermal insulated, as are low temperature storage tanks.

The fire resistant properties of regular thermal insulation are considered in Chapter 12. The fire protection offered by such insulation on storage tanks is discussed in Chapter 22.

16.24.3 Fire insulation

Some form of structural protection against fire, in the form of fire insulation or fireproofing, is normally provided for supporting members, and also for vessels and pipe work. A general account of fireproofing has been given by Waldman (1967).

Factors which need to be taken into account in considering such fireproofing include:

(1) protection criteria
    (a) type of structure,
    (b) height of structure,
    (c) degree of protection;
(2) fireproofing system.

There are differences of practice in the types of structure which are fireproofed. The main emphasis is generally on the protection of supporting members. Fireproofing is sometimes limited to supports of major items such as large columns or vessels, but it is often extended to supports of other items, such as heat exchangers and pipework. In some cases it is applied to the vessels and pipework themselves.

The main object of fireproofing is to prevent the failure in a fire of items containing flammable material which can feed the fire. Fireproofing may not be needed, therefore, for items with a small inventory, unless failure could lead to large loss of containment from some other source.

The height above grade, or ground level, to which the protection extends is also variable. Most fires do not reach much more than 10 m above grade, although there have been instances of damage at heights of 30 m or more. It is suggested Waldman that fireproofing should extend to 35 ft (10m) above grade.

It is also necessary to decide on the degree of protection required. A common criterion is that the steel member should not reach a temperature greater than 1000°F (538°C) under specified fire conditions.

In deciding on the degree of protection required for fireproofing, allowance may be made for other fire protection features, such as water sprays. It is the whole fire protection system which matters. In general, the aim should be to prevent a fire occurring at all near a vulnerable structure. It is better to provide drainage to take the flammable liquid away.

A fireproofing system normally consists of a bulk insulation material which gives protection against fire. This bulk fire insulation may be clad with aluminium, galvanized or stainless steel sheet. Such fire insulation should be distinguished from conventional insulation which is used to reduce heat transfer between the plant and the atmosphere. Such insulation mayor may not have fire resistant properties. Materials which are widely used as the bulk fire insulation include (1) concrete and (2) magnesium oxychloride cement. Concrete is often used in the form of lightweight aggregate concrete, or vermiculite cement.

Protection against fire may also be obtained by the use of a mastic, which may be asphaltic or vinyl acrylic. Mastics are used to fireproof not only plant but also conventional insulations.

Some materials used as the bulk fire insulation have special fire resistant properties. Magnesium oxychloride, for example, contains water of crystallization, which takes up heat when it is driven off. Similarly, some coating materials have properties which increase their effectiveness in fireproofing. Intumescent mastics swell in fire by a factor of 5–10 and this gives increased insulation.

Some features of a fireproofing system include:

(1) insulation properties;
(2) mechanical strength;
(3) corrosion
    (a) substructure,
    (b) reinforcing;
(4) water penetration;
(5) flexibility;
(6) weight;
(7) ease of installation;
(8) cost.

Fireproofing should provide sufficiently effective insulation to keep the temperature of the structural member to be protected below a specified temperature under defined fire conditions. It has been suggested by Kayser (1974) that the ideal system will hold the substrate below 1000°F (538°C) for $1\frac{1}{2}$ h while its surface is exposed continuously to a temperature of 1800°F (982°C). The maximum substrate temperature of 1000°F is that widely quoted, but the maximum period of protection is generally less. Thus Waldman suggests, for example, that in order to allow for spray failure protection is required for 1 h. This time period is also quoted by other workers, as described below.

The mechanical strength of the fireproofing should be sufficient to offer reasonable resistance to damage both from normal plant activities and from water from fire hoses.

The bulk fire insulation should not be corrosive to the substrate or to the reinforcing material. The substrate should be made clean and rust free before the insulation is put on.

It is essential that water should not be allowed to penetrate the insulation and corrode the substrate or the reinforcing material. Corrosion of the steel structural members is difficult to detect, but could have serious results. The coating or cladding used should therefore offer complete protection, particularly at horizontal surfaces where water may get in.

The insulation should be able to accommodate, without cracking, the expansion and contraction of the structure protected. Other desirable features are light weight, ease of application and low cost.

A fireproofing system which is widely used is concrete with galvanized steel sheet cladding (Klootwijk, 1976). Vermiculite cement and magnesium oxychloride cements are also much utilized.

Some illustrations of fireproofing of structural supports are shown in Figure 16.124.

16.24.4 Tests for fire insulation

There is frequently a requirement to test a proposed fireproofing system. Unfortunately, there is no standard test appropriate to structural elements in a flammable liquid fire, which is the typical situation in process plant. Many experimenters have resorted, therefore, to the ASTM E-119 standard time–temperature test, which was devised for building fires. The test involves maintaining the element in a standard fire in which the temperature rises along the standard curve shown in Figure 16.125, curve 1. The criterion of success is the ability of the element to carry out its original function, in this case fireproofing. The ASTM E-119 test is discussed further in Section 16.36 in relation to its original application to fires in buildings. Most workers have used as the criterion of success the ability of fireproofing to keep the temperature of the steel protected below 1000°F (538°C) for a period of 1 h.

It has long been recognized that the ASTM curve tends to underestimate the temperatures which occur in fires of hydrocarbons. An early proposal for a higher temperature relation was made by Waldman (1967), who gave two alternative curves.

The unsatisfactory nature of the ASTM E-119 test in this application has been demonstrated by Castle (1974). He emphasizes that in order to assure similarity of test conditions it is necessary to use not only the same temperature but also the same heat fluxes. He presents experimental results which illustrate this point. He also discusses the alternative pool and pit fire tests and states that a pit fire test is generally a more severe one than the ASTM E-119 test.

Since then several other time–temperature curves have gained currency. Two of these are shown in Figure 16.125. Curve 2 is that of the Norwegian Petroleum Directorate (NPD). Curve 3 is generally known as the 'Mobil curve'.

The use of a standard time–temperature curve for hydrocarbon fires leads to an H rating, as opposed to the A rating obtained by using a curve suitable for building fires.

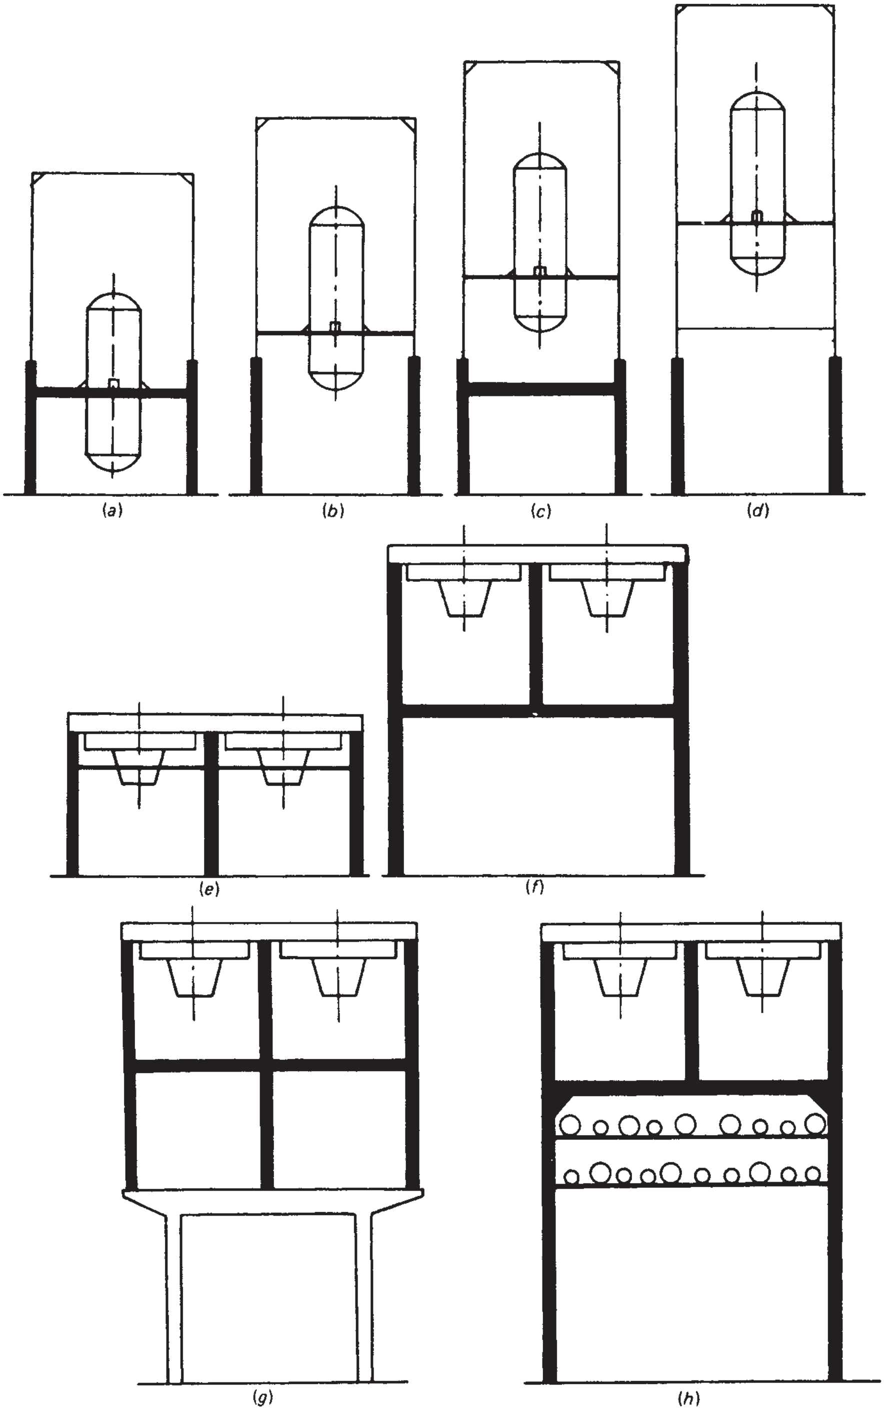


Figure 16.124 *Fireproofing of structural supports (Klootwijk, 1976): (a–d) supporting structure of small storage vessel; (e–g) supporting structure of fin-fan cooler and (h) supporting structure of fin-fan cooler and overhead pipe track*

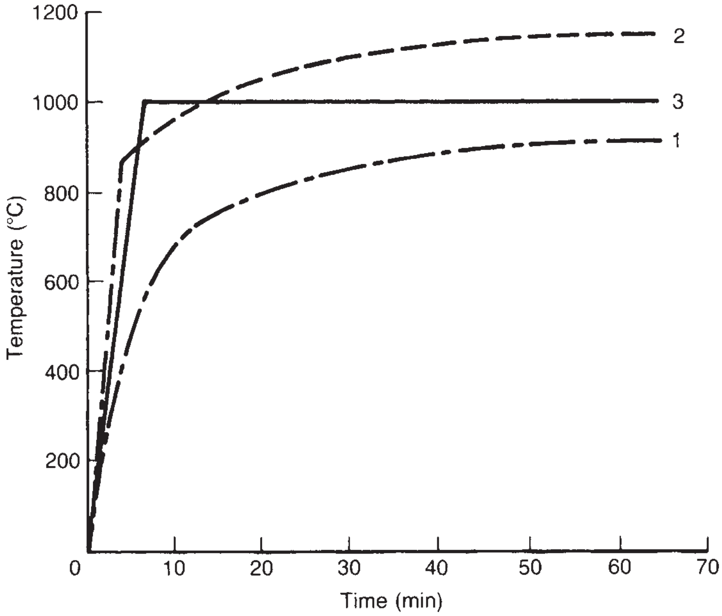

Figure 16.125 *Some time–temperature curves for fires in process plant. Curve 1, ASTM E 119–1988; Curve 2, Norwegian Petroleum Directorate; Curve 3, 'Mobil' curve (after Cullen, 1990)*

Another test which is utilized is the ASTM-84 surface burning test, in which a standard fire is used to evaluate the rate of flame spread across the surface of the element. The later is rated on a scale on which the points 0 and 100 correspond to asbestos cement and redwood, respectively. An index above 25 is generally regarded as unsatisfactory for fireproofing. The use of this test is described by Feldman (1974).

Much equipment and pipework is provided with insulation which serves primarily to conserve heat or cold in the process. Such insulation is different from that used for fireproofing. But it is important to know what degree of protection against fire it offers.

Experiments on insulations commonly used for pipework have been described by McMillan (1974). The test exposed five insulated pipes of 3 in. diameter to a flame area of approximately 30 ft^2 at temperatures corresponding to the ASTM E-119 time–temperature curve. The minimum fire resistance considered acceptable was taken as maintenance of the pipe temperature below 1000°F (538°C) for 1 h.

Systems which met this criterion almost exactly included: a 1 in. calcium silicate insulation with a 10 mil (1 mil = 0.001 in.) stainless steel jacket; a 2 in. ceramic foam insulation with vinyl acrylic mastic or asphaltic mastic coating or 10 mil cladding of aluminium or stainless steel; and a 3 in. rigid polyurethane foam insulation with 10 mil vinyl coated steel cladding.

The behaviour of polyurethane foam insulation in fire has been a subject of some controversy. There are a number of different types of polyurethane foam. In a fire, some foams melt, some char, some both melt and char, and some char and rupture, leaving gaps. According to McMillan, however, a suitable polyurethane foam can give good fire resistance. Detailed experimental work on the behaviour of polyurethane foams in fires is described by Boult, Gamadia and Napier (1972) and by Boult and Napier (1972).

Fireproofing is discussed in the ICI *LFG Code* (ICI/RoSPA 1970 IS/74). For pressurized storage vessels the code suggests that one suitable form of fireproofing is vermiculite cement. For the 2 h protection which is commonly provided, the minimum thickness of vermiculite cement required is 2 in. For refrigerated storage vessels the convenstional insulations are cork, polyurethane and perlite powder. The Code discusses the degree of fire resistance offered by these materials and suggests that an additional fireproof finish may be required to give 2 h fire resistance.

16.24.5 Reactive fire resistant coatings

A quite different method of fireproofing is the use some form of a reactive coating. Accounts of reactive coatings include those by Feldman (1974), O'Rourke (1974), Kawaller (1980), R. James (1988), Gillon (1989) and Droste (1992).

Reactive coating are of three main types: (1) magnesium oxychloride, (2) intumescent coatings and (3) subliming coatings.

Magnesium oxychloride exposed to fire undergoes loss of its combined water so that a porous matrix is formed. It gives a light, hard covering that is resistant to impact, abrasion and weather and provides good fire resistance. A proper formulation should be used; home-made ones can be unsatisfactory. It does, however, have some drawbacks. One is that it requires metal lath reinforcement, another that it is somewhat corrosive so that the equipment needs to be protected, and a third that it tends to lack adhesion and requires a good 'key'.

Intumescent coatings were first used as paint to retard surface spread of flame. They were so successful that a fire resistant coating was developed. In a fire an intumescent coating releases cooling gases and leaves a residue of thick insulating foam. Tests show that a $^1/_4$ in. layer can give a 1-h protection. Langer periods of protection can be obtained using thicker layers with reinforcement.

With a subliming compound the principle of operation is that the coating sublimes so that as long as material remains on the surface the temperature of sublimation is not exceeded. The technique was initially developed for aerospace work. Thus subliming coating ThermoLag 330 has been used to protect the structure holding the Saturn rocket at blastoff when temperatures reach 3000°F (1649°C). The coating material itself is expensive, but is relatively cheap to apply.

The use of subliming coating is described by Feldman (1974). He quotes tests conducted on steel beams in an alcohol pit fire with exposure of 1800°F (982°C) for 2 h. An unprotected beam reached a temperature of 1000°F (538°C) in 10 min, whereas a beam protected by subliming coating rose to a maximum temperature of only 500°F (260°C) over the whole period.

Droste (1992) describes two full-scale tests on a 3.6 m^3 LPG vessel protected in one test by the subliming coating ThermoLag 440 and in the other by the intumescent coating Chartek III. The tests demonstrated satisfactory performance of both cotings for full fire engulfment over 90 min.

Reactive coatings are lightweight and durable. The applications where they are most likely to be economic are those where alternative softer materials are less suitable. Some practicalities of the use of reactive materials are discussed by Kawaller (1980).

16.24.6 Fire protection of steelwork

Turning to the passive fire protection of particular plant features, protection of structural steelwork is of some importance. Accounts of the fire protection of steelwork include those by Kayser (1974), Klootwijk (1976), Buck and Belason (1985), Latham, Kirby and Thomson (1987), Melinek and Thomas (1987), G.M.E. Cooke (1988) and Melinek (1980).

From standard tests information is available on the time for steel configurations, either uninsulated or with insulation arrangements, to reach a given temperature (e.g. Franssen and Bruls, 1986; API RP 520: 1990). A commonly used criterion temperature is 550°C.

Design guidance for fire protection of steelwork is given in *Designing Fire Protection for Steel Columns* (American Iron and Steel Institute, 1980), *Fire Protection for Structural Steel in Buildings* (CONSTRADO, 1983) (the *Yellow Book*) and *Design Manual on the European Recommendations for the Fire Safety of Steel Structures* (ECCS, 1985) and by Law (1972, 1991), Barnfield (1986) and Melinek (1980).

There are a number of models for predicting the times required to attain particular temperatures for insulated steelwork in a fire, including those by the European Convention for Constructional Steelwork (ECCS) (1985) and the National Research Council or Canada (NRCC) and by Wickström (1981/82, 1985) and Melinek (1980).

In estimating these times it is also necessary to define the nature of the fire to which the steelwork might be exposed.

16.24.7 Fire resistant valves

Valves are another type of equipment for which good fire resistance is highly desirable. Fire resistant, or fire safe, valves are available. Accounts of fire resistant valves are given by J.B. Wright (1981) and Cory and Riccioli (1985).

Relevant standards are API Std 589: 1993 *Fire Test for Evaluation of Valve Stem Packing*, API Spec. 6FA: 1994 *Specification for Fire Test for Valves* and BS 6755: *Testing of Valves*, Part 2: 1987 *Specification for Fire-Type Testing Requirements*, which replaces the earlier BS 5146: 1974–.

Interest centres particularly on the fire resistance of ball valves.

Among the features listed by J.B. Wright (1981) as being evaluated in tests are: operability whilst hot, leakage behaviour in a rapidly controlled fire and in a more prolonged one, and ability to withstand/relieve cavity pressure build-up.

16.25 Fire Fighting Agents

16.25.1 Types of firefighting agent

The main types of firefighting agent are (1) water, (2) foam, (3) vaporizing liquids, (4) dry powders, (5) inert gases and (6) other agents.

Accounts of firefighting agents are given in the *Manual of Firemanship* (Home Office, 1974–) and by Guise and Zeratsky (1965, 1982), the Factory Mutual Engineering Corporation (FMEC) (1967), J.R. Hughes (1970), Hearfield (1970), Harpur (1971), the Petroleum Industry Training Board (PITB) (1975/6), Riley (1983), Fuchs (1984), Welker, Martinsen and Johnson (1986), and Scheinson, Penner-Hahn and Indritz (1989) as well as the various contributors to the NFPA *Handbook* referred to below.

The principal firefighting agents are discussed in Sections 16.26–16.33.

16.25.2 Mechanism of fire extinguishment

Firefighting agents have several different mechanisms of operation. These include:

(1) cooling of flame;
(2) reduction of fuel
    (a) cooling of liquid,
    (b) dilution of liquid,
    (c) emulsification of liquid,
    (d) blanketing of liquid;
(3) reduction of oxygen;
(4) interference with combustion reaction.

The flame may be cooled to render it unstable. The supply of fuel to the flame may be reduced by cooling the liquid, by diluting or emulsifying it and so reducing the partial pressure of the vapour, or by blanketing the liquid with some inert material. The partial pressure of oxygen at the flame may be reduced by diluting the atmosphere with inert gas. The combustion reaction may be disrupted by the use of an agent which interferes with the combustion chain reaction.

16.25.3 Hazards of firefighting agents

There are a number of hazards in the use of firefighting agents. They are associated primarily with (1) discharge of the agent, (2) incompatibility between the agent and the material on fire, (3) an electric shock from high voltage equipment and (4) toxic and asphyxiant effects from the agent or its breakdown products.

A treatment of the toxic and asphyxiant hazards is given in GS 16 *Gaseous Fire Extinguishing Systems: Precautions for Toxic and Asphyxiating Hazards* (HSF, 1994). This deals with the hazards associated with systems using inert gases such as carbon dioxide and nitrogen and those using vaporizing liquids such as halons.

These hazards and the precautions to be take against them are considered in more detail in the following sections. Further discussion of the precautions advised in GS 16 is deferred to Sections 16.30 and 16.31 so that an account can first be given of the basic methods.

16.25.4 Methods of delivery

The principal methods of delivery of firefighting agents are, in broad terms, (1) fixed systems, (2) mobile systems and (3) portable systems. Fixed systems encompass both fixed systems consisting of nozzles and feeder pipework and fixed monitors. The following sections give a more detailed discussion of these different types of delivery system.

16.25.5 Application of agents

For fire extinguishment or control agents such as water, foam and dry chemicals are generally applied directly to the burning liquid surface, and fixed systems are arranged to do this.

For agents such as dry chemicals, inert gases and vaporizing liquids, two widely used fixed systems are:

(1) total flooding system;
(2) local application system.

A manual method applicable to the first two of these is the use of a

(3) hand held hose line.

A total flooding system is used to protect a space which is essentially enclosed, whilst a local application system is used for a particular hazard such as an open tank. A hand held hose line is used to direct a jet of the agent at the fire.

Medium and high expansion foams may also be used in total flooding and local application systems.

16.25.6 Compatibility of agents

The compatibility of firefighting agents has two distinct aspects: (1) compatibility with the material and/or a fire of the material and (2) compatibility with other agents.

Some firefighting agents are incompatible with some chemicals. Information on this aspect is given in *Dangerous Substances. Guidance on Dealing with Fires and Spillages* (Home Office, 1972/4), in *Hazardous Loads* (IEF, 1972), *Fire Protection Guide to Hazardous Materials* (NFPA, 1991/27) and by various authors in the NFPA *Handbook*, as described below.

The most widely used firefighting agent is water, but it is not suitable in all cases. For example, water reacts with aluminium alkyls, usually with some violence. In some cases the incompatibility is with the fire of the material rather than with the material as such. For example, water is not incompatible with bulk titanium, but it is unsuitable for a titanium fire. Water is not generally an appropriate agent for fires of alkali metals, sodium chlorate or sodium peroxide. Chemicals which are incompatible with water may generally be expected to be incompatible with water-based foam, particularly the low expansion variety.

It is important that full information is available on the proper agents for fighting fires with the chemicals used in the process, that the right agents are selected and are available on the plant, and that personnel understand the nature of the agents and their use.

The other type of incompatibility is that exhibited between two different agents. It is often desirable to use two agents, either together or in quick succession. An example is the use of dry chemicals to knock down a fire and then of foam to blanket the liquid and prevent reignition. In such applications the agents must be compatible. This aspect is discussed further below in relation to specific agents. Examples of work on the compatibility of foams and dry chemicals are the accounts by Hird and Fippes (1690), the Underwriters Laboratories (1963) and Jensen (1964).

16.25.7 Selection of agents

In firefighting there is no single aim, and the selection of firefighting agents reflects this. An agent may be required to effect (1) extinguishment, (2) control or (3) exposure protection.

For fire extinguishment or control, the first consideration is usally given to water. Water is cheap and generally readily available. It is non-toxic and does not give rise in fire to toxic products. It has a large capacity to absorb heat, whether as sensible or latent heat. It vaporizes to give some 1700 times its own volume of steam, which acts as an inert vapour. Water is therefore particularly useful in fires where high cooling capacity is needed such as those involving solid materials and high flashpoint liquids, and where it is necessary to cool hot metal to prevent flashback.

There are some disadvantages, however, in the use of water. Since water has a higher density than most flammable liquids, it does not generally float on the surface of a burning liquid and so blanket it. Instead it often displaces the liquid from any depression, bund or equipment containing it and may thus cause burning liquid to spread out.

Its effectiveness against liquid fires depends on the type of liquid. This is discussed in more detail below. It is sufficient to note here that with some liquids water is not a very efficient extinguishant.

There are some liquids where the use of water can be positively hazardous. This may be the case where there is an undesirable reaction between the liquid and the water so that an explosive or toxic hazard is created. This aspect has been discussed above.

Where the liquid is a refrigerated liquefied gas, the use of water for firefighting is generally discouraged except for very small fires, since it has the effect of increasing the vaporization of the liquid. Further discussions of the use of water with LNG and with LFG fires are given in Section 16.35.

Water conducts electricity in the solid stream condition and water jets should not be used against electrical fires. This aspect is discussed further in Section 16.34.

Water is a relatively ineffective agent on a weight basis and is not very attractive for self-contained mobile, and particularly portable, equipment. This characteristic is less significant for use in fixed systems, where the quantities used are large.

Fire extinguishment by blanketing may be achieved using foam. Foam is frequently the most effective agent for fire on liquids in spillages, bunds and storage tanks. Foam is essentially expanded water and, apart from its density, has the general characteristics of water. It is just as unsuitable as water for fighting fires involving electrical equipment or substances which have undesirable reactions with water. The uses and limitations of foam are considered in Section 16.28. There are a number of different types of foam, each with its characteristic uses.

The other principal agents are dry chemicals, vaporizating liquids and inert gases. Their uses and limitations are treated below.

It should be appreciated that where use is made of agents which are available in limited amounts only, it is essential to kill the whole fire first time. The supply of dry chemicals, for example, is usually sufficient to last only some tens of seconds. Unless the fire is completely extinguished, it is likely to reignite. On the other hand, foam forms a relatively long-lived blanket on the liquid and thus prevents reignition. This ability to hinder reignition makes foam an especially useful firefighting agent.

It is necessary to establish that the firefighting agent selected is capable of extinguishing a fire on the particular chemical concerned and this may require that tests be conducted. As already mentioned, tests may be needed to check the effectiveness of foam; they may also be necessary to verify that of vaporizing liquids or dry powders.

In selecting a firefighting agent, regard should be given to hazards to personnel. This aspect of selection is discussed in GS 16.

16.26 Fire Protection Using Water: Extinguishment and Control

Water is used in several distinct ways to fight fire. These are:

(1) extinguishment of fire;
(2) control of fire;
(3) fire exposure protection;
(4) fire and explosion prevention.

The third application is discussed in the next section and the others in this section.

Fire protection using water is treated in the NFPA *Handbook* by Hodnett (1986e). Two principal codes are NFPA 13: 1991 *Installation of Sprinkler Systems* and NFPA 15: 1990 *Water Fixed Systems*.

16.26.1 Water as a firefighting agent

Some general characteristics of water as a firefighting agent have been outlined in the previous section. Further aspects are considred here, particularly in relation to fires of flammable liquids.

Water is much the most widely used firefighting agent. The majority of fires which occur are fires in buildings or fires of other solid materials, and for these the most suitable agent is generally water. But water is also important as an agent for fighting fires, including liquid fires, in process plant.

It is most effective against fires of high flashpoint liquids. The principal mechanism is the cooling of the liquid so that its vaporization is reduced. The cooling effect is strong, because water has a high latent heat. With fires of low flashpoint liquids, however, it becomes more difficult using water to achieve a sufficient reduction in the vaporization.

Another important mechanism by which water extinguishes liquid fires is vaporization to form steam, which blankets the fire and cuts off the oxygen.

In fires of particular liquids other mechanisms may be involved. If the liquid is miscible with water (e.g. ethylene oxide), addition of water reduces the vapour concentration. A similar result is obtained if the water added forms an emulsion on the surface of the liquid. If the liquid is denser than water (e.g. carbon disulfide), water floats on the surface and prevents vaporization altogether.

On the other hand, if the liquid has a low boiling point, and particularly if it is a refrigerated liquefied gas, the effect of adding water is not to take heat away from the liquid as latent heat of vaporization of water, but to put heat in as sensible heat of cooling of water, and thus to increase the vaporization of the liquid.

The water used to fight a fire may be large in volume and is liable to become contaminated. Its removal can pose a serious problem. This may well be a factor in the deciding whether water is the appropriate agent to use.

The hazards associated with the use of water for certain types of fire are discussed in Subsection 16.26.3.

16.26.2 Extinguishment of liquid fires

Work has been done by Rasbash and co-workers on the extinction of liquid fires (e.g. Rasbash and Rogowski, 1957; Rasbash and Stark, 1960, 1962; Rasbash, Rogowski and Stark, 1960; Rasbash, 1962). The work has been reviewed in relation to water spray systems by P. Nash (1947b). For this purpose flammable liquids may be divided into three classes, depending on the mechanism of extinction:

(1) liquids not miscible with water and with a fire point >45°C;
(2) liquids miscible with water and therefore capable of having their fire point raised above 45°C by the addition of water;
(3) liquids not miscible with water and with a fire point <45°C.

The first class of liquid may be extinguished by heat transfer from it to water drops which penetrate its surface until its temperature falls below the fire point. Such liquids include heavy fuel oil, diesel oil, gas oil, and, as a borderline case, kerosene.

The water drops must enter the liquid in sufficient quantity despite the updraught of the flames and the evaporation of the spray in the flames. Factors which assist in achieving this are positioning of the spray near the liquid surface, high spray impetus and large liquid drop size. The impetus of the spray depends on the reaction of the nozzle and the width of the spray.

Figure 16.126 shows the results of some experiments of kerosene burning in a 30 cm diameter vessel with downward application of the spray (Rasbash, 1962). The ratio of the water actually penetrating the liquid surface to that expected to do so from geometrical considerations varied from about 10% to about 60%, depending on the thrust of the air current and the drop size of the spray. It was found that a mass median drop size above 0.4 mm is necessary to penetrate the flames effectively, but that at a drop size of about 0.8 mm the penetration becomes nearly independent of impetus and that above this size there begins to be a problem with splash fires caused by the larger drops splashing liquid from the surface so that burning continues even after the average liquid temperature has fallen below the fire point.

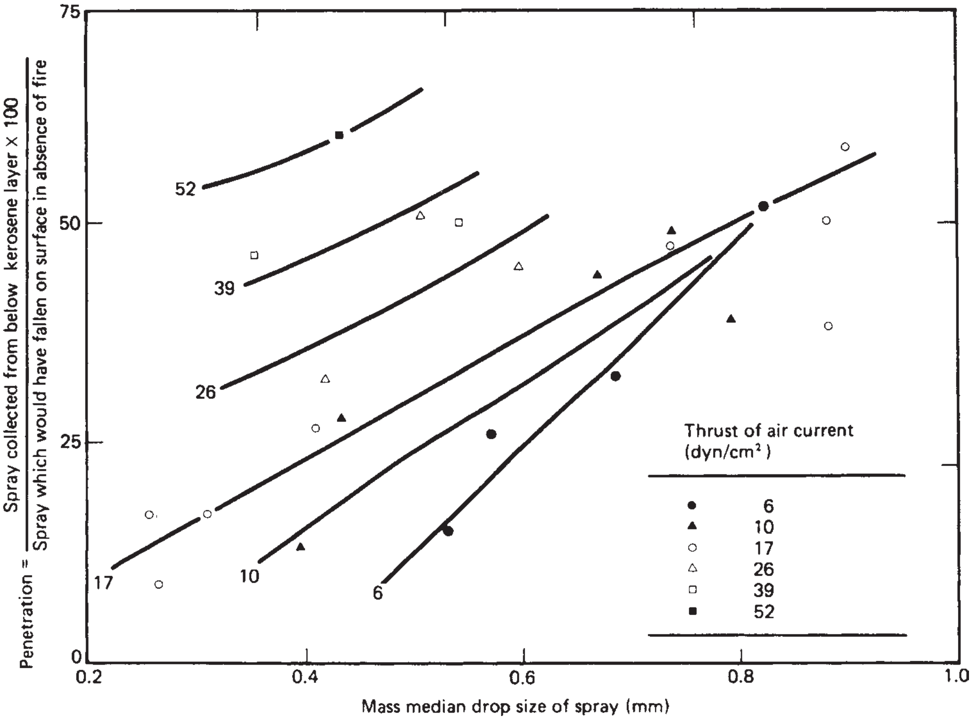

Figure 16.126 *Effect of the mass median drop size on the penetration of a water spray into a flammable liquid surface (Rasbash, 1962): kerosene fire, 30 cm diameter; downward application of spray; pressure at spray nozzle 0.35–2.1 bar (5–30 lbf/in.^{2}); flow rate to fuel surface in absence of fire 0.4–1.2 g/cm^2 min (Courtesy of the National Academy of Sciences)*

The work demonstrated that extinction can be achieved by application of water above a critical rate which is given by the equation

$$R_c = k_1 \frac{D^{n_1}}{\Delta T^{n_2}} \qquad [16.26.1]$$

where D is the mass median drop size (mm), R_c is the critical rate of water application (l/min), ΔT is the difference between the water temperature and the liquid fire point (°C), k_1 is a constant, and n_1 and n_2 are indices.

In practice it is necessary for the value of ΔT to be at least 40°C if the critical rate is not to be excessive. The indices n_1 and n_2 are approximately unity. The constant k_1 is a function of the flammable liquid, the area of the fire and the time for which the fire has already been burning. For a tray of gas oil of 8 ft diameter which has burned for 5 min before spray application, the value of k_1 was approximately 1140.

The time taken to extinguish the fire at rates of water application above the critical value is given by the equation

$$t = 5.2 \times 10^5 \frac{D^{0.85}}{R^{0.67} \Delta T^{1.67}} \qquad [16.26.2]$$

where R is the rate of water application (l/m^2 s) and t is the time to extinguish the fire (s).

Water spray systems for this liquid class typically use rates of water application in the range 0.16–1.2 l/m^2 s (9.6–72 l/m^2 min). High velocity nozzles are used with nozzle pressures of 2.75 bar (40 psig) or above and with a conical spray. The desirable mass median drop size is an even distribution in the range 0.4–0.8 mm and the drops should have a velocity sufficient to penetrate the liquid surface.

When a deep pool of liquid in this class in burning, it may form after a period a 'hot zone' and water below the surface may then boil and cause a 'slopover', thus spreading the fire. This can heppen, for example, with fuel oil which has been burning in depth for 15–30 min. It is necessary, therefore, to try to detect and extinguish fires before a hot zone occurs.

The second class of liquid may be extinguished by diluting the surface layer with water until the fire point of the mixture is raised sufficiently to cause extinction. Typical liquids are ethanol and acetone.

Although in this case the basic requirement for extinction is rather simple, there are certain problems. It is not always easy to tell when extinction has been achieved, since flames may continue to burn at some point and may be difficult to detect due to their low luminosity. Even if the fire is extinguished, the liquid remains flammable unless the whole bulk is diluted, and this may not be easy to achieve without spreading the spillage. Acetone, for example, requires a dilution of some 30 : 1.

The mass median drop size for a water spray for this liquid class should be less than 0.4 mm.

Liquids which are only partially miscible with water and have a low fire point are difficult to extinguish with water and generally their fires can only be controlled. Such liquids include ether and methyl ethyl ketone.

For water spray systems for such partially miscible liquids rates of water application in the range 0.12–0.30 l/m^2 s (7.2–18 l/m^2 min) are normally required with nozzle pressures of 1.4 bar (20 psig) or above.

The third class of liquid may be extinguished by cooling the flame by heat transfer to the water droplets falling through it. Such liquids include petrol and, again as a borderline case, kerosene. It has been estimated that to cool a kerosene flame to extinction it is necessary to remove about 0.1 cal/cm^3 s if extinction is solely by steam formation and about 0.7 cal/cm^3 s if it is entirely by cooling. Thus the rate of heat removal to achieve extinction is of the order of 0.1–1 cal/cm^3 s, depending on the conditions.

The drop size required depends on several factors. In general, the extinction time falls sharply as drop size is reduced. With some liquids such as petrol it is essential that the drops penetrate to the lower part of the flames. There can be some 'sputtering' at the liquid surface, however, in the early stages of extinction if the drop size is too small. A mass median drop size of about 0.3 mm is usually suitable. Medium velocity nozzles of the open or closed type are used.

Additional cooling is obtained from air entrained with the spray. This effect is increased by the use of high nozzle pressures and drop velocities.

Water sprays are also used to deal with certain electrical fires, as described in Section 16.34.

16.26.3 Hazards associated with water

Although water is the most common firefighting agent, there are certain cases where it use is hazardous. One such case is where the material is incompatible with water, as discussed in the previous section. Another is where the fire is incompatible with water. This applies to in particular to metal fires, which are considered in Section 16.34.

The use of water on live electrical equipment involves the hazard of electrical shock. The extent to which water can be used with electrical fires is discussed in Section 16.34.

Also, as already mentioned, the use of water in large quantities and contamination of this water can pose a problem of disposal. Uncontrolled release of such water can cause damage to the environment.

16.26.4 Delivery systems for water

Water is delivered to the fire mainly either by fixed systems such as water sprinkler and water spray systems and fixed water monitors or by mobile systems such as fire hoses. Little use is made of water in portable systems.

Fixed water systems are used both indoors and outdoors. Indoors, widespread use is made of water sprinkler systems. Water spray systems may also be used indoors. Outside water spray systems and fixed water monitors predominate.

16.26.5 Applications of fire extinguishment or control

For most fire protection applications water is the agent of choice.

Fixed water sprinkler systems are used to protect indoor areas. Fixed water spray systems are used indoors to protect specific equipment such as grinding mills or conveyors.

Outdoors, fixed water spray systems are used to protect vulnerable items, loading and unloading facilities, including jetties, and storage vessels. Fixed water monitors are also provided for tank farms and jetties.

Except where it is unsuitable, water is the main agent used in mobile equipment by the works and public fire services for fighting fire wherever it occurs.

16.26.6 Fixed water sprinkler systems

Fixed water delivery systems are widely used in process occupancies. Fixed water sprinkler systems are used for fire extinguishment by delivering specified quantities of water over the protected area, mainly in buildings and warehouses. Fixed water spray systems are used for fire extinguishment or control by delivering specified quantities of water spray, characterized by the nozzle used, onto the protected equipment or area.

There is a considerable literature on fixed water sprinklers systems. It includes treatments by O'Dogherty, Nash and Young (1966), the Fire Offices Committee (1968), Kalelkar (1971), P. Nash (1972a, 1973a, 1976, 1975a,b, 1975 BRE CP 79/75, 1977a,b, 1990), Nash, Bridge and Young (1974 BRE CP68/74), Leworthy (1975), Nash and Young (1975 BRE CP29/75, CP67/75, CP52/76, CP77/75, CP78/75), Rogers (1977 BRE CP9/77), Nicholls (1981), R. Young (1981), Theobald (1987a,b), Yao (1988), FMRC (1991) and Melinek (1993b).

Fire protection by fixed water sprinkler systems is treated in the NFPA *Handbook* by several authors, notably Hodnett who deals with automatic sprinklers (1986a), automatic sprinkler systems (1986b) and water supplies for sprinkler systems (1986d).

Relvant NFPA codes are NFPA 13: 1991 *Installation of Sprinkler Systems*, NFPA 13A: 1987 *Inspection, Testing and Maintenance of Sprinkler Systems*, NFPA 16: 1991 *Deluge Foam–Water Sprinler and Spray Systems* and NFPA 16A: 1988 *Installation of Closed-Head Foam–Water Sprinkler Systems*. Other NFPA publications on sprinklers include *Automatic Sprinkler and Standpipe Systems* (1990/25), *Automatic Sprinkler Systems Handbook* (1994/37) and *Installation of Sprinkler Systems* (1994/39). The relevant British Standard is BS 5306 *Fire Extinguishing Installations and Equipment on Premises*, Part 2: 1990 *Specification for Sprinkler Systems*.

NFPA 13 is a large code, covering the use of sprinklers generally rather than in the process industries.

The elements of a fixed water sprinkler system include the sprinkler alarms, the sprinkler heads, the water distribution pipework, the valves and other fittings, and the water supply system and disposal arrangements.

The NFPA gives a classification of occupancies relevant to sprinkler systems. Those with moderate or substantial amounts of flammable liquid fall into the group Extra Hazard (Group 2).

A sprinkler system needs to respond rapidly so that the fire is extinguished before it can take hold. The time response of the sprinkler head is therefore crucial. Traditionally sprinkler heads have been classed according to the temperature at which they respond (e.g. 68°C). For fast response it is the time constant which matters. Fast response sprinklers are discussed by P. Nash (1972a), Watson (1984), Field (1985), Murrell (1988) and Mullhaupt (1986).

The use of sprinkler systems as fire sensors is considered by Nash and Theobald (1976 BRE CP50/76).

A sprinker system needs to be designed so that each head is supplied with the intended water pressure. The hydraulics of sprinklers are treated in *Hydraulics of Fire Protection Systems* (FMEC, 1977) and *Sprinkler Hydraulics* (Wass, 1983) and by Nickerson (1954), C.M. Wood (1961), Beyler

(1977), Ashfield (1979), Barris and Conte-Russian (1980), Bray (1980), Cresswell (1980), Kitson and Guy (1980) and Crowley (1982).

One way of achieving a uniform distribution of water in a sprinkler system is the use of a balanced system in which this uniformity is assured by the similarity of the pipework from the source to the individual sprinkler heads. For a system which it not balanced in this way it is necessary to ensure uniform distribution by calculating the pressure drops between the source and the individual heads.

16.26.7 Fixed water spray systems

As just indicated, fixed water spray systems are distinguished by the fact that the spray is characteristic of the type of nozzle used.

Accounts of fixed water spray system are given by Rasbash and co-workers, as already described, and by P. Nash (1974b), Hems (1979, 1983), Fritz and Jack (1983), Angelini (1984), Lev and Strachan (1989a,b), McCaffrey (1989), Chow and Fong (1991) and Jackman and Nolan (1994).

Fire protection by fixed water spray systems is treated in the NFPA *Handbook* by Hodnett (1986c).

Relevent codes and standards are NFPA 15: 1990 *Water Spray Fixed Systems* and NFPA 16: 1991 *Deluge Foam–Water Sprinkler and Spray Systems*.

The elements of a fixed water spray system include the fire detection and alarm system, the spray nozzles, the water distribution pipework, the valves and other fittings, and the water supply system and disposal arrangements.

16.26.8 Fixed water monitors

For fire risks involving large quantities of flammable liquid, notably tank farms and jetties, fixed water monitors are generally provided. These monitors are generally dual purpose devices which can be used to project water or foam.

16.26.9 Water rates for extinguishment or control

Recommended water rates for the extinguishment or control of fire are given in the various codes and standards. Those recommended by the NFPA probably have the greatest currency. NFPA 15 distinguishes the four types of application, listed at the beginning of this section, and gives for each type a recommended approach.

NFPA water rates for fire extinguishment

For fire extinguishment, NFPA 15 states that water rates should be based on tests or experience. It gives a general, or default, range of water rates which applies to the protected surface for most combustible solids and flammable liquids. This is 0.2–0.5 USgal/ft^2 min (8.1–20.4 l/m^2 min).

NFPA water rates for control of burning

For control of burning, NFPA 15 states that the water rate on the probable surface of the spill should not be less than 0.5 USgal/ft^2 min (20.4 l/m^2 min).

Control rather than extinguishment of the fire implies that the water flow needs to be maintained. NFPA 15 requires that the system function at full effectiveness until there has been time for the flammable material to be consumed, for the leak to be shut off, for the assembly of repair forces, etc.

NFPA water rates for exposure protection

For exposure protection, or cooling, the water rates recommended in NFPA 15 vary according to the item protected. They are considered in the next section.

NFPA water rates for fire and explosion prevention

For fire and explosion protection NFPA 15 simply states that the water rate should be based on tests or experience.

Critique of NFPA recommended water rates

A critique of water rates traditionally recommended has been given by Fritz and Jack (1983). They take as their starting point the then current edition of NFPA 15 and deal both with water rates for extinguishment or cooling and rates for exposure protection.

They refer in particular to work at the Rubber Reserve Company in the 1940s on horizontal cylindrical vessels containing fuel (gasoline, butane and butadiene–butylenes mixtures) and engulfed in fire.

Fritz and Jack discuss the work of Rasbash and co-workers on fire extinguishment described above. They draw attention to the influence of the water nozzle and spray characteristics on the water rates needed for extinguishment and to the fact that these characteristics are not specified in the NFPA codes. They consider the water rate required to effect extinguishment based on a heat balance model in which the total heat released by combustion goes to evaporate the water. They obtain from this a water rate of 2.5 USgal/ft^2 min. On this basis they suggest that a water rate of 0.5 USgal/ft^2 min is no more than cosmetic. They also discuss the water rate for exposure protection, as discussed in the next section.

16.26.10 Fire water supply systems

The amount of water needed for firefighting and cooling presents a considerable problem. Aspects where better understanding may lead to less onerous requirements include the heat flux from liquid fires, the reflectivity and wetability of tank surfaces, and methods of applying the water to the surfaces.

Water spray systems both for firefighting and for cooling may be of two types. In a wet system the pipes are kept full of water under pressure, whereas in a dry system these pipes are normally empty and are filled by the opening of a master valve only when the system is to be activated. A dry system should be used where there is risk of freezing. It is therefore this type of system which is most suitable for process plants, particularly in the open. The pipework in a dry system needs to be arranged to allow complete drainage.

There should be a secure water supply to the water spray system. This aspect is discussed in Chapter 10 in relation to plant layout.

There are a number of ways in which a water spray system can be rendered ineffective. One of these is freezing up, as just mentioned. Another is leaving valves closed, particularly after maintenance. The latter occurrence needs to be guarded against by specific procedures.

In addition, it is not uncommon for a water spray system to be knocked out by an explosion. The Fourth Edition of the Dow *Guide* (Dow Chemical Company, 1976) states that where an explosion hazard exists, it is a recommended minimum prevention and protection feature that water spray piping of $2\frac{1}{2}$ in. diameter or above be welded or flanged, not threaded.

16.26.11 Fire water disposal systems

As already indicated, the disposal of fire water, particularly contaminated water, can be a serious problem, which it is sufficient here to highlight. As an aspect of plant layout, fire water disposal is treated in Chapter 10. A method of alleviating this problem which merits mention here, however, is the use of foam to obtain a given degree of fire extinguishment or control with a smaller water usage.

16.27 Fire Protection Using Water: Exposure Protection

In the foregoing section an account has been given of the use of water to extinguish or control a fire. In this section consideration is given to its use for exposure protection by cooling of equipment exposed to fire.

Accounts of fire exposure protection are given by Pettit (1945), Chaillot (1966), P. Nash (1973b, 1974a), Fritz and Jack (1983), Billings, Moodie and Beckett (1986), Lev and Strachan (1989b), Lev (1991) and Meiers and Jarman (1993).

As indicated above, a relevant code for exposure protection using water is NFPA 15.

16.27.1 Delivery systems for water

The means of delivery of water for cooling are broadly similar to those used for extinguishment. Water is delivered to the protected surface by fixed systems such as fixed water spray systems and fixed water monitors or by mobile systems such as fire hoses.

16.27.2 Applications of water cooling

Essentially, exposure protection is provided for large flammable gas or liquid inventories which are liable to be exposed to a fire. For the most part such inventories occur in storage tanks and vessels, though protection may also be provided for certain process vessels and for road and rail tankers.

The purpose of providing such protection is to cool the metal and so prevent loss of strength. It is normal to provide the tank or vessel with pressure relief but, even if the relief operators, it will not prevent failure if the wall temperature is allowed to rise too high.

16.27.3 Water rates for cooling

NFPA water rates for cooling

For exposure protection by cooling, NFPA 15 treats the following cases: vessels, structures and miscellaneous equipment, transformation and belt conveyors.

For vessels, the code states that the rules given assume that there is a relieving capacity based on a maximum allowable heat input of 6000 BTU/ft^2 h (18.9 kW/m^2). If there is no such relief, the water rates should be increased accordingly.

For a vertical or inclined vessel surface the water rate should not be less than 0.25 USgal/ft^2 min (10.2 l/m^2 min) of exposed uninsulated surface. Where on such a surface rundown is assumed, the vertical distance between nozzles should not exceed 12 ft (3.7 m). The horizontal extremities of the spray patterns should at least meet.

For a vertical vessel the bottom and top surfaces should be completely covered by directed water sprays with a water rate of 0.25 USgal/ft^2 min (10.2 l/m^2 min) of exposed uninsulated surface. On the bottom surface the horizontal extremities of the spray patterns should at least meet.

The surfaces below the equator of a spherical or horizontal cylindrical vessel cannot be considered to be wetted by rundown.

The code also gives various other provisions.

The structures and equipment considered are primarily horizontal and vertical structural steel members, pipework and pipe racks, and cable trays and cable runs. Water rates are given for each of these.

Critique of NFPA recommended water rates

Mention has already been made of the critique by Fritz and Jack (1983) of the water rates recommended in NFPA 15 for fire extinguishment or control. These authors also review the NFPA recommendations on water rates for exposure protection.

The background to these recommended rates is work on heat fluxes to vessels engulfed in fire, such as the tests listed in API RP 520: 1990 and earlier editions, which include the Rubber Reserve Company tests mentioned in the previous section.

In this case the authors base their estimate of the cooling water requirement on a heat removal rate of 20,000 BTU/ft^2 h, effected by a rise in water temperature to a few degrees above the boiling point. On this basis they obtain an estimate of 0.04 USgal/ft^2 h for the required water rate. They suggest that the NFPA recommended value of 0.25 USgal/ft^2 h is higher than it need it.

Thus Fritz and Jack's critique of the NFPA water rates recommended is that for fire extinguishment they are too low, but that for exposure protection they are too high.

Other Recommneded Water Rates

For the exposure protection of storage tanks containing low fire point liquids a rate of water application over the surface of the tank of 0.2 UKgal/ft^2 min (0.16 l/m^2) is recommended by P.H. Thomas and Law (1965 FRS Fire Res. Note 609).

The Fourth Edition of the Dow *Guid*e (Dow Chemical Company, 1976) gives as a recommended minimum fire prevention and protection feature exposure protection a rate of 0.2–0.35 USgal/ft^2 min (0.14–0.24 l/m^2 s) for directional sprays. The later editions give water rates as part of the loss control credits, but these refer to indoor sprinkler applications.

For the exposure protection of LFG vessels the ICI *LFG Code* (ICI/RoSPA 1970 IS/74) recommends a rate of 0.20 UKgal/ft^2 min (0.16 l/m^2 s), but allows a reduced rate if certain precautions are taken. This is discussed more fully in Chapter 22.

16.27.4 Cooling of tank exposed to a pool fire

A tank exposed to fire, including an engulfing fire, may be cooled by applying water. The water rates recommended have just been described. At these water rates the total water requirements may be very large. The requirements for exposure protection generally greatly exceed those for extinction of fire.

This generalized requirement is not difficult to meet for small tanks, but becomes much more onerous for large ones. Thus, based on this criterion, the water requirement for an 80 m diameter tank is of the order of 150 t/min. The power required to lift and distribute the water is large also, being about 1 MW.

The water needed for exposure protection is greatly reduced if application is restricted to the tank roof and ullage sections. Figure 16.127, given by P. Nash (1973b, 1974a), illustrates this difference. The curves are based on the water rates recommended in the then current edition of NPFA 15, which were 0.25 USgal/ft^2 min. Curves A1 and B1 give, respectively, the water requirements for extinction and exposure with coverage of the whole tank and with coverage of the roof and ullage sections only. Curves A2 and B2 give the corresponding water requirements for exposure only.

A further discussion of the use of water sprays for protection against fire exposure is given in relation to storage in Chapter 22.

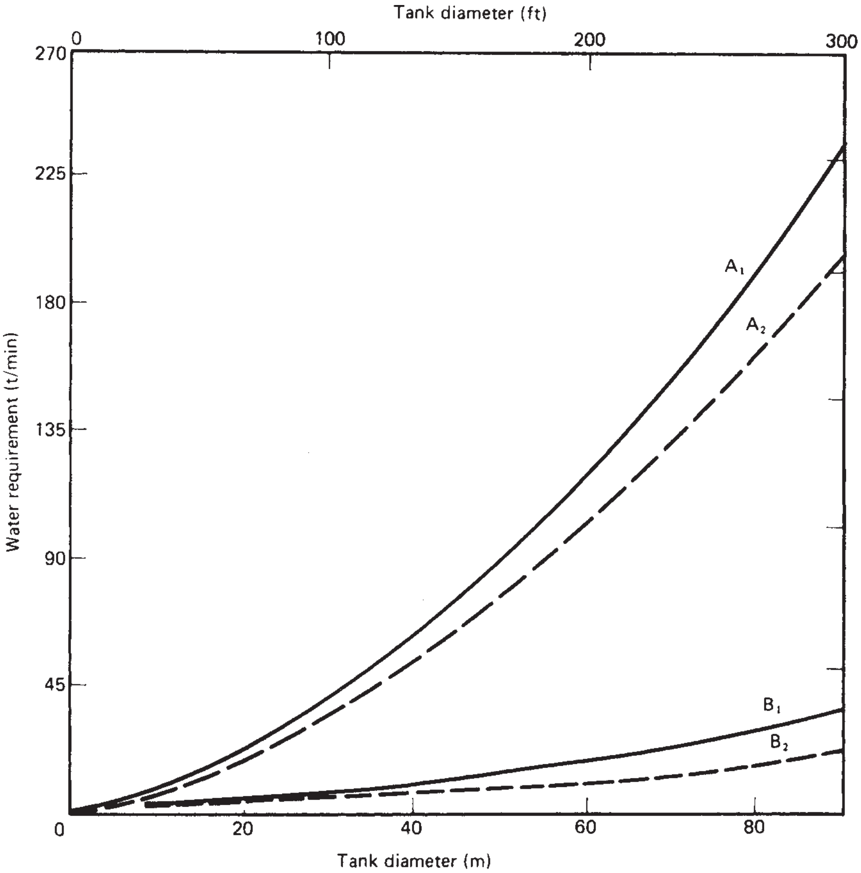

Figure 16.127 *Water requirements for protection against exposure to fire and for extinction of fire for a storage tank (P. Nash, 1974a): A_1, NFPA 15 – extinction and exposure;A_2, NFPA 15 – exposure only; B_1, 'economial' requirement – extinction and exposure; B_2, 'economical' requirement – exposure only (Reproduced by permission of HM Stationery Office. 16.27.5 Cooling of vessel exposed to an impinging jet flame

A rather different, and stringent, fire protection requirement arises where a jet flame impinges directly on a target. This problem has been studied by Lev and Strachan (1989b) and Lev (1991).

The surface of a vessel exposed to a jet flame is likely to rise to a temperature of over 100°C very rapidly. A continuous film of water over the metal surface is capable of intercepting radiant heat, but as the heat flux is increased the protection so afforded is gradually lost as the water film thins and then disintegrates.

A model for a water spray system to protect against jet flames has been described by Lev (1991). It has three main elements which model: (1) the three-dimensional droplet trajectory, (2) the in-flight evaporation loss and (3) the heat transfer between the cooling water and the metal surface.

For the droplet trajectory, the equation of motion of a droplet moving through a parallel gas stream is written as

$$m_\mathrm{d}\frac{\mathrm{d}v}{\mathrm{d}t} = C_\mathrm{d}\rho_\mathrm{g}(U - v)(|U - v|)\frac{\mathrm{A}}{8} - m_\mathrm{d}g \qquad [16.27.1]$$

where$A$ is the surface area of the droplet (m^2), C_d is the drag coefficient, g is the acceleration due to gravity ($\mathrm{m/s}^2$), m_d is the mass of the droplet (kg), t is the time (s), U is the gas velocity (m/s), v is the droplet velocity (m/s) and ρ_g is the gas density ($\mathrm{kg/m}^3$).

The drag coefficient is taken as given by the following relations for a non-evaporating droplet, the correction for evaporation being small:

$$C_\mathrm{d} = 24/\mathrm{Re} \quad \mathrm{Re} < 2 \quad \text{Stokes regime} \qquad [16.27.2]$$

$$C_\mathrm{d} = 10/(\mathrm{Re})^{1/2} \quad 2 < \mathrm{Re} < 500 \quad \text{Intermediate regime} \qquad [16.27.3]$$

$$C_\mathrm{d} = 0.44 \quad \mathrm{Re} > 500 \quad \text{Newton's regime} \qquad [16.27.4]$$

with

$$\mathrm{Re} = \frac{D(|U - v|)}{\nu} \qquad [16.27.5]$$

where D is the droplet diameter (m) and v is the gas kinematic viscosity (m^2/s).

For the in-flight evaporation loss, use is made of the correlation of Ranz and Marshall (1952), with the correction for high stream temperatures given by Yuen and Chen (1978):

$$\mathrm{Nu}(1+B) = 2 + 0.6\,\mathrm{Re}^{0.5}\mathrm{Pr}^{0.33} \quad [16.27.6]$$

with

$$B = (h_s - h_d)/L \quad [16.27.7]$$

where B is a mass transfer number, h_d is the surface enthalpy of the droplet (J/kg), h_s is the free stream enthalpy (J/kg) and L is the latent heat of evaporation of the droplet (J/kg). The properties are evaluated at the film temperature.

Since the work of Yuen and Chen was done using streams of hot air, it is necessary also to introduce a term for absorbed radiant heat:

$$M_r = cQA\delta t/L \quad [16.27.8]$$

where c is an absorption coefficient, M_r is the rate of evaporation loss due to thermal radiation (kg/s), Q is the heat flux to the droplets (W/m^2) and δt is the time of exposure of the droplet (s).

For the heat transfer between the cooling water and the surface, the relation used is that of Yao and Choi (1987):

$$Q = 29.5 \times 10^{-4} G^{0.76} \quad [16.27.9]$$

where G is the liquid mass flux (kg/m^2 s) and Q is the heat flux between the water and the surface (W/m^2).

Information on the flame temperature and surface emissive power in jet flames has been reviewed by Lev (1991). A study by Blything (1983 SRD R263) quotes a flame temperature of about 1300°C and heat fluxes of about 300–400 kW/m^2. Work on jet flames by Cowley and co-workers (Cowley, 1989; Tam and Cowley, 1989; Cowley and Pritchard 1991) on several different configurations has shown heat fluxes in the range 50–250 kW/m^2.

The model described was used to obtain results relevant to spray system design. These showed that the heat transfer passes through a marked maximum with surface temperature, this maximum occurring around 140–150°C. Thus the water mass flux to remove the heat from an incident heat flux of 250 kW/m^2 was 12 kg/m^2 min at 150°C but 50 kg/m^2 min at 300°C. Due to instabilities, maintenance of conditions where the lower water rate is sufficient is dubious. Lev recommends, therefore, a design cooling water rate of some 60–120 kg/m^2 min.

In order to deliver this cooling water under conditions where there is likely to be in-flight evaporation and crossflow losses, the droplets need to be large and to be projected at high velocity. Lev presents results from the model showing the fraction of water droplets reaching the target as a function of crossflow velocity and droplet diameter. Droplets of less then 0.5 mm diameter are vulnerable and a droplet size of more than 1 mm diameter should be aimed for.

Typical medium velocity (MV) nozzles tend to produce a high proportion of droplets less than 0.5 mm in diameter. They appear less suitable that high velocity (HV) nozzles. Alternative modes of water delivery are hand-held monitors and fixed monitors. Suitable HV nozzles mounted less than 1 m from the target are capable of delivering the 60–120 kg/m^2 min required. There are hand-held monitors which from a distance of 16 m can deliver water at a rate of 120 kg/m^2 min, wetting an area of 6 m^2.

The method just described is applicable to impining jet flames of LPG with stream temperatures of 500–1300°C and stream velocities up to 40 m/s with radiative heat fluxes of 50–250 kW/m^2 and for metal surface temperatures of 150–300°C.

16.27.6 Fixed water cooling systems

Exposure protection is effected using fixed water spray systems. Proper cooling requires that water be applied such that the whole surface protected is wetted by the water rate specified. The spray nozzles should be located so that the extremities of the spray pattern at least meet, and for wetting below a vessel equator reliance should not be placed on rundown. More detailed requirements have been given in the previous section.

The relevant codes, notably NFPA 15, have been discussed in the previous section.

16.28 Fire Protection Using Foam

A prime alternative to water, particularly for large fires, is foam. Accounts of foam are given by Burgoyne (1949a), Burgoyne, Katan and Richardson (1949a), the American Chemical Society (ACS) (1956), Burgoyne and Steel (1962), Vervalin (1964b,d), Meldrum and Williams (1965), Ashill (1966b), G. Nash (1966), Hearfield (1970), Hird, Rodrigues and Smith (1970), Meldrum (1972, 1982), P. Nash (1973b), Corrie (1974, 1975 BRE CP25/75), Nash and Young (1975 BRE CP42/75), Burford (1976), Gillespie and Dimaio (1977), Murphy (1981), Boughen (1983), J.L. Evans (1985, 1988), SKUM (1986), A.A. Briggs and Webb (1988), Tabar (1989), Waters (1990 LPB 91) and M. Clarke (1992). Fire protection using foam is treated in the NFPA *Handbook* by Lockwood (1986).

Relevant codes and standards are NFPA 11: 1988 *Low Expansion Foam and Combined Agent Systems*, NFPA 11A: 1988 *Medium and High Expansion Foam Systems*, NFPA 16: 1991 *Deluge Foam–Water Sprinkler and Spray System*, NFPA 16A: 1988 *Installations of Closed Head Foam–Water Sprinkler Systems*, NFPA 11C: 1990 *Mobile Foam Apparatus* and BS 5306: 1976– *Fire Extinguishing Installations and Equipment on Premises*, Part 6: Foam, Section 6.1: 1988 *Specification for Low Expansion Foams* and Section 6.2: 1989 *Specification for Medium and High Expansion Foams*.

16.28.1 Mechanisms of fire extinguishment

Foams are widely used against liquid fires. Initially the foam acts as a blanketing agent and then, as the water drains from the foam, as a cooling agent.

16.28.2 Types of foam

Foams are water based and come in several kinds. These include:

(1) chemical foam;
(2) protein-based mechanIcal foam
    (a) standard, low expansion foam,

  - (b) high expansion foam,
  - (c) medium expansion foam;
- (3) special foams
  - (a) fluorochemical foam,
  - (b) fluoroprotein foam;
- (4) detergent foam;

There is now a large family of foams of different types and applications. One broad distinction is made on the basis of the viscosity of the foam. The blanket formed by the more viscous type is resistant to rupture by flame, but the less viscous type flows more readily over a liquid surface. Other relevant properties of foams are their resistance to oil and alcohols.

Chemical foam

Chemical foam is produced by reacting aqueous solutions of sodium bicarbonate and aluminium sulfate in the presence of a foam stabilizer. The reaction generates carbon dioxide, which both forms foam and ejects the mixture from the apparatus. This type of foam may be regarded as obsolete, its use long having been almost entirely confined to mobile and portable equipment.

Protein, or mechanical, foam (P)

Mechanical foam is generated by mechanical aeration of aqueous solutions of certain chemicals, which usually have a protein base. One type is based, for example, on blood hydrolysed by caustic soda. Standard foam is made by introducing the foam compound into the water in the hose to give a 3–6% aqueous solution and then mixing the solution with air in an ejector nozzle to give an approximately 10 : 1 expansion. This type of foam is the most widely used both for fixed and mobile apparatus. Such standard low expansion foam is very cheap.

High expansion foam is generally similar to standard foam but has an approximately 1000:1 expansion. This type of foam contains little water so that it acts almost entirely by blanketing rather than by cooling. It is very light and is easily blown away, and is thus more suitable for fires in containers such as tanks or ships' holds than for those in open situations such as in a bund.

Medium expansion foam is again generally similar to standard foam, but has an approximately 100–150 : 1 expansion. This type of foam is also light, but is not so easily blown away as high expansion foam.

Both medium and high expansion foams have a good three-dimensional extinction capability and can be used against fires on piles of materials such as rubber.

A disadvantage of protein foams is that if the foam blanket is broken the liquid may re-ignite and burn back the blanket. Low expansion foam, however, has reasonably good heat and 'burnback' resistance.

Fluorochemical, or light water, foam

Agents have been developed to overcome this problem. One type is fluorochemical foam. This includes 'light water' foam, which contains a straight-chain fluorocarbon surface active agent. This has the effect that as the water drains from the foam it spreads in a thin film over the liquid and seals it. Even if the film is disturbed by agitation, it reforms rapidly. Light water foam behaves differently, however, on different liquids, and it is not universally effective. The cost of light water foam is high.

Fluoroprotein foam (FP)

Another agent which works in a similar manner is fluoroprotein foam, which contains a branched chain fluorocarbon. It is therefore a candidate where good burnback resistance is needed. It is less expensive and appears in many cases to be more effective than light water foam. Fluoroprotein foam is less prone to pick up oil particles when passed through oil. This 'fuel-shedding' property is useful in subsurface foam injection on storage tanks. This type of foam tends to have good compatibility with dry chemicals.

Synthetic detergent foam (S)

Synthetic detergent foam is generated by mechanical aeration of aqueous solutions containing 2–3% of detergent. This foam is less stable than protein-based foam. The most effective method of usage appears to be massive application is a knockout attack. Detergent foam has enjoyed some popularity, the attraction being that it is cheaper even than protein foam.

Aqueous film forming foam (AFFF)

AFFF has low viscosity and spreads easily over a liquid fires. Another useful property of AFFF is that does not need elaborate foaming devices and can be utilized in many water sprinkler and spray systems.

Film forming fluoroprotein foam (FFFP)

FFFP foam is another type of foam which has low viscosity and good spreading properties and can be used in many water spray systems. FFFP foam tends to drain rapidly and is therefore less reliable in maintaining a foam blanket.

Alcohol resistant (AR) foam

Regular air foams do not perform well on liquids which are of the polar solvent type, notably alcohols. For these AR foams have been developed. The first generation of AR foams were not entirely satisfactory, but effective foams have been developed. One type of AR foam is polymeric alcohol resistant AFFF.

Low temperature foams

Foams have been developmed for use at low ambient temperatures; one quoted temperature for such foams is −29°C. These foams come in both protein and AFFF types.

16.28.3 Properties of foam

A foam for firefighting should possess certain general properties, which include (1) expansion, (2) cohesion, (3) stability, (4) fluidity, (5) fuel resistance and (6) heat resistance.

Clearly, the foam must have an appreciable expansion ratio, its bubbles must cohere together and form a blanket, it must retain its water and remain stable, it must flow freely over the liquid surface and around any obstacles, it must not pick up so much fuel that it is itself liable to burn and it must resist the heat of flames on the liquid. Foams for use on alcohols must also be alcohol resistant.

Three quantitative criteria for foam are (1) the expansion, (2) the fluidity and (3) the drainage time. Expansion is measured by the expansion ratio.

A measure of fluidity is the shear stress. A shear stress in the range 150–200 dyn/cm^2, measured on a torsional viscometer, is typical of a good foam.

The drainage of liquid out of the foam is usually expressed as the '25% drainage rate', which is the time in minutes for 25% of the total liquid content to drain away under standard conditions. For a good foam this drainage time is typically 2–5 min.

Foam can be affected by the quality of the water used. A study by Dimaio and Lange (1984) detected deleterious effects from contaminants such as corrosion inhibitors, anti-fouling agents, etc. In general, however, such effects were found to be much weaker if high application rates were used.

Compatibility with other firefighting agents is another important property of foams. This aspect has been discussed above and is considered further below.

16.28.4 Tests for foam

There are a number of standard tests to evaluate the performance of foam in extinguishing fire. Standard tests include the Underwriters Laboratories and Det norske Veritas (DnV) tests and those specified in the MIL Specification MIL-F.24385, the draft ISO/DP 7203 and, in the United Kingdom, Defence Standards 42–21, 42–22, 42–24 and BS 6535: Part 6: 1988–. Such tests are discussed by J.L. Evans (1988) who compares the performance of different foams in different tests.

Tests may be required to establish the effectiveness of a foam in a particular application. Details of the conduct of tests to select a foam for methylisobutyl ketone (MIBK) have been given by Corrie (1974).

16.28.5 Hazards associated with foam

Foam is water based and, to this extent, hazards associated with water apply to foam also. They include increased vaporization of low boiling liquids, reaction with incompatible materials and electric shock from live wihe incompatible materials and electric shock from live electrical equipment.

Another hazard is rupture of the foam blanket and burnback, which may put firefighters at risk.

Hazard can arise from the use of a foam on a liquid at a temperature of 100°C or above. The formation of steam can cause a four-fold expansion of the foam with slopover of the burning liquid.

In the case of the medium and high expansion foams used to fill spaces, there is the hazard of asphyxiation.

16.28.6 Hazards associated with foam: static electricity

Another hazard is ignition of hydrocarbons in a storage tank roof by static electricity from foam injection, as described by Howells (1993 LPB 114). This author describes several incidents in which ignition of volatile refined products in a floating roof storage tank appears to have been caused by foam injection. He suggests two possible modes of charge generation: (1) the settling of water droplets through the hydrocarbon liquid and (2) the streaming current of the foam mixture leaving the nozzle.

Using Equation 16.7.173, Howells obtains for the case of a tank filled to a depth of 3 m with the bottom earthed, an estimated liquid surface potential of 27 kV, a value which has been shown in work on road tankers to be hazardous. He suggests that an even higher potential may occur if the foam jet is applied directly to the liquid surface so that the concentration of foam in the fuel is orders of magnitude higher than that used in this calculation.

With regard to the second mechanism, aqueous foam systems, has a high conductivity and any charge generated at the nozzle would be quickly dissipated back to the branch pipe or the tank walls. However, if charged foam enters the liquid the charge could be retained. The streaming current of foam of foam is not readily calculable, so experimental work was undertaken. At the time of writing this work was inconclusive.

16.28.7 Delivery systems for foam

Foams is delivered to the fire by means essentially similar to those used for water. The means used are mainly fixed systems such as foam–water spray systems and fixed foam–water monitors or mobile foam–water systems such as fire hoses. Little use is made of foam in portable devices.

The delivery of foam involves three stages: (1) proportioning of the foam concentrate, (2) foam generation and (3) foam distribution. There are a number of methods for the proportioning of the foam concentrate.

The devices for the generation of the foam are incorporated in the devices used for its distribution, as just described. The basic method of generation is aspiration of air into the foam.

A detailed account of methods of proportioning and distribution is given by Lockwood (1986).

16.28.8 Applications of foam

Fire extinction by blanketing may be achieved using foam. Low expansion foam is mainly used to prevent, extinguish or control fires in storage tank tops and bunds and on spills.

Foam should be used only if it is compatible with the hazardous liquid. In particular, foam is essentially expanded water and, apart from its density, has the general characteristics of water. It is just as unsuitable as water for fighting fires involving electrical equipment or substances which have undesirable reactions with water.

Other conditions for the use of foam are that the liquid surface be horizontal and that the temperature of the liquid be not too high. The liquid temperature should be below the boiling point. If the liquid temperature is below the boiling point but above 100°C, water in the foam will turn to steam, which can result in a very large expansion of the foam.

There are optimum rates of application of foam. For low expansion foam with an expansion ratio of 8 : 1 an application rate of 0.1 USgal/ft^2 will give 0.8 USgal/ft^2 min of foam. Foam application rates are discussed by Lockwood (1986). The foam should be applied gently.

Medium and high expansion foams are used to prevent, extinguish or control fire in spaces such as ships' holds. Application systems for these foams comprise both (1) total flooding systems and (2) local application systems.

16.28.9 Fixed foam systems

For low expansion foam, one type of fixed foam system is the foam–water deluge system. Another type of system is the foam–water monitor. Fixed foam systems are used for fire prevention, extinguishment and control in bunds or on spills.

Relevant codes are NFPA 11 for low expansion systems, NFPA 11A for medium and high expansion systems, NFPA 16 for deluge foam–water sprinkler and spray systems and NFPA 16A for closed head foam–water sprinkler systems.

The fighting of a major fire requires a very large quantity of foam. An example quoted by G. Nash (1966) is a requirement of 300 × 5 UKgal drums for a 30 min foam attack on a single 150 ft diameter oil storage tank. The supply, and disposal, of such a large number of drums in an area congested with fire appliances and hoses constitutes a major problem. He describes the alternative of providing a piped supply of foam concentrate.

16.28.10 Fixed foam systems for storage tanks

A particularly important application of foam is the protection of storage tanks. A variety of systems are used. Accounts of foam systems for storage tanks are given by E.M. Evans and Whittle (1974), P. Nash and Whittle (1978), Lockwood (1986) and SKUM (1986). A relevant code is NFPA 11.

For fixed roof tanks some principal arrangements are foam chambers, internal tank distributors and subsurface foam injection. Foam chambers are installed at intervals on the outside near the top of the tank wall, providing an over-the-top foam generation (OFG). An alternative is internal distributors fitted inside the tank.

Application of foam at the top of the tank poses several problems. If the fire is initiated by an explosion, this may well also disable the foam system. The upward flow of air caused by the fire may interfere with the distribution of the foam. In a large tank the foam may not reach the centre.

Subsurface foam injection is designed to counter these difficulties. Foam is injected under pressure up through the liquid in the tank. Injection may be through the product pipe or a dedicated line, Mobile foam trucks may be used to provide the foam supply.

Floating roof tanks may be open top or closed. They have a good fire record so that foam systems are generally not required, with one exception, This is the need to cater for rim fires which can occur on either type. An open-type floating roof tank may be protected by a fixed foam system which pours foam into the annulus formed by the tank wall and a foam dam. A closed floating roof tank may be protected using a top injection system similar to those used in fixed roof tanks. Subsurface foam injection is not generally used for floating roof tanks since a tilted or sunken roof can cause poor foam distribution.

16.28.11 Mobile foam systems

Foam trucks are the principal mobile mode of delivery for foam. The trucks are typically purpose built twin agent trucks with a capability of delivering dry chemicals also.

Relevant codes are NFPA 1901 which covers basic water systems with a foam option, and NFPA 11C which covers foam trucks.

Foam trucks carry a supply of foam concentrate and delivery hoses and can be equipped with telescopic booms of articulated towers. They have low clearances to allow passage under pipe bridges. A combined agent truck might typically carry AFFF and dry chemical. Monitor capacities are of the order of 500–1000 USgal/min.

There are a variety of mobile devices that can be used to apply foam to the top of a storage tank which is on fire. They include mobile foam monitors and foam towers. There are a number of problems in using a foam monitor for this purpose, such as crosswinds and fire updrafts, and a significant proportion can be wasted. Lockwood advises making an allowance of 60% above the desired application rate to allow for such factors.

16.28.12 Vapour suppression by foam

Fire control and extinguishment is not the only use of foam. Another important application is the suppression of vaporization from toxic liquid spills. This use of foam is treated in ASTM-F-1129-88 *Standard Guide for Using Aqueous Foams to Control the Vapor Hazard from Immiscible Volatile Liquids*. Vapour suppression using foam is discussed in Chapters 15 and 18.

16.29 Fire Protection Using Dry Chemicals

An alternative to water or water-based foam is dry chemicals, or dry powders. Accounts of dry chemicals include those by T.G. Lee and Robertson (1960), Vervalin (1964e), Laffitte *et al.* (1965), Emmrich (1971), Wesson (1972), Woolhouse and Sayers (1973), Schweinfurth (1974), Stauffer (1975), MITI (1976) and Ewing *et al.* (1989a,b). Fire protection using dry chemicals is treated in the NFPA *Handbook* by Haessler (1986).

Relevant codes and standards are NFPA 17: 1990 *Dry Chemical Extinguishing Systems* and BS 6535: 1989– *Fire Extinguishing Media*, Part 3: 1989 *Specification for Powder.*

The use of dry chemicals has been developed particularly in Germany, wher some large fixed and mobile systems have been used. Since with dry chemicals it is essential to apply enough agent to extinguish the fire outright, their use on large fires requires the availability of large quantities.

16.29.1 Mechanisms of fire extinguishment

The principal mechanism by which dry chemicals act against fire is to cause chain termination of the combustion reactions. There are several other less significant mechanisms. The bicarbonate chemicals release carbon dioxide in an endothermic reaction. To some extent the gas evolved blankets the liquid and the gas evolution reaction has a cooling effect, whilst the particle cloud reduces the heat transfer between the flame and the liquid surface.

Treatments of the inhibition mechanisms and general theory of dry chemicals are given by Laffitte *et al.* (1965), Laffitte and Bouchet (1959), Dewitte, Vrebosch and van Tiggelen (1964), Birchall (1970), Iya, Wohowitz and Kaskan (1975), McHale (1975), Spence and McHale (1975), Vanpee and Shirodkar (1975), Mitani (1981, 1982, 1983) and Mitani and Niioka (1982).

The combustion chain reactions are broken by adsorption on solid surfaces. Thus for a given material a large powder specific surface enhances the effectiveness. Haessler (1986) states that best results are obtained with a particle size range of 10–75 μm with a median size of 20–25 μm.

16.29.2 Types of dry chemical

Some basic dry chemicals are (1) sodium bicarbonate (standard dry chemical), (2) potassium bicarbonate, (3) potassium chloride, (4) urea potassium bicarbonate (5) monoammonium phosphate. There are also the formulations (6) general purpose powder (ABC) and (7) Monnex powder.

Standard dry chemical consists principally (over 90%) of sodium bicarbonate with additives to improve fluidity, non-caking and water repellent characteristics. Potassium bicarbonate formulation, however, are also used and are about $1\frac{1}{2}$–2 times as effective as those with the sodium bicarbonate base.

General purpose powder is a mixture of ammonium dihydrogen phosphate, diammonium hydrogen phosphate and ammonium sulfate.

Monnex is a potassium alkali based material. The particles disintegrate in contact with the flames and thus give a greatly enhanced surface area. Its effectiveness is about 5–6 times that of standard dry chemical.

16.29.3 Properties of dry chemicals

Dry chemical formulations may be ranked in respect of their effectiveness in extinguishing fires according to their performance in test. This performance is a function both of the chemical composition and the particle size.

Some types of dry chemical based on sodium or potassium bicarbonate are not compatible with foam. The dry chemical, and particularly the additives, tend to break down the foam bubbles. However, foam-compatible forms for dry chemical are also available.

In storage, dry chemicals are stable at normal and low temperatures but deteriorate at high temperature. Haessler quotes an upper temperature for storage of 120°C. Different dry chemicals should be segregated. Mixing of alkali and acid agents can result in release of carbon dioxide, and incidents have occurred where extinguishers have exploded.

16.29.4 Hazards associated with dry chemicals

One hazard from the use of dry chemicals is that due to the sudden release of the agent. Another hazard is unexpected reignition. The main toxic hazards following the use of dry chemicals will generally be those due to the combustion process. Dry chemicals themselves are non-toxic.

16.29.5 Delivery systems for dry chemicals

Dry chemicals are delivered to the fire mainly by fixed systems, from cylinders or by mobile systems. They are also on of the agents used in portable extinguishers. Delivery from cylinders is by hand held hose line.

16.29.6 Applications of dry chemicals

Dry chemicals are used to extinguish fire. They are utilized on class A fires (combustible materials), Class B fires (flammable liquids) and Class C fires (electrical equipment) in the NFPA classification. With regard to the latter, dry chemicals tend to be somewhat corrosive and to insulate contact surfaces. They are not suitable, therefore, for fires in delicate electrical equipment but can be used on fire of equipment such as transformers and circuit breakers.

Dry chemicals are an extremely versatile type of agent. They are low hazard and non-toxic. They can deal with a wide range of fires. They find application to extinguishment of large outdoor fires, to protection of spaces indoors and in portable extinguishers.

A dry chemical agent acts by extinguishing the fire in a single shot. In this it can be extremely effective. It is necessary, however, to use sufficient powder to ensure that the flame is completely extinguished. Otherwise once the powder is exhausted reignition is liable to occur. A dry chemical has little cooling effect and does not leave behind an inert atmosphere.

There are also other potential causes of reignition when a dry chemical is used. Vapours from a flammable liquid may be reignited by a hot surface, a combustible solid may be reignited by smouldering material and an electrical fire may reignite due to continued arcing.

If the fire is one in a combustible material and there is no reason why water should not be used, it may be advisable to use follow up with water to complete the extinguishment of the fire.

16.29.7 Fixed dry chemical systems

Fixed dry chemical systems may be (1) total flooding systems or (2) local application systems. A fixed system may be supplemented by hand held hose lines from cylinders.

16.30 Fire Protection Using Vaporizing Liquids

Another type of firefighting agent is the vaporizing liquid. Accounts of vaporizing liquids include *Halogenated Fire suppressants* (Gann, 1976) and those by Burgoyne and Richardson (1949a), Rasbash (1968), Hirst (1974a,b), Boughen (1979, 1982), Forrester (1982), Peissard (1982), Capper (1983), C.C. Grant (1985), Hoskins (1985), R.J. Martin, Shepherd and Hamlin (1986), Goodall (1988), Boyce (1990) and Senecal (1992a,b). Fire protection using vaporizing liquids is treated in the NFPA *Handbook* by D.W. Moore (1986).

Relevant codes and standards are NFPA 12A: 1992 *Halon 1301 Fire Extinguishing Systems*, NFPA 12B: 1990 *Halon 1211 Fire Extinguishing Systems*, NFPA 2001: *Clean Agent Fire Extinguishing Systems*, BS 5306: 1976– *Fire Extinguishing Installations and Equipment on Premises*, Part 5: 1982– *Halon Systems* and BS 6535: 1989– *Fire Extinguishing Media*, Part 2: 1989– and *Halons*, Section 2.1: 1989 *Specification for Halon 1211 and Halon 1301* and Section 2.2: 1989 *Code of Practice of Safe Handling and Transfer Procedures*.

16.30.1 Mechanisms of fire extinguishment

Vaporizing liquids act against fire by essentially the same two mechanisms of interruption of the chain reactions and of blanketing. Treatments of the inhibition mechanisms and general theory of vaporizing liquids are given by Belles and O'Neil (1975), Spence and McHale (1965), W.E. Wilson, O'Donovan and fristrom (1969), Dixon-Lewis and Simpson (1977), P.F. Thorne (1978b), Westbrook (1982c) and Mitani (1983).

16.30.2 Types of vaporizing liquid

The substances used as vaporizing liquids are halogenated hydrocarbons. They include the following classes: halon (H), hydrofluorocarbon (HFC), hydrochlorofluorocarbon (HCFC) and perfluorocarbon (PFC). The halons contain bromine and the perfluorocarbons contain fluorine as the only halogen.

Prominent halons are:

Halon 1211	Bromochlorodifluoromethane (BCF)	CF_2ClBr
Halon 1301	Bromotrifluoromethane (BTM)	CF_3Br

HCFCs include:

HCFC-22	Chlorodifluoromethane	$CHClF_2$
HCFC-124	Chlorotetrafluoroethane	C_2HF_4Cl

Vaporizing liquids are available which are much more effective extinguishants than carbon dioxide. Table 16.87 shows the relative effectiveness of various vaporizing liquids in extinguishing a hexane test fire (Hearfield, 1970). Whereas a concentration of 28% was required for carbon dioxide, the concentrations required with the vaporizing liquids were as shown in the table.

One of the most efficient extinguishing agents is Halon 1301. The relative fire extinguishing capability of other vaporizing liquids may be expressed in terms of the relative mass extinguishing efficiency (RMEE), defined as the ration of the mass extinguishing concentration of the agent

Table 16.87 *Extinction of hexane test fire by vaporizing liquids (after Hearfield, 1970)*

		Hexane fire extinction (%v/v)
Bromochlorodifluoromethane (BCF)	$CBrClF_2$	5.2
Dibromodifluoromethane	CBr_2F_2	3.6
Trifluoromethyl bromide	CF_3Br	4.2
Chlorobromomethane	CH_2ClBr	6.4
Methyl bromide	CH_3Br	7.7
Carbon tetrachloride	CCl_4	9.9

to that of Halon 1301 in a standard test. One such standard test is the ICI cup burner test.

Halon 1211, or bromochlorodifluoromethane (BCF), is now the principal vaporizing liquid. A comparison at 20°C of Halon 1211 with carbon dioxide shows that the specific gravities relative to air are 6.35 and 1.52 and the vapour pressures 2.61 and 57.2 bar, respectively. Thus BCF gives a better blanketing action and does not require such high strength containers.

Halon 1211 is a very effective extinguishing agent for flammable liquid and electrical fires. It is electrically non-conducting. Its cooling capacity, however, is low (latent heat 134 kJ/kg). It is capable, therefore, of dealing with a small solids fire but not with a large one.

Most Halon 1211 and Halon 1301 systems are of the total flooding type used to protect an enclosed space. The concept is that the halon is injected into the space and develops an approximately uniform concentration capable of extinguishing a fire anywhere in the enclosure. The alternative method of deployment of halon systems in local application in which the jet of halon is directed at the seat of the fire.

It is usually desirable to follow up the extinction of fire by Halon 1211 with water of foam cooling. This does not apply, however, to electrical fires or to situations where electrical equipment is near the seat of the fire.

16.30.3 Properties of vaporizing liquids

Vaporizing liquids may be ranked in respect of their effectiveness in extinguishing fires according to their performance in tests. There are numerous tabulations of relative effectiveness in particular tests.

Properties of a vaporizing liquid which bear on its effectiveness as a fire fithting agent include (1) chemical action, (2) vapour pressure and (3) density.

The ability to arrest combustion by interfering with the chain reactions is obviously a prime property.

The vapour pressure is significant in several respects. It determines the ability of the agent to discharge under its own pressure, the extent to which the flow in the pipework is two-phase and the behaviour of jet.

The density of the agent affects the mixing in the space into which is it discharged.

Compatibility with foams is another relevant property of vaporizing liquids.

In storage, early vaporizing liquids tended to give rise to corrosion problems. Halon 1301 and Halon 1211 have little corrosive action, provided that free water is not present.

16.30.4 Hazards associated with vaporizing liquids

There are certain toxic hazards associated with the use of vaporizing liquids. These include the toxic effects of (1) the agent, (2) the breakdown products of the agent and (3) the combustion products of the fire.

The first vaporizing liquid used was carbon tetrachloride, which is toxic. It was superseded by methyl bromide, which is highly toxic. Dibromofluoromethane is a convulsant. Chlorobromomethane is moderately toxic and produces narcosis. Bromochlorodifluoromethane (BCF) has a low acute toxicity. Bromotrifluoromethane (BTM) has an even lower acute toxicity, but also a very low boiling point (−58°C), so that contact can cause freezing of the skin and eyes by evaporation.

Vaporizing liquids give rise to decomposition products in fires. Halon 1211 yields the products hydrogen chloride, hydrogen bromide and hydrogen fluoride, which are extremely irritating to the eyes, nose and throat.

D.W. Moore (1986) gives the following approximate lethal concentrations of the natural vapour and of the decomposed vapour for a 15 min exposure:

	Lethal concentration (ppm)	
	Natural vapour	*Decomposed vapour*
Methyl bromide	5,900	9,600
Bromochlorodifluoromethane	324,000	7,650
Bromotrifluoromethane	832,000	14,000

The toxicity of the combustion products of the fire is another significant factor in firefighting using vaporizing liquids.

16.30.5 Delivery systems for vaporizing liquids

Vaporizing liquids are delivered to the fire mainly by fixed systems. They are the agents used in portable extinguishers. Vaporizing liquids are less suitable for delivery from cylinders by hand held hose line or from mobile equipment. In addition, vaporizing liquids are used in fixed systems to suppress combustion inside plant.

16.30.6 Applications of vaporizing liquids

Vaporizing liquids are used to extinguish fires. They are utilized for this purpose in enclosed spaces, and in portable extinguishers. They are also used to suppress incipient combustion inside plant.

16.30.7 Fixed vaporizing liquid systems

Fixed vaporizing liquid systems may be (1) total flooding systems or (2) local application systems.

The hydraulics of some vaporizing liquid systems may involve two-phase flow. Although Halon 1211 can usually be treated as a single liquid phase in the pipework, Halon 1301, which exists as a single liquid phase in storage, begins to vaporize as it travels down the pipe. The flow characteristics of halon systems are discussed by Williamson (1976) and Wiersma (1978). Computer programs for halon hydraulics have been developed by suppliers.

Halon systems tend to be subject to corrosion. The problem is discussed by Peissard (1982).

16.30.8 Vapour retention tests

A feature of interest for a space protected by a halon system is the retention time of the halon. A method for the determination of this has been developed by the NFPA based on its Enclosure Integrity Test. In this integrity, or pressure, test, portable fan equipment is used to create a pressure difference between the protected volume and the surrounding space. Measurements are made from which the effective leakage area of the enclosure can be estimated. This is then used to calculate the halon retention time. Vapour retention tests are discussed by Genge (1989), Sreeves (1989) and Whiteley (1989).

16.30.9 Precautions

As stated earlier, guidance on the precautions to be taken to counter the toxic and asphyxiation hazards of halon and of inert gas extinguishing systems is given in GS 16. There are a number of general precautions to be taken with any gaseous extinguishing system. If the system is an automatic one activated by rapid response fire detectors, two separate detection signals should be provided in order to reduce the frequency of false activations. The space protected should be provided with warning signs at all entrances. There should be an indication as to whether the system is set for manual or automatic activation.

If the system is a manually activated one, the release devices should be so located such that the person operating the device is not at risk from the fire or the discharge of the agent. For a total flooding system, activation of the system should be accompanied by an audible alarm distinct from the fire alarm. The entrances should have continuous warning signs which remain on until the space has been certified as fit to re-enter. There should be suitable escape routes. The space should be provided with adequate means of ventilation after a fire and/or discharge of the agent.

The installation should be covered by a safe system of work. The system should be subject to regular inspection by a competent person. GS 16 states that such an inspection should be done not less than twice a year and should result in an inspection report. It also details the precautions to be taken during maintenance. One measure required is the provision of a means of isolating the agent storage tank for maintenance or other circumstances where normal escape might be difficult.

GS 16 gives guidance on the selection of the agent and the system. The choice should have regard to the hazards to personnel. A local application system tends to involve less risk of personnel being trapped and may be preferable in some circumstance. If a total flooding system is used, the volume of the space protected should be kept to a minimum and the design should avoid excessive concentrations of the agent.

Account should be taken of the possibility that discharge of the agent may raise a dust cloud, with the attendant risk of a dust explosion.

With regard to the precautions which relate specifically to the agent, for a total flooding system using Halon 1211 the system should ensure that discharge does not occur whilst personnel are present. For a local application system for Halon 1211 the requirement is to design so that there is no foreseeable risk of a hazardous concentration being produced.

For Halon 1301 the precautions required are related to the concentration of the agent which may be attained. GS 16 states that, provided the concentration of this halon will not exceed 6%, and subject to certain other qualifications, an automatic total flooding system may be used to protect a normally occupied space. The space should be evacuated before the concentration of Halon 1301 exceeds 6%. It may be appropriate to incorporate a short time delay and pre-discharge alarm, but in order to ensure rapid response to the fire, the delay should not usually exceed 30 s.

16.30.10 Halon phase-out

The discovery by Molina and Rowland (1974) that chlorine can act as a catalyst for the conversion of ozone to molecular oxygen in the upper atmosphere initiated a growing concern for the state of the ozone layer. It was subsequently shown that halons have a particularly damaging effect.

This has led to the Montreal Protocol on Substances that Deplete the Ozone Layer, 1987, which lays down a programme for the phasing out of halons. Amendments to the treaty have been made at meetings in 1990 and in November 1992. Accounts of the Montreal Protocol and its implications for halon systems are given by Senecal (1992a,b), Hough (1993) and Simmonds (1993). The halons discussed are primarily Halon 1211 and Halon 1301. The original Montreal Protocol provides that the production of halons be reduced to 50% of the 1986 level by 1994 and to 0% by 1999.

With regard to the continued use of existing halon systems and to the recycling of halons for use in such systems, national policies vary. Germany has banned the use of halon firefighting systems. According to Simmonds, in the absence of a suitable halon destruction technology, it is current policy not to dismantle the systems or return them to the suppliers but to let them remain on site capped off.

In the United States, it is government policy to permit continued use of existing systems and the recycling of halons for use in such systems.

The United Kingdom also is evidently moving towards a policy of permitting continued use of existing systems, as evidenced by the HSE draft guidance on *Gaseous Fire Extinguishing Systems*.

Amendments to the Montreal Protocol also cover HCFCs, the production of which is to be frozen at 1989 levels and phased out by 2030, or possibly earlier.

16.30.11 Halon replacement and clean agents

The demise of the use of halons has led to a search for alternatives. These alternatives include both other vaporizing liquids and agents other than vaporizing liquids. Alternatives to halons have been reviewed by the Halons Technical Options Committee (G. Taylor, 1991) of the UN Environment Programme (UNEP). Other accounts of alternatives include those by Senecal (1992a,b), Hough (1993), McKay (1993) and Simmonds (1993). NFPA 2001: 1994 deals with clean agent alternatives to halons.

A review of vaporizing liquids used or proposed for use as fire extinguishing agents is given by Senecal (1992b), who covers HCFCs, HFCs and PFCs as well as CO_2, with a comparative tabulation of relevant properties and a detailed discussion of each agent.

Hough (1993) also reviews alternatives, but ranges more widely, from designing out of the need, through other vaporizing liquids, notably HCFCs, to foam, dry powder and fogging systems.

An account of work on the later has been given by McKay (1993). Building on research on burner nozzle technology, a fine water spray system has been developed which uses water droplets in the diameter range 80–200 μm and is claimed to be a highly effective suppressant alternative to halons.

16.31 Fire Protection Using Inert Gas

The last of the principal firefighting agents is inert gas. Here a distinction needs to be made between the use of inerting of equipment to prevent internal fire or explosion, as described in Chapter 17, and the use of inert gas to extinguish fire, which is considered here.

Accounts of the use of inert gas for fire extinguishment include those by Burgoyne, Katan and Richardson (1949b), McGuire (1864) and Bryant (1991). Fire protection using inert gas is treated in the NFPA *Handbook* by P.F. Johnson (1986) and, for carbon dioxide, by Williamson (1986).

Relevant codes and standards are NFPA 12: 1993 *Carbon Dioxide Extinguishing Systems* and BS 5306: 1976– *Fire Extinguishing Installations and Equipment on Premises*, Part 4: 1986 *Specification for Carbon Dioxide Systems* and BS 7273: *Code of Practice for the Operation of Fire Protection Measures*, Part 1: 1990 *Electrical Actuation of Gaseous Total Flooding Extinguishing Systems*.

16.31.1 Mechanisms of fire extinguishment

Extinguishment of fire by an inert gas is effected by reducing the concentrations both of the fuel and of oxygen. Design of an inert gas system is based on reducing the concentration of oxygen below that which will support combustion. A further, more recently favoured, mechanism is the reduction of the flame temperature below that necessary for combustion – the thermal ballast effect.

Inert gas also has a cooling effect. A large mass flow of gas over a liquid surface can be beneficial in preventing ignition when the discharge ceases and the liquid again comes in contact with air.

These latter mechanisms indicate that it is desirable that the inert gas have a high heat capacity.

16.31.2 Types of inert gas

The principal individual inert gases used in fire protection applications are carbon dioxide and nitrogen. Use is also made of inert gas mixture formulations.

16.31.3 Properties of inert gas

Properties of an inert gas relevant to its use fire protection include (1) its density, (2) its vapour pressure, (3) the minimum concentration required for extinguishment and (4) its gas specific heat.

The density of the gas affects both its ‘throw’ and its subsequent flow.

The vapour pressure is relevant to the ability of the gas itself to provide the pressure necessary for discharge. An advantage of carbon dioxide, for example, is that its vapour pressure at room temperature is high enough to give satisfactory discharge.

The minimum concentration for extinguishment sets the lower limit of concentration of inert gas to be used. Information on this minimum concentration has been given by Coward and Jones (1952 BM Bull. 503), and has been widely reproduced. Values for carbon dioxide are tabulated by Williamson (1986).

As just indicated, a high gas specific heat is beneficial in that it enhances the thermal ballast and cooling effects of the inert gas. This is one of the advantages of carbon dioxide with its high heat capacity.

16.31.4 Hazards associated with inert gas

The two principal inert gases used are carbon dioxide and nitrogen. Carbon dioxide is mildly toxic, but the main hazard with both gases is hat of asphyxiation. This hazard is present in all fire situations, but insofar as the extinguishment of fire requires high concentrations of inert gas the hazard is enhanced.

The density of the gas is relevant to the asphyxiation hazard; the density of nitrogen is close to that of air, whilst that of carbon dioxide is appreciably greater, so that it may accumulate in low lying spaces.

16.31.5 Delivery systems for inert gas

Inert gases are delivered to the fire by fixed systems, but not normally by mobile systems. The inert gas carbon dioxide is one of the agents used is portable extinguishers. In some cases hand held hose liens from cylinders are used to supplement a fixed delivery system.

16.31.6 Applications of inert gas

Inert gases are used to extinguish fires. They are utilized for this purpoe in enclosed spaces, and in portable extinguishers.

16.31.7 Fixed inert gas systems

Inert gases are used in (1) total flooding systems, (2) local applicaton systems and (3) hand held hose lines.

In a total flooding system the inert gas is injected into an enclosure in sufficient quantity to ensure the minimum concentration for extinguishment.

In a local application system a jet of inert gas is directed at the surface protected, which is typically a tank surface but may also include the adjacent floor area. There is a minimum discharge time for effective extinguishment, that recommended for carbon dioxide being 30 s.

For carbon dioxide, hand held hose lines from cylinders are also used.

16.31.8 Precautions

The precautions given in GS 16 for halon and inert gas extinguishing systems have been outlined in the previous section. Those for an inert gas are broadly similar to those for Halon 1211. The essential requirement is to ensure that operation of the system does not expose personnel to hazardous concentrations. For a total flooding system this means that the arrangement should prevent the system from operating when personnel are present, whilst for a local application system the requirement is to design so that there is no foreseeable risk of a hazardous concentration being produced.

16.32 Fire Protection Using Special Methods

In addition to the methods just described, there are also several special methods of fighting fires. They include the use of (1) solids and powders, (2) wet water or wet water foam and (3) combined agent systems. Fire protection using such special methods is treated in the NFPA *Handbook* by P.F. Johnson (1986).

16.32.1 Solids and powders

In addition to dry chemicals, use is also made of various kinds of dry powder, sand and other solid materials. One group of solid agents comprises those used for metal fires, for example, talc, soda ash and graphite.

Another solid agent is glass granules used for the control of LNG bund fires (Lev, 1981). The granules are stores within the bund and, when an LNG spill occurs, they float to the top. The mechanism of action is reduction of the radiation from the flame to the surface and thus of the evaporation of the fuel.

A third solid agent is carbon microspheres used for extinguishment of metal fires (McCormick and Schmitt, 1974).

Treatments of the extinguishment mechanisms of dry powders, including inert particulates, are given by Dolan (1957), McCamy, Shoub and Lee (1957), Morikawa (1976) and G. Russell (1977).

The provision of sand buckets for dealing with small fires has long been common practice on process plant. Sand is also used for diking in, and thus containing, liquid spillages.

16.32.2 Wet water and wet water foam

A second special method is the use of wetting agents to modify the properties of water, thus producing 'wet water'. A relevant code is NFPA 18: 1990 *Wetting Agents*.

In this context a wetting agent is one which, when added to water, effects a substantial change in its surface tension, thus increasing its ability to penetrate and spread. The wetting agent may also impart emulsifying and foaming characteristics.

The use of a wetting agent makes the water more 'effective' so that less is needed. This is of particular value in firefighting where water is in short supply. A typical application is to forest fires.

If the wetting agent has suitable foaming qualities, a wet water foam is produced.

Fixed water sprinkler and water spray systems, as described in NFPA 13 and NPFA 15, may be designed to operate on wet water.

16.32.3 Combined agent systems

A third special method is the use of a combination of agents. An early application of the combined agents technique was the use during World War II of a combination of carbon dioxide and foam to attack a spill of aviation fuel from an aircraft and so rescue the aircrew.

Some agent combination used are (1) water and foam, (2) carbon dioxide and foam and (3) certain dry chemicals and foam. Thus foam is prominent as one of the agents in such combinations.

In some cases the agents are applied simultaneously, in others they are used in rapid succession. A typical case of the application of a dry chemical and foam combination might be to extinguish fire on a flammable liquid by a large but short discharge of dry chemical and then to blanket the liquid with foam to prevent reignition.

16.33 Fire Protection Using Portable Extinguishers

So far only passing reference has been made to portable fire extinguishers. These are, however, another important resource for fire protection. Accounts of portable fire extinguishers are given by Guccione (1961), Guise and Zeratsky (1965, 1982) and P. Nash (1969, 1991). Fire protection using portable fire extinguishers is treated in the NFPA *Handbook* by M.E. Petersen (1986a,b).

Relevant codes and standards are NFPA 10: 1990 *Portable Fire Extinguishers* and BS 5423: 1987 *Specification for Portable Fire Extinguishers* with its associated standard BS 6643: 1985– *Recharging Fire Extinguishers*. There are also a number of Underwriters Laboratories (UL) standards.

It is a fundamental principle of firefighting that a fire should be hit hard and quickly, preferably before it has a chance to take hold. Usually the time which elapses before the fire brigade arrives is measures in minutes, even tens of minutes, and by then the fire may be well developed. For some hazardous items prompt response can best be achieved by an automatic fire protection system. For others, portable fire extinguishers provide the necessary means.

Conditions for success in the use of portable fire extinguishers are that the fire be small, that extinguishers be accessible, that they be of the right type, that they operate when activated and that personnel capable of using them are present.

These conditions have a number of implications. The potential sources of fire need to be idenftified and extinguishers with appropriate agents located at suitable points. The selection and maintenance of the extinguishers should take account of any potential unrevealed failure. Personnel should be trained in their use.

Fires of combustible materials (NFPA Class A), flammable liquids (Class B), electrical equipment (Class C) and metals (Class D) can all be dealt with by the use of suitably chosen portable fire extinguishers.

Principal agents used in portable fire extinguishers are (1) water, (2) foam, (3) carbon dioxide, (4) dry chemicals, (5) vaporizing liquids and (6) dry powders. Broadly, water is used on Class A fires and foam (AFFF) on Class B fires. Carbon dioxide and suitable dry chemicals and vaporizing liquids (Halon 1211) are used on fires of Classes A–C and dry powder is used on Class D fires. Some dry chemicals are suitable for fire Classes B and C and others for Classes A–C. A detailed tabulation of agents and their applications is given by M.E. Petersen (1986b).

There are several different principles of operation of a portable fire extinguisher. For water and foam extinguishers the three traditional types have been: (1) stored pressure, (2) pump tank and (3) inverting. In a stored pressure type the agent is expelled by an expellant gas held in the same chamber. In a pump tank type expulsion of the agent is effected by pressure generated by operation of the hand pump. The inverting type has been obsolete for some years; manufacture in the United States ceased in 1969. The agents used only in this type, soda acid and foam, have also become obsolete.

Other portable extinguishers utilize (1) stored pressure, (2) cartridge or (3) self-expulsion methods. As just explained, in the stored pressure type, the agent and expellant gas are held in the same chamber, whilst in the cartridge type the expellant is held in a separate cartridge. Dry chemical extinguishers use both stored pressure and cartridge methods. Halon 1211 extinguishers tend to use stored pressure. In carbon dioxide extinguishers the agent is self-expelling.

16.34 Fire Protection Applications

Firefighting applications in process plant may be classified according to the material on fire or according to the plant and storage protected. The applications considered here are, by material, (1) combustible solids fires, (2) flammable liquid fires, (3) electrical fires and (4) metal fires and, by plant or storage (1) storage tanks and (2) warehouses.

16.34.1 Combustible solids fires

A type of fire common in all occupancies is a combustible solids fire (NFPA Class A). In the process industries combustible solids occur in bulk and powder forms both in process and in storage. Process operations which typically involve combustible solids include dust handing plant, conveyors and packaging plant. Storage sites such as silos and warehouses may contain large quantities of combustible solids.

There are a number of NFPA codes covering particular solid materials. They include NFPA 43A (oxidizers), NFPA 43B (organic peroxides), NFPA 490 (ammonium nitrate), NFPA 654 (powders and dusts) and NFPA 655 (sulfur). Other NFPA codes for metals are given in Subsection 16.34.4.

Fixed fire protection systems are provided in selected cases. The design options depend on the situation. For example, a total flooding design is practical only if the solids are being handled in an enclosure and it will not endanger personnel.

Where solids are handled indoors, regard should be had to the potential difficulties of fighting the fire once it has taken hold and is producing large volumes of smoke. It may be only minutes before entry into the building becomes impossible. This implies that any fixed fire protection system should respond rapidly and strongly.

The fire protection of warehouses is considered further in Subsection 16.34.7.

16.34.2 Flammable liquid fires

Another type of fire common in the process industries particularly is a flammable liquids fire (NFPA Class B). Process industry activities involve the processing and storage of a wide variety of flammable liquids. Storages may contain large quantities of flammable liquids.

Fixed fire protection systems are provided for process operations and areas vulnerable to releases and spills, for loading and unloading facilities and, above all, for storage tanks and vessels. Storage tanks are commonly provided with a bund. It is therefore necessary to protect not only against a fire in the tank itself but also against one in the bund.

The fire protection of storage tanks in general is considered further in Subsection 16.34.6. Further accounts of the protection of particular types of storage tank such as LPG, LNG and ammonia tanks are given in Chapter 22.

16.34.3 Electrical fires

There are also certain special types of fire that require treatment, once of which is the electrical fire (NFPA Class C). If electrical equipment is involved in a fire on a process plant, this is generally due to an explosion at the equipment itself or to a spread of a fire from the rest of the plant. If there is a fire at a piece of live electrical equipment, it is usually appropriate to de-energize the equipment, unless there are good reasons for not doing so.

In respect of fire, electrical equipment may be divided into (1) equipment which has exposed contacts and (2) equipment such as transformers and circuit breakers.

Among the agents used on electrical fires are water, dry chemicals, vaporizing liquids and inert gases, but not all agents are suitable for every type of electrical fire.

Water as a continuous jet conducts electricity and should not be used in this form on electrical fires. In the form of spray, however, this hazard is much less and is generally negligible (O'Dogherty, 1965).

Some electrical equipment is protected using a fixed water spray system. Water sprays are used, for example, to protect against fires in oil cooled electrical equipment such as transformers, Such a fire is generally the result of an electrical breakdown which causes an explosion. Such mixed fires of hot oil and hot metal are difficult to handle. Typically the oil is being pumped over metal surfaces which become hot and sustain the fire. It is important, therefore, to ensure that such situations are detected and dealt with as early as possible, The protection of such electrical equipment with water sprays is a specialist matter. It is discussed by P. Nash (1974a).

Fixed systems for the protection of electrical equipment tend to use dry chemicals of carbon dioxide. As already stated, the former is not suitable for equipment with exposed contacts which are liable to suffer adhesion and corrosion. Fires of electrical equipment are mainly fought using portable carbon dioxide or dry chemical extinguishers.

16.34.4 Metal fires

Another type of fire which requires special treatment is metal fires (NFPA Class D). Accounts of metal fires and methods of dealing with them are given by Reuillon *et al.* (1977), Sharma, Lal and Singh (1987), Varshney, Kumar and Sharma (1990), Cardillo and nebuloni (1992) and Sharma, Varshney and Kumar (1993). Metal fires are treated in the NFPA *Handbook* by Prokopovitsh (1986) and by P.F. Johnson (1986).

The NFPA codes on the storage of certain metals are of some relevance. These are NFPA 48 (magnesium), NFPA 481 (titanium) and NFPA 482 (zirconium).

Metal fires involve a number of hazards. Characteristic hazards are (1) extremely high temperatures, (2) steam explosion and (3) hydrogen explosion, as well as the usual hazards of (4) toxic combustion products and (5) oxygen depletion.

Extinguishment of a metal fire is not always achievable and it may be necessary to settle for control of the fire. The agent used should be matched to the metal: an agent suitable for dealing with a fire of one metal may be quite unsuitable for that of another. Water should not be used on a sodium fire, and a vaporizing liquid should not be used on a magnesium fire. That said, there are some powder agents which are suitable for fires of several metals, as described below.

Combustible metal extinguishing agents are classified according to whether they are (1) approved or (2) proprietary. Approved agents are those proprietary agents which are tested and approved by organizations such as the UL. There are also proprietary agents and non-proprietary agents.

Prominent proprietary agents are Pyrex G1 powder, which is a coke powder with an organic phosphate additive. Metalguard powder has a similar formulation. Another agent is Met-L-X powder, which has a sodium chloride base, again with additives. Prokopovitsh gives a tabulation of the comparative capabilities of G1 and Met-L-X powders in dealing with fires of a number of metals, including aluminium, magnesium, sodium, potassium, titanium, zirconium and lithium. He also discusses the use of other proprietary agents and of non-proprietary agents such as talc powder, soda ash, salt and sand.

16.34.5 Storage tanks

Turning to the fire protection of particular plant and storage, protection of storage tanks is a prominent theme. Accounts of fire protection of storage tanks and bunds are given by A.H. Warren (1966), Hearfield (1970), J.R. Hughes (1970), Vervalin (1973f). P. Nash and Young (1975 BRE CP42/75), Peyton (1984) and M. Wilson (1993) Fire protection of storage tanks is treated in the NFPA *Handbook* for flammable liquids by M.F. Henry (1986) and for chemicals by Bradford (1986b).

Relevant codes and standards for storage tanks, including low temperature storages, are NFPA 30: 1990, API Std 620: 1990 and API Std 650: 1993, and BS 799: 1972–, BS 2654: 1989, Bs 4741: 1971 and BS 5387: 1976. There are also codes for the Storage of particular chemicals such as NFPA 43A: 1990, which covers liquid oxidizers.

Fire protection of a storage tank needs to address several different scenarios: (1) a fire near to the tank, (2) a fire in the top of the tank and (3) a fire in the bund. There are therefore requirements for exposure protection by cooling of the tank and for fire extinguishments and control in the tank itself, in the bund and of a liquid spill outside the bund.

Among the facilities which may be provided for the fire protection of a storage tank are (1) fire resistant thermal insulation or fire insulation, (2) a fixed water system for cooling, (3) a fixed foam system for the tank top, (4) a fixed foam system for the bund, (5) fixed water/foam monitors and (6) mobile water/foam monitors, There may also be a role for fixed water spray systems for the extinguishments and control of liquid spills.

Foam systems for storage tanks have been discussed in section 16.28. A further account of fire protection of storage tanks is given in Chapter 22. Firefighting on storage tanks is discussed in the next section.

16.34.6 Storage vessels

The fire protection of storage vessels, particularly those containing liquefied flammable gas, is equally important. Accounts of the fire protection of storage vessels are given by Petitit (1945), Bray (1964, 1966), Chaillot (1966), the FPA (1966), ICI/RoSPA (1970 IS/74), Eijnhoven, Nieuwenhuizen and Wally (1974), I. Williams (1984) and B.M. Lee (1989). Fire protection of storage vessels for LFG is treated in the NFPA *Handbook* by walls (1986).

Relevant codes and standards for storage vessels for LFG are NFPA 54: 1992, NFPA 58: 1992, NFPA 50: 1990, NFPA 59A: 1990, the ASME *Boiler and Pressure Vessel Code*, Section VIII and BS 5500: 1991. NFPA 50: 1990 covers liquid oxygen and NFPA 50A: 1989 and NFPA 50B cover gaseous and liquid hydrogen, respectively.

Among the facilities which may be provided for the fire protection of a storage vessel are (1) drainage, including sloped ground, (2) fire resistant thermal insulation or fire insulation, (3) a fixed water system for cooling and (4) depressuring facilities.

A further account of the fire protection of storage vessels is given in Chapter 22.

16.34.7 Warehouses

Warehouses are another type of storage which contain large quantities of combustible material. The account here is limited to fire protection systems; a fuller account of warehouses, including prevention of fire, is given in Chapter 22.

Accounts of fire protection of warehouses include those by P. Nash (1972a, 1977), P. Nash, Bridge and Young (1974 BRE CP68/74), Bridge (1977), Young and Nash (1977), Parnell (1979), Field (1985), Murrell (1988) and Murrell and Field (1990).

Much of the work described by these authors was conducted at the Fire research Station, with one programme in the mid-1970s (e.g. FRS, 1972 Fire Res. Note 914, 916, 944; P. Nash, 1977) and another in the mid-1980s (e.g. Field, 1985; Murrell, 1988).

A relevant code is NFPA 231C: 1991 *Rack storage of Materials*.

The fire problem is particularly acute in automated high bay, or high rack, warehouses. The FRS work has shown that in such situations fire develops rapidly, with flames propagating upwards, mainly in the flues between adjacent pallets. The fire typically reaches the top of the rack within 2 min. It becomes virtually impossible to fight the fire by conventional means.

The earlier FRS programme also showed that conventional sprinklers with glass bulbs set to operate at 68° C do not respond quickly enough to counter the fire before it gains hold. An alternative system was developed in which the bays are zoned with setsof sprinklers dedicated to a zone and actuated by a fire detection wire 'laced' through the racking. This system was criticized as being too complex and liable to false alarms and was not taken up by industry.

The later programme, described by Field (1985), concentracted on the response of the sprinkler head. A solder-link sprinkler was identified which proved satisfactory. For a single localized ignition source the sprinkler system operated to extinguish the fire with a maximum water volume of 350 UKgal.

16.35 Firefighting in Process Plant

The foregoing account has described some of the passive measures used to prevent fire and to protect against it and some of the agents and equipment available for active measures of actual firefighting. It is now necessary to discuss some of the general principles underlying fire fighting in process plants, bearing in mind the wide variety of types of fire which may be encountered.

General accounts of firefighting are given in *Manual of Firemanship* (Home Office, 1974–), *Fire fighting in Factories* (HSE, 1970 HSW Bklt 10) and *Fire Attack, Fire Service Communications for Fire Attack and The Extinguishment of Fire* (NFPA, 1966/4, 1972/8, 1974/11). Firefighting in the process industries and with chemicals is discussed in *Fire Protection Manual for Hydrocarbon Processing Plants* (Vervalin, 1964a, 1973a) and the *Fire Training Manual* (PITB, 1975/6) and by several other authors, particularly Risinger (1964b,c,f,g).

In most firefighting operations on process plant it is necessary not only to fight the fire but also to protect the vessels exposed to it. This second activity is just as important as the first.

A fundamental principle of firefighting is to attack the fire at as early a stage as possible and to hit it hard. Once a fire is well established and has heated up large quantities of metal and liquids, it becomes much more difficult to contain it and prevent it growing. There are a number of case histories, described in Appendix 1, which illustrate the problems of firefighting in process plants.

16.35.1 Liquid fires

There are two important distinctions to be made in considering firefighting of burning liquids. One is that between (1) contained fires and (2) uncontained fires.

A liquid fire is contained if the liquid is held in a well-defined container such as a storage tank, bund or deep depression. In other situations, such as spillages or pools, the liquid fire is uncontained. In some cases it may even be flowing.

The other distinction is between fire of (1) high flashpoint liquids and (2) low flashpoint liquids. A liquid with high flashpoint can generally be extinguished by cooling with water, whereas one with a low flashpoint usually needs to be blanketed by foam or dry chemicals.

Contained fires of either high or low flashpoint liquids can normally be extinguished by foam. Fires of contained high flashpoint liquids can alternatively be extinguished by cooling with water.

With a highflash point product, such as refined oil, the rise in liquid temperature is generally confined to a layer of about 2 in. (5 cm) below the liquid surface, even when the liquid has been burning for a long time. In consequence, when water or foam is added, the heat in the liquid is generally not sufficient to cause an oil–water slopover, unless the surface is very close to the top of the container.

The fact that the bulk oil remains relatively cold means that it also possible to cool the surface layer by agitating the oil. This may be done, for example, by directing a fire water jet down into the liquid.

It sometimes occurs that a high flashpoint liquid is contaminated by error with some low flashpoint material. Usually the amount of contaminant does not exceed 5%. In such cases the more volatile material tends to burn off in the early stages of the fire, leaving an essentially high flashpoint liquid again.

With uncontained fires the first step is generally not to extinguish the fire but to cut off the flow of liquid from the containment. If such a fire is merely extinguished without cutting off the flow of fuel, there is a serious risk that it will re-ignite and cause a much larger fire or possibly an explosion. It is difficult to overemphasize the importance of this point. To quote Risinger (1964g): 'It is more important to know when not to put a fire out than to know the details of actual extinguishments.' With low flashpoint liquids the risks include that of a vapour cloud explosion.

Often the flow of liquid may be stopped by shutting off an emergency isolation valve. It is good practice that such valves should have remote operation for just this situation. Where it is necessary to approach the fire in order to close a valve, a water fog may be used to provide a shield from the heat.

Another device which may be adopted where a flammable liquid which has a density below that of water is flowing from a pipe connected to the bottom of a tank, is to inject water into the tank and so replace the liquid flowing through the pipe with water.

An uncontained fire of a high flashpoint liquid can generally be extinguished by the use of water. For a fire on a low flashpoint liquid, foam or dry chemicals should normally be used.

Often where dry chemicals are used, it is necessary to use water also. Although the former are effective in putting out the fire, there is generally a high risk of re-ignition from the metal which has been heated by the fire. Typically, it is necessary to apply water to cool this metal, then use dry chemicals to extinguish the fire, and then apply water to cool the liquid.

With dry chemicals the quantity which can be used and therefore the time of application are both strictly limited, the latter being generally of the order of some tens of seconds. It is essential, therefore, to put the fire out in the initial attack.

In some cases there are simultaneous contained and uncontained fires. A typical example is burning petroleum liquid flowing over the side of a storage tank. In such a case the procedure is to put out the uncontained fire first. If this is done, the uncontained part does not readily re-ignite because the more volatile components have already been burned off in the tank, whereas if the converse approach is taken, the spillage does tend to be re-ignited by flame travel over the liquid surface.

It is not always either practical or desirable to extinguish a liquid fire. It is generally impractical, for example, to extinguish a very large fire of LPG in an open container or spillage. Moreover, even if it were, extinction of the fire would create the risk of a vapour cloud explosion.

The procedure in such cases, therefore, is to cut off the flow of liquid to the fire, to cool the container and other exposed surfaces and to seek not to put out the fire itself but to control it. It is particularly important to cool the surface of tanks above the liquid level. If the fire is causing any blowtorch effect, the area affected by this should also be cooled.

The use of large quantities of water, or to a lesser extent foam, involves the hazard of spreading the fire by displacing and/or floating the burning liquid. This hazard should be borne in mind in firefighting operations.

Further information is given by Risinger (1964g).

16.35.2 LFG fires

Fires of liquefied flammable gas (LFG) are often fought using dry chemicals or foam, or both in combination. Although the extinction of fire is generally desirable, it may not always be appropriate or possible. It is nevertheless a worthwhile objective to control the fire and so reduce the heat radiation from it.

Large-scale tests on the effectiveness of foam and of dry powder on fires have been carried out as part of the experiments by MITI (1976), described earlier. In one test liquid ethylene was poured into a 3 m diameter bund with a wire netting cover and ignited. An attempt was then made to extinguish the flame using high expansion foam with an expansion ratio of 500 from fixed foam generators with a combined output of 200 m^3/min. The first foam generator was started 2 min after ignition and the second 1 min later. The rate of application of foam was 7.07 m^3/m^2 min. The foam brought the fire about 50% under control within about $3\frac{1}{2}$ min after ignition, and 80% under control just over 6 min after ignition. Thereafter the effectiveness of control remained unaltered. It was concluded that liquid ethylene fires can be kept under control using high expansion foam.

In another test the fire extinguishing agent used was dry powder of ammonium phosphate discharged from two vehicles near the bund. An initial discharge of dry powder for 7 s was observed to extinguish the fire, but a second discharge of 4 s was applied to make sure. The rate of discharge was 45 kg/s to an area of 20 m^2 and, assuming that 50–80% of the powder covered this area, the rate of application was 1.3–1.8 kg/m^2 s. This compares with a slightly higher rate of 2.4 kg/m^2 s reported from other Japanese work.

16.35.3 LNG fires

As already described, the quantities of LNG held in storage are very large. A fire on a large LNG spillage radiates intense heat and can do extensive damage. The behaviour of LNG fires was discussed in Sections 16.11 and 16.17.

As stated above, firefighting will often be conducted with the aim of controlling rather than extinguishing the fire. The control of LNG fires has been the subject of investigations over a period of time and in a number of countries. Early work by Burgoyne and Richardson (1948) showed that foam forms a frozen blanket on burning liquid methane, leaving only small tears which can be readily extinguished with dry chemicals.

Small LNG fires can in fact be extinguished by most firefighting agents. Thus water, foam, dry chemicals, vaporizing liquids and carbon dioxide are all effective on fires sufficiently small to allow the whole area of the fire to be extinguished simultaneously.

With larger LNG fires the problem is more difficult. The feasibility of extinguishing large LNG fires has been a matter of doubt. Walls (1973), for example, states: 'Foams and water will not extinguish LNG fires.'

Dry chemicals can extinguish an LNG fire, but only if extinction is complete in the short application period, which is difficult to achieve. He continues: 'An LNG fire extinguishing system should be considered essentially as a fringe benefit which will be nice if it works but which a plant had better be able to do without.'

The limitation of the effects of LNG fires is described by Wesson *et al.* (1973a) as follows:

> Water has long been considered the prime – if not the only – agent suitable for controlling LNG fires. Water curtains and direct contact water sprays protect exposed structures until fire intensity is tolerable. However, for major LNG spills or tank fires the rate of water application required is unrealistic (30,000–50,000 gpm) if several proximate exposures require simultaneous protection from the high radiant heat fluxes, which can reach 10,000 BTU/h ft^2.

The control of LNG fires by agents such as foam or dry chemicals has thus contined to appear attractive.

Work at Lake Cahrles, Louisiana, in a 1961 on the extinction of LNG fires has been reported by Burgess and Zabetakis (1962 BM RI 6099). Tests were done using dry chemicals. The surface area of the burning liquid pools was 400 ft^2. Extinction was achieved using sodium and potassium bicarbonates at application rates of 0.14 lb/ft^2 s. In one test extinction was achieved in 3 s at this rate of application.

More recently an extensive series of tests on the extinction of large LNG fires conducted by the University Engineers has been sponsored by the American Gas Association (AGA) and has been reported by Wesson and co-workers. The control of LNG fires using foam is described by Wesson, Welker and Brown (1972) and Wesson *et al.* (1973a). Twelve tests were conducted, of which eleven were concerned with vaporization behaviour. The surface areas of the burning pools were in the range 400–1200 ft^2. The fire conditions were steady state with an evaporation rate of approximately 0.5 in./min from the spillage surface. It was found that high expansion foam was effective in bringing the fire under control and thus reducing heat radiation, although in the majority of cases the fire was not actually extinguished, and that a foam with an expansion ratio of 500 : 1 was the most suitable. The foam quickly froze in open cellular form at the foam–LNG interface, and was light enough to float on the LNG, but had sufficient structural strength to support several feet of additional foam without collapsing. A fire control time was defined as the time for the heat flux sensors to reach a new, reduced reading after initial application of the foam and while the foam was still being applied. Using a high quality foam with a 500 : 1 expansion ration, a fire control time of 120 s was achieved with a foam application rate of 8 cfm/ft^2. Reduction in heat radiation up to 97% were measured at a distance of about one fire diameter from the fire edge.

Wesson *et al.* (1973) also report work on the extinction of LNG fires using dry chemicals. The fire sizes were in the range 200–1200 ft^2. The dry chemical application rates and extinction times obtained for a 1200 ft^2 fire are given in Table 16.88. The work described applies to steady-state LNG fires with an evaporation rate of not more than 0.5 in./min. Immediately after a spillage the vaporization of LNG is very rapid. Even 1 min after the initial spillage and ignition, the evaporation rate could be 1 in/min on average dry soil, which is twice the long-term burning rate due only to heat transfer by flame radiation to the liquid surface.

The effectiveness of the firefighting agents depends on the fire conditions, including the weather, the ground and the process plant. The foregoing account should be regarded, therefore, only as a guide. Further details are given in the original paper.

16.35.4 Storage tank fires

The occurrence of storage tank fires was discussed in Section 16.11 and the pool fire characteristics of such fire Section 16.17. A fire in a storage tank which has lost its roof may be dealt with in two ways. One is to try to extinguish it; the other is to let it burn itself out. Such a fire is normally extinguished by the use of water or foam. The blanketing action of the latter is particularly effective against fires in open storage tanks.

There is a risk, however, that the addition of water or foam may cause a slopover of oil–water mixture. This can occur if there is a deep layer of hot oil at the burning liquid surface. Such a layer tends to develop in a crude oil but not in a refined one. The depth of the layer is greater after the fire has been burning some time. The hazard to slopover may be detected by such methods as the addition of small

Table 16.88 *Application rates for extinction of LNG fires by dry powders (after Wesson et al., 1973b)*

	Threshold rate		*Optimum rate*	
	Application rate (lb/ft^2 s)	*Extinction time* (s)	*Application rate* (lb/ft^2 s)	*Extinction time* (s)
Sodium bicarbonate (SB)	0.012	18	0.0192	9.0
Potassium bicarbonate (PB)	0.007	30	0.0125	8.2
Urea–potassium bicarbonate (U–PBP)	0.00275	25	0.00417	10.9

amounts of water to one edge of the tank or the use of a strip of water to one edge of the tank or the use of a strip of heat sensitive paint down the side of the tank. Methods of reducing the hazard include mixing the hot oil in the tank with cold oil, by pumping the liquid out and in again, or by using only small quantities of water or foam until frothing subsides. Alternatively, the fire may simple be allowed to burn itself out. Often it is possible to pump out most of the liquid in the tank to another receiver so that the scale and duration of the fire are much reduced.

As described in Section 16.17, in a storage tank fire a heat wave moves down through the liquid. The fire is sustained by a zone of liquid at the top which is at a higher temperature than the rest of the contents. This fact can be exploited to control a tank fire by agitating the liquid with air. The method is described by P.F. Johnson (1986).

Other fires at storage tanks include a fire or a liquid spillage at the base of the tank. In this case it is generally appropriate to attempt to extinguish the liquid fire or to run the burning liquid off while cooling the tank to prevent its overheating.

In general, the fighting of storage tank fires involved not only extinction of the fire itself but also protection of other exposed tanks. Suitable water application rates are given in Section 16.27.

Storage tank fires are discussed by Risinger (1964b, f).

16.35.5 Fog nozzles

There is a wide variety of nozzles which can be fitted to fire hoses. Accounts of such nozzles are given by Purington (1986) and Rosenhahn (1986).

In certain situations the requirement is not so much to project water onto the fire as to permit the firefighters to advance towards the fire. This might be the case, for example, where an attempt is to be made to shut a valve. In such cases use may be made of a fog nozzle, which is more fit for this purpose than a regular hose nozzle.

16.35.6 Water curtains

A technique which finds application in certain situations involving a leak or fire of a flammable material is the use of a water curtain. One application of a water curtain is to disperse a leak of flammable vapour, before it can ignite. This has been described by Beresford (1981) and is considered in Chapter 15. Although not strictly a firefighting measure, the deployment of a such water curtain is likely to be the responsibility of the works fire service and to be made in a fire situation.

Another use of water curtains is to attenuate the thermal radiation from a fire. Accounts are given by Stephenson and Coward (1987), Maini and Stephenson (1989) and Coppalle, Nedelka and Bauer (1993). The first two sets of authors describe a project to explore the use of water curtains to protect the crew of a tanker as they make their way to lifeboats during a shipboard fire. The design basis fires and heat fluxes are described by Stephenson and Coward and the modelling of and full scale experimental work on the water curtain is described by Maini and Stephenson.

The issues to be determined were the stability of the curtain and its capability to attenuate thermal radiation. The aim was to design a curtain some 5 m high which would remain stable in a 6 m/s wind. The modelling showed that heat attenuation is effected by a curtain of small droplets, which thus has a large total surface area, falling at low velocity. Work on curtain stability showed that to obtain a stable curtain it was better to use narrow angle nozzles rather than wide angle nozzles. With the former the droplets leave with a high initial velocity and then decelerate so that the velocity becomes such lower. There was relatively little difficulty in obtaining stability in the initial zone of 2–3 m, but below this the curtain can become unstable. It was found that in order to achieve a stable curtain it was necessary to obtain a sufficient momentum flow, where

$$\text{Momentum flow} = \text{Mass flow} \times \text{Exit velocity}$$

and that for the nozzles used a minimum value of the momentum flow was some 60 Ns/s. Given a momentum flow in excess of this value, narrow angle nozzles provided a stable curtain.

Work on attenuation of thermal radiation was performed using fires with surface emissive powers of the order of 50 kW/m^2. It should that in order to obtain adequate attenuation in the upper zone it was necessary to deploy, in addition, wide angle nozzles. One arrangement which gave good performance was narrow angle nazzles spaced at 1 m intervals with two wide angle nozzles in each interval. With this arrangement attenuation was effected in the upper zone by the small slow droplets from the wide angle nozzles and in the lower zone by the small, slowed droplets from the narrow angle nozzles. The fractional attenuations obtained ranged from 30% to 70%, being an approximately linear function of the optical thickness. Models were developed for the behaviour of the water curtain with respect to both stability and attenuation; the results for the latter show close agreement with the experimental values.

Commenting on this work, the authors state that the essential requirement for such a water curtain is the combination of high momentum flow with small droplet size. The design which they favour is one with narrow and wide angle nozzles. They refer to the need for a water supply at a pressure of at least 5 barg. They indicate that the curtain should be stable in winds up to 6 m/s but not in very high winds.

16.35.7 Hazards to fire fighters

Firefighting is always a hazardous task, but this is particularly so on a process plant. Some of the hazards encountered are:

(1) heat and flames;
(2) falling structures and brands;
(3) flashback;
(4) explosion;
(5) toxic fumes;
(6) asphyxiating fumes;
(7) refrigerated liquids;
(8) chemical hazards;
(9) hazards due to firefighting activities
    (a) spread of burning liquids,
    (b) slopover due to foam,
    (c) fumes from vaporizing liquids,
    (d) discharge of dry chemicals.

Many process plant fires involve liquids. These are difficult to extinguish and tend re-ignite, particularly if there are areas of hot metal. There is a danger, therefore, that flashback of the fire may occur.

Fires often cause explosions in vessels, particularly those containing liquids. It is standard practice to cool vessels with water to lessen the chance of their rupturing or exploding, but nevertheless explosions do occur. Process plants also contain many other objects which may explode.

Large quantities of toxic fumes are frequently involved in fires. They may come not only from process materials but also from lagging and from firefighting agents. In particular, hydrogen chloride and other acid gases are often produced.

Some materials produce more insidious fumes. For example, the fumes of toluene diisocyanate not only cause euphoria and lead firemen to undertake rash actions but also attack the nervous system and can lead to permanent disability. Outright asphyxiation due to lack of oxygen is another hazard in such fires.

Some liquid spillages involve refrigerated liquefied gases. Contact with these can cause freezing of and injury to parts of the body.

Fire causes loss of containment of other chemicals, such as corrosive substances, which constitute further hazards to personnel.

Some of the hazards arise from the firefighting activities. The use of water may cause burning hydrocarbon liquids to spread, particularly into drains. The addition of foam to a tank where the fire has formed a hot zone can cause slopover. The fumes from vaporizing liquids tend to be highly toxic. The high velocity discharge of dry chemicals can cause injury.

Although local authority firemen should be generally familiar with the hazards of process plants in their area though training and exercises, it is important for them to be fully informed of the particular hazards presented by a fire which they are called on to fight.

16.35.8 Planning and training

It is essential to plan for emergencies and fires and to train personnel in emergency procedures and firefighting. A detailed account of emergency planning is given in Chapter 24. This includes devising scenarios of accidents and conducting full-scale emergency and firefighting exercises.

The *Fire Training Manual* of the Petroleum Industry Training Board (PITB) (1975/6) givers guidance on training for firefighting related specifically to process plant fires.

16.36 Fire and Fire Protection in Buildings

The most serious fires, with respect both to loss of life and to damage, are those which occur in buildings. Although fire in buildings does not have the same relative significance for process plant, it is still important, because there are many plants which need to be housed in buildings and there are on virtually all sites a range of other buildings from laboratories, workshops and offices, to stores and warehouses.

Accounts of fire and fire protection in buildings are given in *Fire Safety in Buildings. Principles and Practice* (Langdon-Thomas, 1972), *Handbook of Industrial Loss Prevention* (FMEC, 1967), *Fire protection Handbook* (NFPA, 1991/28) and *Background Notes on Fire and its control* (FPA, 1971/14). Further information is available in the publications of the FPA and NEPA, some of which are given in Appendix 28.

The problem of fire in buildings falls under three main headings: (1) hazard to life, (2) hazard of damage to the building and (3) hazard of exposure of nearby buildings. Fire protection of buildings, as of plants, is based on a combination of passive measurers such as structural design, and active ones, such as firefighting systems.

16.36.1 Fire load

The maximum size of fire which can develop in a building depends on the amount of material available for combustion.

The severity of a fire in a building is a function of the material available for combustion. In a classic study, described below, Ingberg (1928) put forward the concept of 'fire load' as the determinant of the severity of a fire.

The fire load is the total heat which can be generated by the combustible material within the building. It is the product of the mass of material and its heat of combustion, or calorific value. The fire load density is the heat per unit area of floor which can be generated. Alternatively, the fire load density may be expressed as the equivalent mass of wood per unit area of floor. A discussion of fire load is given by Langdon-Thomas (1972).

Fire load density has been classified as follow (this table assumes a calorific value of 8000 BTU/lb for wood):

	Fire load density		*Typical occupations*
	(lb/ft^2)	(BTU/ft^2)	
Low	12.5	$<1 \times 10^5$	Dwellings, offices
Medium	12.5–25	$1\text{–}2 \times 10^5$	Factories
High	25–50	$2\text{–}4 \times 10^5$	Warehouses

Langdon–Thomas comments that it is preferable to estimate the fire load density for the particular building under study. Generalized estimates are available but appear to vary widely.

The calorific values of some common materials, as given by the FPA (1971/14), are shown in Table 16.89. Further data are given in the Association National pour la Protection centre l'Incendie (1972).

16.36.2 The time–temperature curve

It has been shown that under standard conditions there is a close relationship between the time for which a building fire burns and the temperature which it attains. This was first demonstrated in 1928 by Ingberg (1928), who carried out a series of test burns in an experimental building at the National Bureau of Standards (NBS). Similar work has been done by other investigators and has led to the development of a number of standard time–temperature curves.

Table 16.89 *Calorific value of some common materials (Fire Protection Association, 1971/14)*

	(kJ/kg)
Paper	15,600–18,100
Cotton	16,750
Woods	17,500–21,000
Coals	20,000–30,000
Wool	20,700
Rubber	≈40,000
Petroleum products	43,000–48,000

A standard time–temperature curve which has been widely used is that of ASTM E-119 which has changed relatively little over the years. There is also a British Standard curve, given formerly in BS 476: Part 8: 1972 and now in Part 20: 1987.

The BS 476: Part 20: 1987 curve is defined by the following equation:

$$T = 345 \log_{10}(8t + 1) + 20 \quad t < 360 \qquad [16.36.1]$$

where t is the time (min) and T is the temperature (°C) The ASTM E-119 curve is defined as a set of time–temperature values. These are given below together with values of the BS 476: Part 20: 1987 curve calculated from Equation 16.36.1:

Time (min)	*Temperature* (°C)	
	ASTM E-119	*BS 476: Part 20: 1987*
5	538	576
10	704	678
30	843	842
60	927	945
120	1010	1049
240	1093	1153
360	–	1214
>480	1260	

The ASTM and BS time–temperature curves are shown in Figure 16.128.

A fire at 900°C appears cherry red, one at 1100°C orange, and one above 1400°C white. Building fires generally look orange or yellow, which suggests a temperature in the range 1100–1200°C. This has been confirmed in practice.

The area under the time–temperature curve corresponds effectively to the fire load density. The greater the fire load density, the longer the duration of the fire and the higher its temperature.

The standard time–temperature curves are widely used for the testing of structural components for fire grading. The component is put in a furnace and the temperature of the furnace is controlled to follow the curve. There is, however, a view that a test based on heat flux might be more satisfactory.

16.36.3 Fire severity

The fire load was used by Ingberg (1928) to define the severity of a potential fire. The time–temperature profile of a real fire exhibits a rapid rise to a maximum value, followed by a gentler decline. The fuel consumed is related to the area under the curve. The profile thus differs from that of a standard time–temperature curve.

The proposition put forward by Ingberg is that two fires should be regarded as of equal severity if the area under the time–temperature curve, above a certain datum temperature, is equal, a concept which has become known as the 'equal area hypothesis'.

The relationship given by Ingberg between fire load and fire severity may be expressed as:

Combustible content (kg/m^2 of wood equivalent)	*Thermal equivalent* (GJ/m^2)	*Standard fire duration* (h)
49	0.90	1
73	1.34	1.5
98	1.80	2
146	2.69	3
195	3.59	4.5
244	4.49	6
293	5.39	7.5

Here the thermal equivalent is based on the floor area and on a heat of combustion of wood of 18.4 MJ/kg.

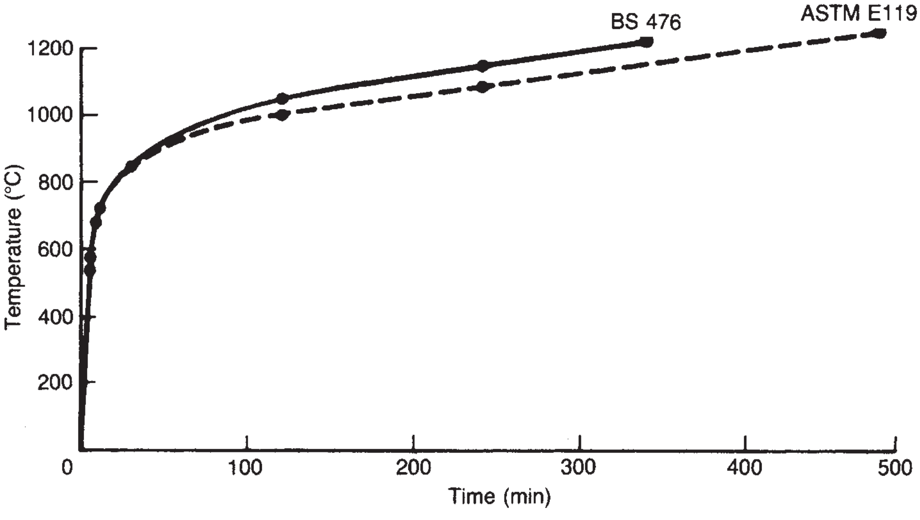

Figure 16.128 *Standard time–temperature curves for building fires. ASTM E119: 1988; BS 476: Part 20: 1987*

16.36.4 Fire grading of buildings

A scheme for the fire grading of buildings in the United Kingdom which is based essentially on the concepts of fire load and the time–temperature curve was proposed in *Fire Grading of Buildings*, Part I, *General Principles and Structural Precautions* (Ministry of Works, 1946). An outline of this system is given in Table 16.90. Buildings of Types 1 and 2 have steel frames with concrete protection, brick walls and reinforced concrete or equivalent resistance floors. In Types 4 and 5 the buildings have load-bearing brick walls, timber floors and roofs, and fire-retardant roof covering; ordinary houses are of this type. A Type 6 building is made of incombustible material, such as corrugated iron or asbestos cement. A Type 7 building is one of combustible material such as wood. Although the system was never adopted as such, it illustrates some general principles of fire grading.

A different approach to fire grading is that developed by law (1971), who investigated the relation between fire severity and fire resistance. In this work a real fire was modelled as having a temperature equal to its peak temperature maintained for a period equal to the ratio $M_{\mathrm{f}}/\dot{m}$, where $\dot{m}$ is the rate of mass loss and M_{f} is the total mass of combustible material. Fire resistance of insulated columns was investigated using unsteady-state heat transfer models to determine the time to failure. The following relation was obtained:

$$t_{\mathrm{f}} = k_{\mathrm{f}} \frac{M_{\mathrm{f}}}{(A_{\mathrm{W}} A_{\mathrm{T}})^{1/2}} \qquad [16.36.2]$$

where A_{T} is the total area of the internal surface, excluding ventilation openings (m^2), A_{W} is the area of the ventilation openings (doors, windows) (m^2), M_{f} is the total combustible load (kg of wood equivalent), t_{f} is the effective fire resistance time, or fire grading (min), and k_{f} is a constant. With the units quoted, the value of the constant k_{f} is approximately unity.

Table 16.90 *Minimum fire resistance requirement for types of construction (after Ministry of Works, 1946)*

Grading of construction		*Minimum fire resistance*[a] (h)
Type 1	Incombustible fire resisting construction Fully protected in relation to high fire loads, e.g. warehouses	4
Type 2	Incombustible fire resisting construction Fully protected in relation to moderate fire loads, e.g. shops and factories	2
Type 3	Incombustible fire resisting construction Fully protected in relation to low fire loads, e.g. offices and residential buildings	1
Type 4	Fire resisting construction but not necessarily incombustible and may therefore include timber floors and timber roof construction. Partially protected only in relation to all fire loads	½
Type 5	Externally protected construction Fire resisting incombustible external walls, non-fire resisting internal construction	–
Type 6	Non-fire-resisting construction Incombustible	–
Type 7	Non-fire-resisting construction Combustible	–

[a] This refers to floors and roofs and to columns and beams supporting them. Walls and columns and beams supporting them have a minimum fire resistance equal to or greater than this.

16.36.5 Fire growth in buildings

Ignition is important not only in the initiation of fire but also for its spread. After the fire has started, its growth depends on the ease with which further combustible material is ignited.

Solid materials do not have a well-defined ignition temperature, but they tend to ignite at relatively low temperatures. The ignition temperature for wood, for example, is generally taken as about 200°C. But if wood is left in contact with a hot surface such as a steam pipe for a long period, it can undergo chemical changes so that it ignites at a much lower temperature. The maximum temperature at which wood can be safely exposed for a long period has been given as 65°C (FPA 1971/14).

Once ignition has occurred, the immediate growth of the fire is affected by the form of the nearby materials. Here the surface area of the materials is important:

	Surface area (cm^2/g)
Tinder	>20
Kindling	2–20
Bulk fuel	<2

The fire then grows by heat transfer and flame spread.

All three heat transfer modes (convection, conduction and radiation) contribute to fire growth. Convection within the space where the fire has started is important initially; so is conduction along burning objects. As the fire grows, convection to the ceilings and conduction through the wall become significant. When the fire is well developed and temperatures are high, the contribution of radiation becomes important.

Fire spread can be considered as occurring in three ways: (1) flame spread across combustible surfaces, (2) fire spread through a continuous fuel bed and (3) fire spread through a discontinuous fuel bed.

Flame spread across a combustible surface differs somewhat according to whether it is vertical or horizontal. Spread is more rapid in the vertical direction, because the surface is preheated by convection. However, in both cases flames can spread very quickly.

Fire spread through a continuous fuel bed requires little explanation except that this description includes spread between any types of object which can act as a fuel, including whole buildings. The fuel bed is effectively continuous if the flames pass right through it.

With a discontinuous bed, by contrast, it is necessary for the fire to spread by one of the modes of heat transfer and to cause ignition by heating other objects to their ignition temperature without the aid of direct flame contact.

16.36.6 Flashover

If a fire takes hold in a compartment, a point is reached when the fire is no longer localized, but spreads throughout the whole space. There is sudden propagation of flame through the unburned gas below the ceiling and all the combustible surfaces become involved in the fire. This condition is known as 'flashover'.

In this situation the rate limiting feature frequently is no longer the fuel but the air supply. If the air supply is suddenly increased, as by the cracking of windows, the opening of a door or other means, there will be a sudden increase in the rate of burning.

With flashover, the fire is fully developed. Flashover is discussed further in Section 16.36.10.

16.36.7 Fire spread through buildings

The spread of fire through a building depends on a number of factors. Staircases, lift shafts and open corridors encourage the rapid spread of flames. Features such as gaps in walls where pipes pass through or doors left open allow flames to bypass enclosing elements which are intended to be a barrier to fire. Fire spread is also strongly influenced by the surfaces in the building. Some surfaces support a very rapid passage of flame.

16.36.8 Fire spread from buildings

Fire spread from a building across an open space is generally almost entirely by radiation, although there may sometimes be a contribution from convection and there may also be flying brands. Usually the object is heated by radiation to a temperature at which it is ignited by a small brand or spark. This is known as pilot ignition. Such pilot ignition of dry unpainted wood in the open can be obtained if the heat flux onto it is about 12.6 kW/m^2. A lower value is sufficient to ignite the wood in a closed room.

A method of calculating the heat radiation from the windows of a burning building has been developed by Law (1963 FRS Fire Res. Tech. Pap. 5) and has been used in conjunction with fire resistance data to determine suitable separation distances between buildings. The method is described in the original paper and in an explanatory memorandum to the Building Regulations 1965.

The amount of heat radiated from a building is a function of the area radiating heat and of the heat flux per unit area. The assumption that there is fire at all windows is a conservative one, particularly for larger buildings. The additional radiation from flames outside the windows is not generally significant.

The upper limit of the intensity of heat radiation from a fire in a room of a building can generally be taken as 168 kW/m^2, but a lower value applies for lower fire load densities (Langdon-Thomas, 1972).

The spread of fire between buildings depends on the distance between them, the sizes and angles of the radiating surfaces, the contents of the buildings and the construction of the buildings. The contents of the burning building determine the temperature reached and the extent to which flying brands are produced, and the materials of walls and roofs of the two buildings determine the extent to which the burning building radiates heat and produces brands and the extent to which the exposed building is vulnerable to them.

16.36.9 Effects of fire in buildings

Fire in a building presents three hazards to life: (1) toxic gas, (2) smoke and (3) heat.

People may be overcome or may be burned. Most people who die in fires do so in the early stages of the outbreak, not infrequently before the alarm has been raised. Usually they are killed by toxic gases which arrive before the fire itself reaches that part of the building. Others are overcome by toxic gas or become trapped and then die in the fire itself.

Toxic gases produced by building fires are principally the normal products of combustion, that is, carbon monoxide and carbon dioxide. The amount of carbon monoxide produced is increased if the air supply to the fire is limited. Carbon monoxide has almost the same density as air and so spreads easily through the building. It is odourless, and so is not readily detected. At a concentration of 1.3% it causes unconsciousness after a few breaths.

Carbon dioxide is also toxic, but in building fires acts mainly as an asphyxiant. A concentration of about 9% is generally enough to cause unconsciousness within a few minutes.

Other more toxic gases may be produced by the combustion of materials such as plastics and rubber. These include hydrogen chloride, sulfur dioxide, hydrogen cyanide and phosgene.

Smoke has the effect of reducing visibility and hindering both escape and rescue. The quantity of smoke generated is greater if the air supply is restricted and the burning material is wet.

It is often the case that smoke rising up a staircase causes people trying to escape to turn back, even though the route is actually passable. It is a prime function of fire doors, therefore, to prevent the spread of smoke. It is desirable that people in the building understand these points.

The damage done to the building by fire is due partly to the fire itself and partly to smoke and water. Some estimates of fire damage attribute more than half to water damage.

16.36.10 Modelling of building fires

Some progress has been made in the modelling of fires in buildings. Accounts of the modelling of building fires are given by Drysdale (1985), Babrauskas (1986c), Budnick and Evans (1986), Budnick and Walton (1986) and Law (1991).

Most modelling has been directed to the characterization of the fire in a compartment. There are also some models of other aspects such as fire spread along corridors.

A compartment fire may (1) burn out, (2) self-extinguish due to lack of air or (3) progress to flashover.

'Flashover' has been used with a number of meanings, as reviewed by P.H. Thomas (1982). There are three in common use: (1) transition from a localized fire to a conflagration involving all the fuel surfaces in the enclosure; (2) transition from fuel to ventilation controlled burning and (3) sudden propagation of flame through the unburnt volatiles collected under the ceiling.

The modelling of a compartment fire proceeds broadly along the following lines. The fire load in and ventilation conditions of the compartment are determined. In the preflashover stage, the fire is modelled first under 'free burn' conditions. As the fire grows, a transition may occur from the regime of free burning to one of ventilation controlled burning. Prior to flashover, the features of interest include (1) the fire regime, (2) the rates of mass loss and heat release, (3) the upper gas temperature and (4) the radiant heat flux.

Determination of these variables permits an estimate to be made of the possibility that flashover will occur. There are a number of criteria for flashover, which utilize (1) the upper gas temperature, (2) the radiant heat flux and (3) the heat release rate. These variables are, of course, related. The various equations involve time in some way, and hence provide a means of estimating the time to flashover, assuming that it does occur.

For the post-flashover stage, the features of interest are (1) the rates of mass loss and heat release and (2) the compartment temperature. Principal purposes of the modelling of compartment fires include determining whether flashover will occur, the time to flashover and the temperature profile after flashover.

Programmes of experimental work which have provided data for workers in the field include the Home Fire Project (Croce, 1975) and the project of the Conseil Internationale du Batiment (CIB) (Heselden and Melinek, 1975 FRS Fire Res. Note 1029).

16.36.11 Models of pre-flashover compartment fire

In the pre-flashover stage, the mass loss rate is at first relatively low. The fire regime is one of fuel controlled burning. As the fire grows, the quantity of air required increases markedly, and the regime becomes one of ventilation controlled burning.

The mass loss rate in the initial, free burning stage necessarily depends on the particular scenario, but the work of P.H. Thomas, Simms and Wraight (1964, 1965) on the modelling of crib fires provides one approach.

An equation for the mass loss rate under conditions of ventilation controlled burning has been given by Kawagoe (1958):

$$\dot{m} = k_{\mathrm{v}} A_{\mathrm{W}} H^{1/2} \qquad [16.36.3]$$

where A_{W} is the area of the ventilation opening (m^2), H is its height (m), $\dot{m}$ is the mass burning rate (kg/s) and k_{v} is a constant (kg/m$^{3/2}$ s). The term $A_{\mathrm{W}}H^{1/2}$ is referred to as the 'ventilation factor'. The value given for k is 0.09, which is often rounded to 0.1. In another widely used form of the equation, $\dot{m}$ is expressed in kg/min and k_{v} has the value 6.

The heat release rate is

$$\dot{q} = \dot{m}\Delta H_{\mathrm{c}} \qquad [16.36.4]$$

where ΔH_{c} is the heat of combustion (kJ/kg) and $\dot{q}$ is the heat release rate (kW).

A number of equations have been given for the estimation of the upper gas temperature in pre-flashover conditions. One is that by Quintiere (1983), quoted by Babrauskas (1986c). The temperature is a function of, among other things, the heat release rate, the ventilation conditions and time.

Another model, described by Drysdale (1985), has been given by McCaffrey, Quintiere and Harkleroad (1981).

P.H. Thomas (1974) and Ove Arup (1977) have developed a model, quoted by Budnick and Evans (1986) and Law (1991), which allows for limitation by fire load. It is

$$T_{\mathrm{u}} = T_{\mathrm{o}} + \frac{6000}{\eta^{1/2}}[1 - \exp(-0.1\eta)][1 - \exp(-0.5\tau)] \qquad [16.36.5]$$

with

$$\eta = \frac{A_{\mathrm{T}}}{A_{\mathrm{W}}H^{1/2}} \qquad [16.36.6]$$

$$\tau = \frac{L}{(A_{\mathrm{W}}A_{\mathrm{T}})^{1/2}} \qquad [16.36.7]$$

where L is the mass of fuel (kg), η is a ventilation term ($m^{-1/2}$) and τ a fire load term (kg/m^2).

The radiant heat flux from the fire to the compartment boundaries is typically obtained by determining the radiative power of the flame and estimating the thermal radiation intensity as that at the surface of a hemisphere.

There are a number of criteria for flashover in a compartment fire. One takes the form of a limiting value of the upper gas temperature. Hagglund, Jansson and Onnermark (1974) and Fang (1975) obtained in their work a value of 600°C. Other workers such as Lawson and Quintiere (1985) use 500°C. Another criterion is the radiant heat flux to the floor of the compartment. Work by Waterman (1968) indicates a critical value of 20 kW/m^2. Also relevant is that in his work flashover did not occur below a mass loss rate of 40 g/s.

Since the upper gas temperature is related to the heat release rate, the flashover criterion can also be expressed in terms of a limiting heat release. One such relation, based on a flashover temperature of 600°C and enclosures with materials having a density similar to that of gypsum board, is

$$\dot{q}_{\mathrm{fo}} = 378 A_{\mathrm{W}}H^{1/2} + 7.8 A_{\mathrm{T}} \qquad [16.36.8]$$

where $\dot{q}_{\mathrm{fo}}$ is the heat release rate at flashover (kW). Another such equation is that by Lawson and Quintiere (1985).

16.36.12 Models of post-flashover compartment fire

Flashover results in a rapid rise in temperature, possibly up to 1100°C.

There are a number of models of the post-flashover compartment fire. It is usually assumed that the atmosphere in the compartment is perfectly mixed. The models differ in two main ways. One is in the terms which are included in the heat balance. The other is in the estimation of the individual terms, and particularly the rates of mass loss and hence heat release.

Models for this stage include those by Kawagoe and Sekine (1963), Pettersson, Magnussson and Thor (1976), Babrauskas and Williamson (1978) and Babrauskas (1981). Expositions of these models have been given by Drysdale (1985) and Babrauskas (1986c).

The general nature of the models is illustrated in the account given by the latter author, who describes his own model (Babrauskas, 1981) for the post-flashover upper gas temperature in a compartment fire:

$$T_{\mathrm{u}} = T_{\mathrm{o}} + (T^{*} - T_{\mathrm{o}})\theta_1\theta_2\theta_3\theta_4\theta_5 \qquad [16.36.9]$$

where T_{o} is the ambient temperature (K), T_{u} is the upper gas temperature (K), T^{*} is an empirical constant, and θ_1, θ_2, θ_3, θ_4 and θ_5 are factors which allow respectively for (1) the burning rate stoichiometry, (2) the steady-state heat loss through the wall, (3) the transient heat loss through the wall, (4) the effect of the height of the opening and (5) the combustion efficiency.

A determining factor in such models is the expression used for the mass loss rate. As described above, there are two distinct regimes. At low ventilation rates the mass loss rate is ventilation controlled, whilst at high ventilation rates it is fuel controlled.

Under ventilation controlled conditions, the expression commonly used for the mass loss rate is that by Kawagoe, given above as Equation 16.36.3. The range of validity of this equation, however, is restricted. Its limitations are discussed by Drysdale. Work by Bullen (1978) points to a family of curves of the same general form as Equation 16.36.3, but with different values of the constant and hence with different slopes. In other words the group $(\dot{m}/A_W H^{1/2})$ is not a constant. Rather it is a function of factors such as the heat of gasification of the volatiles and the heat flux to the burning surface.

If the ventilation is increased, there comes a point at which the regime becomes fuel controlled. However, fuel control is appreciably more complex. The predominant factor is the geometry of the fuel, and above all its surface area. For this regime, therefore, there is no single criterion for transition and no single expression for the mass loss rate.

There exist methods, such as that by Harmathy (1972), for the determination of the transition from ventilation to fuel control. The application of this criterion is discussed by Drysdale, who shows that there is appreciable scatter.

In view of the variety of mass loss rates within the fuel control regime, the most widely applicable approach would appear to be to estimate the values of the mass loss rate using a correlation for each of the two regimes and to identify the transition point in this way. There is no generally applicable relation for the estimation of the mass loss rate $\dot{m}$. Bullen and Thomas (1979) have obtained a correlation which includes some of the important variables. It may be expressed as

$$\dot{m} \approx IA_f/L_v \qquad [16.36.10]$$

where A_f is the surface area of the fuel (m^2), I is the thermal radiation intensity (kW/m^2) and L_v is the heat of gasification of the volatiles (kJ/kg).

Babrauskas (1986c) treats this aspect by utilizing for both regimes expressions for the burning rate stoichiometry factor θ_1 which are a function of the ratio ϕ of the actual mass loss rate to that at stoichiometric air flow. Separate expressions are used for the fuel-rich and fuel-lean regimes, in other words for ventilation control and for fuel control.

Treatments of a fully developed compartment fire frequently use Equation 16.36.3, which is applicable to the ventilation controlled regime.

16.36.13 Models of flame projection

Flame projected from an opening may cause fire to spread to the storey above. It may impinge on an object outside and is in any event a source of radiant heat.

Flame projection has been correlated by P.H. Thomas and Law (1972) who obtained the equation

$$z + H = 12.8(\dot{m}/B)^{2/3} \qquad [16.36.11]$$

where

$$x/H = 0.454/n^{0.53} \qquad [16.36.12]$$

$$n = 2B/H \qquad [16.36.13]$$

where B is the width of the window (m), H is its height (m), n is a shape factor, x is the horizontal reach of the flame (m) and z is the height of the flame up above the soffit, or top, of the window (m). Thus $(z + H)$ is the height of the flame above the base of the window.

16.36.14 Models of fire spread

The spread of fire from a compartment into other parts of a building has received less attention. Quintiere (1979) has reviewed work on this aspect.

Tests in which fires were lit in buildings due for demolition indicate that the volume of the fire tends to grow exponentially.

A particular aspect which has been studied is fire spread from a room into a corridor. Work on this has been described by Quintiere, McCaffrey and Kashiwagi (1978).

Another route for the spread of flames is through an opening and up to the next storey. Work on this indicates that such spread is influenced by the shape factor ($2B/H$), where B is the width of the opening and H is the height. For narrow windows and thus small values of this group, flame spread may occur with only a relatively small projection, whereas for wide windows a greater projection is required.

16.36.15 Models of detector response

A quite different type of fire model is that used to, investigate the response of temperature measuring devices used for fire detection. An account of such models is given by Budnick and Evans (1986).

16.36.16 Models of smoke

The agent responsible for the majority of deaths in building fires is smoke. The treatment of the production and movement of smoke in such fires is therefore a significant aspect.

Smoke is produced by smouldering fires and by flaming combustion, but the types of smoke are very different. Smouldering tends to produce an oily smoke and flaming produces solid particles. Smoke generally contains unburned carbon and toxic gases. The carbon particles in smoke are the result of incomplete combustion, as is carbon monoxide. Other gases, such as hydrogen chloride or phosgene, may also be present, depending on the materials burned. Features of smoke which relevant here are that it reduces visibility and that it is toxic.

Characterization of the yield and composition of smoke is difficult due to the wide variety of materials that become involved and the range of conditions that are prevalent in fires. From the practical viewpoint, the significant feature is the rate of production of smoke, which is governed by the burning rate. The use of a suitable model for the smoke production rate permits the determination of the rate of smoke extraction required to prevent the layer of the hot smoke under the ceiling exceeding a certain depth.

One method of estimating of the rate of smoke production is to infer it from the rate of air entrainment. P.H. Thomas *et al.* (1963) have described a model based on this approach. Another model on these lines is that by Butcher and Parnell (1979).

The movement of smoke is governed by buoyancy and air movement effects. The fire itself generates hot gases and creates buoyancy effects, whilst the smoke itself has a temperature in excess of that of the atmosphere, creating a stack effect. Natural and forced ventilation are responsible for the air movement.

16.36.17 Computer models

A number of computer codes have been developed incorporating models of fires in buildings. An account is given by Budnick and Walton (1986). These computer models are of two main types: (1) enclosure fire models and (2) special purpose models.

Enclosure fire models include not only deterministic models but also probabilistic ones. A large proportion of the former are zone models in which the enclosure is divided into control volumes, or zones, and the conditions in each zone are simulated. Typically the enclosure might be divided into a lower and an upper zone. Probabilistic models deal with the transitions between different stages in the development of a fire, often using techniques such as Markov models.

There are also a number of special purpose models which address topics such as detector actuation, smoke control, structural response and evacuation.

Tabulations of the codes available are given by Budnick and Walton.

16.36.18 Fire protection by structure

The objectives of fire protection by means of the structural design of buildings are to (1) limit fire spread between buildings, (2) limit fire spread within buildings, (3) facilitate escape, (4) facilitate firefighting and (5) limit water damage.

The Building Regulations 1976, particularly Part E, contain requirements which deal *inter alia* with: restriction of the spread of flame; provision of compartment walls and floors; fire resistance of elements of the structure, floors and doors; fire protection of penetrations, cavities and shafts; and means of escape. These requirements cover both materials and construction. Other requirements are designed to limit fire spread between buildings and deal with distances between other buildings and boundaries and with the construction and combustibility of external walls and roofs.

These regulations were revoked by the Building Regulations 1985, which are much less detailed (31 pages as opposed to 295), though they retain in Schedule 1 certain minimum requirements. The provisions of the earlier regulations retain value as an indication of good practice.

The material and component properties which are important are indicated by the tests specified in BS 476: 1970– *Fire Tests on Building Materials and Structures*. These include:

Part 3: 1975	*External Fire Exposure Roof Test*
Part 4: 1970	*Non-combustibility Test for Materials*
Part 5: 1979	*Method of Test for Ignitability*
Part 6: 1989	*Method of Test for Fire Propagation for Products*
Part 7: 1987	*Method of Classification of the Surface Spread of Flame of Products*
Part 8: 1972	*Test Methods and Criteria for the Fire Resistance of Elements of Building Construction* (obsolescent, replaced by Parts 20–23)
Part 13: 1987	*Method of Measuring the Ignitability of Products Subjected to Thermal Irradiance*
Part 20: 1987	*Method for Determination of the Fire Resistance of Elements of Construction (General Principles)*
Part 21: 1987	*Methods for Determination of the Fire Resistance of Load-bearing Elements of Construction*
Part 24: 1987	*Method for Determination of the Fire Resistance of Ventilation Ducts*
Part 32: *1987*	*Guide to Full Scale Fire Tests within Buildings*

BS 476: Part 8: 1972 is obsolescent, being replaced by BS 476: Parts 20–23: 1987, which cover, respectively, (1) general principles, (2) load-bearing elements, (3) non-loading bearing elements and (4) certain special components.

The constructional features which are relevant to fire protection include:

(1) compartmental construction;
(2) fire resistance;
(3) limitation of openings;
(4) partitions and linings;
(5) roofs;
(6) vents;
(7) escape routes.

Compartments are spaces in buildings which are enclosed by fire-resistant walls and floors, and have all openings protected by fire-resistant construction. The object of compartmentation is to confine a fire to the compartment where it originates and to control the movement of flames, smoke and heat.

The maximum size of compartment is usually set by consideration of hazard to life and of ease of firefighting. The size should be kept to a minimum consistent with the basic purpose of the building.

The fire resistance of the floors and walls should be capable of containing the most severe and prolonged fire which is likely to occur. The nature of such a fire depends on the likely contents of the compartment.

The openings between compartments should be minimal. In some explosives factories openings are virtually eliminated. But, in general, openings are acceptable, provided appropriate precautions are taken. All openings should be protected with fire-resisting doors or shutters. All vertical shafts such as staircases, lifts and hoists should have fire-resistant walls and fire-protected openings. All unnecessary openings should be closed, including those around services and pipework.

Linings for walls and ceilings should be of non-combustible material or should have low flame spread characteristics.

Roofs should be constructed so that fire does not spread either internally beneath the roof or externally over it. Flame spread beneath the roof is reduced by the use of incombustible or low flame spread materials and partitioning, and that above the roof is reduced by the use of incombustible materials and partition walls.

Vents should be provided for the release of hot gases and smoke. These control the spread of fire and smoke and assist firefighting. The design of vents depends on the type of building.

The Building Regulations 1976, Regulation E5, specify minimum periods of fire resistance which are a function of the type and size of building and the part of the building. The required minimum periods do not exceed 2 h, except for basements in large buildings and forlarge storage buildings.

16.36.19 Fire protection by sprinklers

As already mentioned in Section 16.26, the installation of fixed water sprinkler systems has proved very effective and is wholeheartedly supported by the insurance companies. Sprinkler systems for buildings are usually automatic, with a detection system which actuates the sprinklers and sounds the fire alarm.

Detection is usually based on heat or smoke. Heat sensitive detectors are dealt with in BS 5445: Part 5: 1977.

Sprinkler heads are usually arranged to cover an area not exceeding 12 m^2 per head. The amount of water required depends on the risk protected. For storage, for example, water requirements in the range 0.041–0.514 l/m^2 s have been determined, the latter being for high stacked, closely packed materials in which water penetrates with difficulty (O'Dogherty, Nash and Young, 1966).

In a large proportion of cases where a sprinkler installation has not been effective in protecting a building, this has been due to the fact that it was disabled in some way. Often the main system valve was closed. It is necessary, therefore, to have specific procedures to prevent this.

16.36.20 Smoke control

Smoke control may be applied to a space where smoke from a fire may occur and also to escape routes. Methods of smoke control include removal by venting and exclusion by maintaining a positive pressure.

The design of a smoke venting system has been treated by P.H. Thomas *et al.* (1963), P.M. Thomas and Hinckley (1964) and Butcher and Parnell (1979). Relevant factors are the height of the space, the size of the design fire, the type of roof and the pressure at the roof. A positive pressure on the roof will reduce and may negate the effectiveness of a vent. The spread of smoke under the roof may be limited by installing smoke curtains hanging down from it.

The use of smoke vents has certain drawbacks. One danger is that venting may hinder the operation of smoke detectors. Another problem is that venting of the smoke at a high level requires a compensating introduction of air at a low level, which may exacerbate the fire. Each case needs to be considered on it merits.

An escape route may be protected from smoke by the use of closed doors, by applying positive pressure and/or by venting the smoke from the space where it is being produced. Where reliance is placed on closed doors, it must be ensured by means of suitable measures, including training, that they remain closed in fire conditions. Where positive pressurization is used, air locks may be required to ensure that an adequate pressure is maintained.

16.36.21 Other fire precautions

Other fire precautions which should be taken in buildings include the following:

(1) fire alarm system;
(2) escape routes;
(3) firefighting equipment;
(4) fire notices;
(5) fire drills.

The building should be provided with a fire alarm system which can be heard in all parts of the building and which is tested regularly. There should be clearly marked escape routes from all parts of the building. Firefighting equipment such as portable fire extinguishers and hoses should be provided, as appropriate. The fire extinguishers used should be suitable for the types of fire which are likely to occur. Notices on the procedures to be followed should be prominently posted. Fire drills should be practised regularly.

16.37 Fire Protection in Transport

The account so far has dealt with the fire protection of fixed installations. It is also necessary to give brief consideration to fire protection, and firefighting, in transport. The consideration here is confined to road, rail and marine transport.

In large part, the fire hazard in road, rail and marine transport is addressed by measures to prevent accidents and to ensure appropriate design and maintenance.

The principles of fighting fires arising from transport accidents are, in general, no different from those for buildings, but two aspects are of particular importance. These are the wide variety of chemicals which are carried and the relative lack of familiarity of the local authority fire services with these chemicals.

A considerable effort has been made, therefore, to furnish information to the fire services in advance about the hazards of chemicals which they may encounter. *Dangerous Substances. Guidance on Dealing with Fires and Spillages* (Home Office, 1972/4) and *Hazardous Loads* (IFE, 1972) provide some information on this aspect.

Transport aspects are discussed in more detail in Chapter 23.

16.37.1 Road transport

Accounts of fire protection and firefighting in road transport are given in *Transportation Fire Hazards* (NFPA, 1973/10), *Hazardous Materials Response Handbook* (NFPA, 1992/30) and by Stillman (1971) and Ward (1978). Fire protection in road transport is treated in the NFPA *Handbook* by McGinley (1986).

Relevant codes for road transport are NFPA 385: 1990 *Tank Vehicles for Flammable and Combustible Liquids*, NFPA 1901: 1985 *Automotive Fire Apparatus*, NFPA 512: 1990 *Truck Fire Protection* and NFPA 513: 1990 *Motor Freight Terminals*, and, for explosive materials NFPA 495: 1992 *Explosive Materials Code* and NFPA 498: 1992 *Explosives Motor Vehicles Terminals*.

Firefighting in road transport needs to be seen as one aspect of the wider topic of handling the emergency. With regard to firefighting proper, principal points are prompt action in using portable extinguishers, alerting of the fire services, alerting of the public and discouragement of spectators. The firefighting agents used should be compatible with the materials constituting the load.

Where a road tanker contains LPG, a notable hazard of a fire is that of a BLEVE.

16.37.2 Rail transport

An account of fire protection and firefighting in rail transport is given in *Manual of Firemanship*, Book 5, *Incidents Involving Aircraft, Shipping and Railways* (Home Office, 1985). Fire protection in rail transport is treated in the NFPA *Handbook* by Fitch (1986).

Fire arrangements for rail transport are not well served with national codes, the matter tending to be left to the carrier. As with road tankers, a fire on an LPG rail tank car involves the hazard of BLEVE. The risk of such an event is much increased if there are a number of such tank cars, perhaps with a flame from the pressure relief valve of one playing on another.

16.37.3 Marine transport

Accounts of fire protection and firefighting in marine transport are given in *Fire Aboard* (Rushbrook, 1979), *Manual of Firemanship*, Book 5 (Home Office, 1985), already referred to, and by Tanner (1976), Wynne (1986) and McKenna (1989). Fire protection in marine transport is treated in the NFPA *Handbook* by Keller, Kerlin and Loeser (1986).

Fire control is an important feature of the fighting capability of a warship. An account is given by Dimmer (1986).

A relevant code is NFPA 306: 1993 *Control of Gas Hazards on Vessels*. Other codes and standards, notably the IMO codes, are detailed in Chapter 23.

The much larger storages of flammable materials in marine transport provide more scope for, and necessitate, fire protection arrangements more similar to those used in fixed installations.

Fire protection measures include the use of inerting and operational procedures to counter static electricity.

The fire protection arrangements on chemical tankers and gas carriers and the application of water sprinkler, mechanical foam, vaporizing liquid and carbon dioxide systems are discussed by Keller, Kerlin and Loeser (1986).

Another aspect of fire protection in marine transport is that relating to jetties. Accounts are given by Dicker and Ramsey (1983) and Gebhardt (1989).

Ship fire protection is considered in more detail in Chapter 23.

16.38 Fire Hazard

The types of fire typical of the process industries are those described above. The hazard of a large industrial fire may be assessed by consideration of the historical record of such fires and their effects and/or of assumed scenarios using appropriate frequency estimates and hazard and effects models.

The process industries also suffer the more common types of fire such as fires in warehouses and in buildings. Both types of fire may cause extensive damage and the latter may give rise to a high death toll.

16.38.1 Historical experience

Fire constitutes the largest proportion of major accidents involving property damage which have occurred in the process industries. However, most accidents involving large loss of life involve explosions. Frequently large fires are associated with explosions, either causing the fire or resulting from it.

A classification of fires in the process industries has been given in Section 16.1. The main headings are (1) vapour cloud fires, (2) fireballs, (3) jet flames, (4) liquid fires, (5) solids fires, (6) warehouse fires and (7) fires associated with oxygen. These various types of fire are now considered, except for jet flames and solid fires.

In Section 16.1 vapour cloud fires are classified as: Type 1, fire with no explosion; Type 2, fire resulting from explosion; and Type 3, fire resulting in explosion.

Taking these three types of fire in turn, it is not easy to identify major fires without explosion, partly because such a fire does usually result in some explosions, notably BLEVEs, and partly because even if no explosion has occurred, this is generally not stated in the account given. Major fires on large sites therefore tend to involve explosions. Major fires on cross-country pipelines which do not involve explosions are relatively more frequent for the simple reason that targets vulnerable to a BLEVE are generally absent.

Thus a Type 1 fire occurred on an NGL pipeline at Austin, Texas, in 1973 (Case History A62), The fire engulfed and killed people in the vapour rich zone formed before ignition occurred and then burned back to the pipeline; there were six deaths.

With respect to Type 2 vapour cloud fires, such fires often occur following the explosive rupture of a vessel and release of its contents. One such fire was that at the campsite at San Carlos, Spain in 1978, described in Appendix 16, which resulted from the rupture of a passing road tanker and caused some 216 deaths.

It is common for the aftermath of a large vapour cloud explosion to involve extensive fires, particularly in the storage area of the site. Cases in point are those at refinery at Lake Charles, Louisiana, in 1967 (Case History A40) and at the chemical works at Flixborough, UK, in 1974, described in Appendix 2, which burned for 2 weeks and 1 week, respectively. The fires on Piper Alpha following the gas explosion in C Module were Type 2 fires.

An explosion characteristic of Type 2 vapour cloud fires is the BLEVE. Outstanding examples are the vapour cloud fire at Port Newark, New Jersey, 1951, in which more than 70 horizontal bullet tanks on site were destroyed (Case History A19), and that at Mexico City, Mexico, 1984, described in Appendix 4, in which the entire storage area was destroyed, with some 15 explosions being recorded over a $1\frac{1}{2}$ h period.

Turning to fireballs, these are generally associated with the BLEVE of a vessel containing liquefied gas, but a type of fireball occurs also on oil storage tanks. A large proportion of fireballs recorded have been on transport: pipelines, road tankers and, above all, rail tank cars.

Fireballs at fixed installations include those occurring during the BLEVEs at Feyzin, France, 1966 (Case History A38), West St Paul, Minnesota, 1974, and Mexico City, Mexico, 1984, described in Appendix 4.

Fireballs on rail tank cars occurred in the BLEVEs of: propane at Crescent City, Illinois, 1970 (Case History A50); VCM at Houston, Texas, 1971 (Case History A53); propane at Kingman, Arizona, 1973 (Case History A63); and LPG at Belt, Montana, 1976. A fireball on a road tanker is exemplified by the propane fireball at Lynchburg, Virginia, 1972 (Case History A59). The radii of these fireballs have been estimated at 75–100, 150, 150, 150 and 60 m, respectively. An even larger fireball occurred on an LPG pipeline at Donnellson, Iowa, 1978, with an estimated radius of 305 m (Case History A91).

A type of liquid pool fire which figures prominently among the large losses is the tank fire. A prominent example is the fire on a 66 ft high × 256 ft diameter oil storage tank which occurred in the refinery at Milford as: Haven, UK, 1983 (Case History A106).

A major running liquid fire involving oil froth occurred at the refinery at Signal Hill, California, 1958 (Case History A26). The oil froth eventually covered some 27 acres, causing extensive damage and the loss of two lives. In 1970, in the refinery at Beaumont, Texas, lightning struck a 40 ft high × 60 ft diameter oil tank, causing a massive release of oil which spread to create a fire involving 16 nearby undiked tanks (Case History A46).

There have also been major running liquid fires involving LNG and LPG. The fire at Cleveland, Ohio, 1944, followed the rupture of an LNG storage tank which discharged its entire contents over the plant and the nearby urban area (Case History A12). The LNG ignited and a major fire ensued. Some of the LNG flowed as liquid down storm sewers where it mixed with air, with consequent explosions. The death toll was 128.

The release of a massive wave of liquid propane at the gas plant at Umm Said, Qatar, 1977, was, at least he primarily, a liquid fire (Case History A88).

Warehouse fires constitute another category. These a can involve large loss, though the death toll is usually not great.

Examples are two warehouse fires in Britain, at Renfrew in 1977 (Case History A85) and at Salford in he 1982, both of which involved explosions of stored sodium at chlorate.

An example of a fire associated with an oxygen release is that at Brooklyn, New York, 1970, when the vessel of for a road tanker ruptured violently, releasing liquid oxygen (Case History A48). A number of fires broke out as the oxygen came into contact combustible materials, and two people were killed.

There are also fires that occur during construction, maintenance and decommissioning operations. The Staten Island fire in 1973, in which 40 died, occurred in an empty LNG storage tank on which men were working (Case History A67). The tank was insulated with he polyurethane foam with an aluminium–polyester lining. It was this insulation which was the main seat of the fire.

The historical record indicates that large death tolls from process fires are relatively infrequent compared with those from explosions. However, it should be emphasized that, overall, process fires are responsible for a large proportion of fatalities and damage in the process industries.

16.38.2 Hazard assessment

Hazard assessment of fire on process plant generally involves: the development of a set of scenarios for fire, principally by release and ignition, and of the associated event trees; an estimation of the frequency/probability of the initial events and of the events in the branches in the event trees from a mixture of historical data and synthesis of values; and modelling of the outcome events in the event tree, including both physical events all and damage/injury.

A hazard assessment involves, in principle, the formulation of a set of scenarios and a full assessment of the frequency and consequences of the events. An assessment which is confined either to the estimation of the frequency of the events or to the modelling of the consequences is a partial one. Hazard assessments may be generic or may relate to specific hazardous situations.

Overviews of generic process plant fire scenarios have been given for LPG by Rasbash (1979/80) and for LNG by Napier and Roopchand (1986). Essentially, the principal scenarios involve various modes of release of vapour and liquid, including rupture of pressure vessels and storage tanks and releases from pipework, hoses, pumps, and so on.

A large proportion of such releases will give rise to a vapour cloud. The assessment of this cloud involves: the modelling of cloud formation and of mixing with air during the initial release; any liquid flashing and evaporation; the dispersion of the cloud and the mass of fuel within the flammable limits; the ignition of the cloud; and the development of any overpressure. If the event gives no overpressure, it is a vapour cloud, or flash fire.

A jet, or torch, fire and an engulfing fire tend to be of interest primarily as events which may cause a vessel to suffer a BLEVE. Likewise, a fireball on a vessel are generally considered as part of the BLEVE event. Separate treatment is given to a flame on, or fireball from, a pipeline.

Some principal types of model used for the hazard assessment of fires on process plants are those for (1) vapour cloud fires, (2) fireballs, (3) jet flames, (4) pool fires (5) engulfing fires and (6) pipeline fires. Accounts of some of the models available have been given above.

An early, essentially representative, hazard assessment of fire is that given in the vulnerability model by Eisenberg, Lynch and Breeding (1975), who studied among other things the area affected by a flammable vapour cloud and the lethality of flash fires from such a cloud. The events of principal interest which they consider are marine spillages of 20,750, 83 and 0.8 t of LNG on water with drifting of the vapour cloud towards populated areas. For gas dispersion they use a modification of the Pasquill–Gifford model. For ignition of the cloud they assume that an ignition source is located at the centre of each population cell and that ignition occurs if a flammable mixture reaches such an ignition source. The type of ignition source is specified for each cell by the user, the two types giving fire or explosion, respectively. For thermal injury they utilize their own probit equation, as described in Section 16.22. The populations at risk are defined in terms of the cell model already described. Some results obtained are as tabulated below:

LNG spillage (t)	*Wind direction towards* (°)	*Ignition*		*Fatalities*	
		Time of travel (min)	*Distance travelled* (km)	*Explosion*	*Flash fire*
20,750	50	4.2	1.01	984	
20,750	53	4.2	1.01	1238	534
83	50	5.6	1.35	921	617
83	53	No ignition			

Both explosions and flash fires are considered. The results are sensitive to the location of the population cells relative to the wind direction, so that for the cases considered the flash fire casualties for the 83 ton release were actually greater than those for the 20,750 ton one. For the 83 ton release with flash fire the effective thermal radiation intensity and time duration were 124 kW/m^2 and 0.08 min, respectively, and 58% of the people in the cell affected were killed.

The First *Canvey Report* (HSE, 1978b) included assessments of: the hazard at the specific installations at Canvey from oil spillage over the bund at storages; a vapour cloud fire from the British Gas LNG storage; and vapour cloud fires from several LPG storages. These assessments were refined in the second report (HSE, 1981a). An account of this work is given in Appendix 7.

The *Rijnmond Report* (Rijnmond Public Authority, 1982) gives hazard assessments for storages at Rijnmond of acrylonitrile, propylene and LNG. It considers vapour cloud fires, fireballs, jet flames and pool fires. An account of this work is given in Appendix 8.

The hazard assessments of BLEVEs by Drysdale and, David (1979/80), Blything and Reeves (1988 SRD R488) and Selway (1988 SRD R492) include extensive treatment of fire events which could cause a BLEVE.

A general account of hazard assessment for warehouses is described by G.T. Atkinson, Jagger and Kirk 1992).

16.39 Hazard Range of Fire

The hazard range of a fire depends on the type of fire concerned. Fires other than a vapour cloud, or flash fire occur at a fixed point, and therefore the range of the fire is essentially determined by radiant heat transfer. The intensity of thermal radiation from a fire decays according to the inverse square law. For a flash fire, it is also necessary to take into account the movement of the cloud, which is likely then to be the dominant factor.

A set of relations for the hazard range of fire from LPG has been given by Considine and Grint (1985). Their treatment is based on combining models for various types of fire or flame with injury relations. The injury relations used are those of Hymes (1983 SRD R275). These give the 1% and 50% lethality levels as a function of thermal toad. The relations cover flash fires, fireballs, pool fires and jet flames.

16.39.1 Vapour cloud fires

The relations given by Considine and Grint for the hazard range of a flash fire are based on their relations for dense gas dispersion, which are given in Chapter 15. These are used to determine the distance to the lower flammability limit (LFL) and the flammable mass in the cloud.

The authors derive their results for a flash fire from a flash fire code in which the flame is assumed to travel radially away from the ignition source. The thermal load at a given location is then evaluated numerically. They present the results for a quasi-instantaneous release as the plots shown in Figure 16.129. Two pairs of graphs are given, one pair, those shown in Figure 16.129(a,b), for a cloud with concentrations between the upper flammability limit (UFL) and the LFL and another pair, shown in Figure 16.129(c,d) for a cloud with concentrations above the UFL. Figure 16.129(a,b) give the hazard ranges for 1% and 50% lethality for the first type of cloud and Figure 16.129(c) and give the corresponding hazard ranges for the second type. Both types of cloud will burn: the first has the potential to give a vapour cloud explosion, whilst the second will burn by diffusion.

For a quasi-continuous release, the authors state that the envelopes for 1% and 50% lethality do not cover an area significantly different from that covered by the flammable plume and suggest that engulfment in the burning plume be taken as the basis for evaluating fatality.

16.39.2 Fireballs

For fireballs, Considine and Grint use the model of A.F. Roberts (1981/82) described in Section 16.15. The lethality relations are then

$$\left.\begin{aligned} r_{50} &= 22t^{0.379}M^{0.307} \\ r_1 &= 30t^{0.366}M^{0.306} \end{aligned}\right\} \begin{aligned} &10 < M < 3000; && [16.39.1] \\ &10 < t < 300;\ t < t_d && [16.39.2] \end{aligned}$$

with

$$t_d = 4.5M^{0.33} \qquad [16.39.3]$$

where M is the mass of LPG (te), r is the distance to a given lethality (m), t is the exposure time (s), t_d is the duration time (s) and subscripts 1 and 50 denote 1% and 50% lethality, respectively. The distances r are measured from the centre of the release. The maximum exposure time is limited to the duration time of the fireball.

The CCPS *QRA Guidelines* (1989/5) give the hazard distance for a fireball as

$$r_{50} = 38.9M_T^{0.432} \qquad [16.39.4]$$

where M_T is the mass of fuel (ton) and r is the distance to 50% lethality (m).

Another set of hazard distances are those given for a propane fireball by Prugh (1994), as described in Section 16.22:

$$r_{50} = 38M_T^{0.46} \qquad [16.39.5]$$

where M_T is the mass of fuel (ton) and r is the distance to 50% lethality (m). He draws attention to the similarity between his model and that of the CCPS.

Prugh also gives the following relations for lethal distance

$$r_{01} = 5.0W_T^{0.46} \qquad [16.39.6]$$

$$r_{50} = 3.6W_T^{0.46} \qquad [16.39.7]$$

$$r_{99} = 2.5W_T^{0.46} \qquad [16.39.8]$$

where r is the distance to the given lethality (ft) and it W_T is the mass of fuel (lb), and for second degree burns

$$r_{50} = 5.3W_T^{0.46} \qquad [16.39.9]$$

and first degree burns

$$r_{50} = 3.6W_T^{0.46} \qquad [16.39.10]$$

where now r is the distance to the given degree of injury (ft).

16.39.3 Pool fires

For pool fires, the model used by Considine and Grint is that by Considine (1984 SRD R297) described in Section 16.17. The treatment does not take into account flame tilt or trailing, and therefore is limited to conditions with little or no wind. Hazard range relations are given for the case of an unhanded quasi-instantaneous spill with immediate ignition and with a spreading, burning pool. The relations are

$$r_{50} = 16.1M^{0.38} \qquad [16.39.11]$$

$$r_1 = 21.7M^{0.38} \qquad [16.39.12]$$

The distances r are measured from the centre of the pool. The exposure time is assumed to be equal to the total burning time, and therefore does not appear explicitly in the correlations.

16.39.4 Jet flames

For jet flames of LPG, the model used by considine and Grint is

$$L = 9.1\dot{m}^{0.5} \qquad [16.39.13]$$

$$W = 0.25L \qquad [16.39.14]$$

Where L is the length of the flame (m). $\dot{m}$ is the mass release flow (kg/s) and W is the half-width of the flame at the flame tip (m).

Two sets of hazard range relations are given, one for persons end on and one for those side on to the flame. The end on relations are

$$\left.\begin{aligned} r_{50} &= 16t^{0.4}\dot{m}^{0.47} \\ r_1 &= 2.8t^{0.38}\dot{m}^{0.47} \end{aligned}\right\} \begin{aligned} &1 < \dot{m} < 3000; && [16.39.15] \\ &10 < t < 300 && [16.39.16] \end{aligned}$$

where r is the distance from the edge of the flame for a given

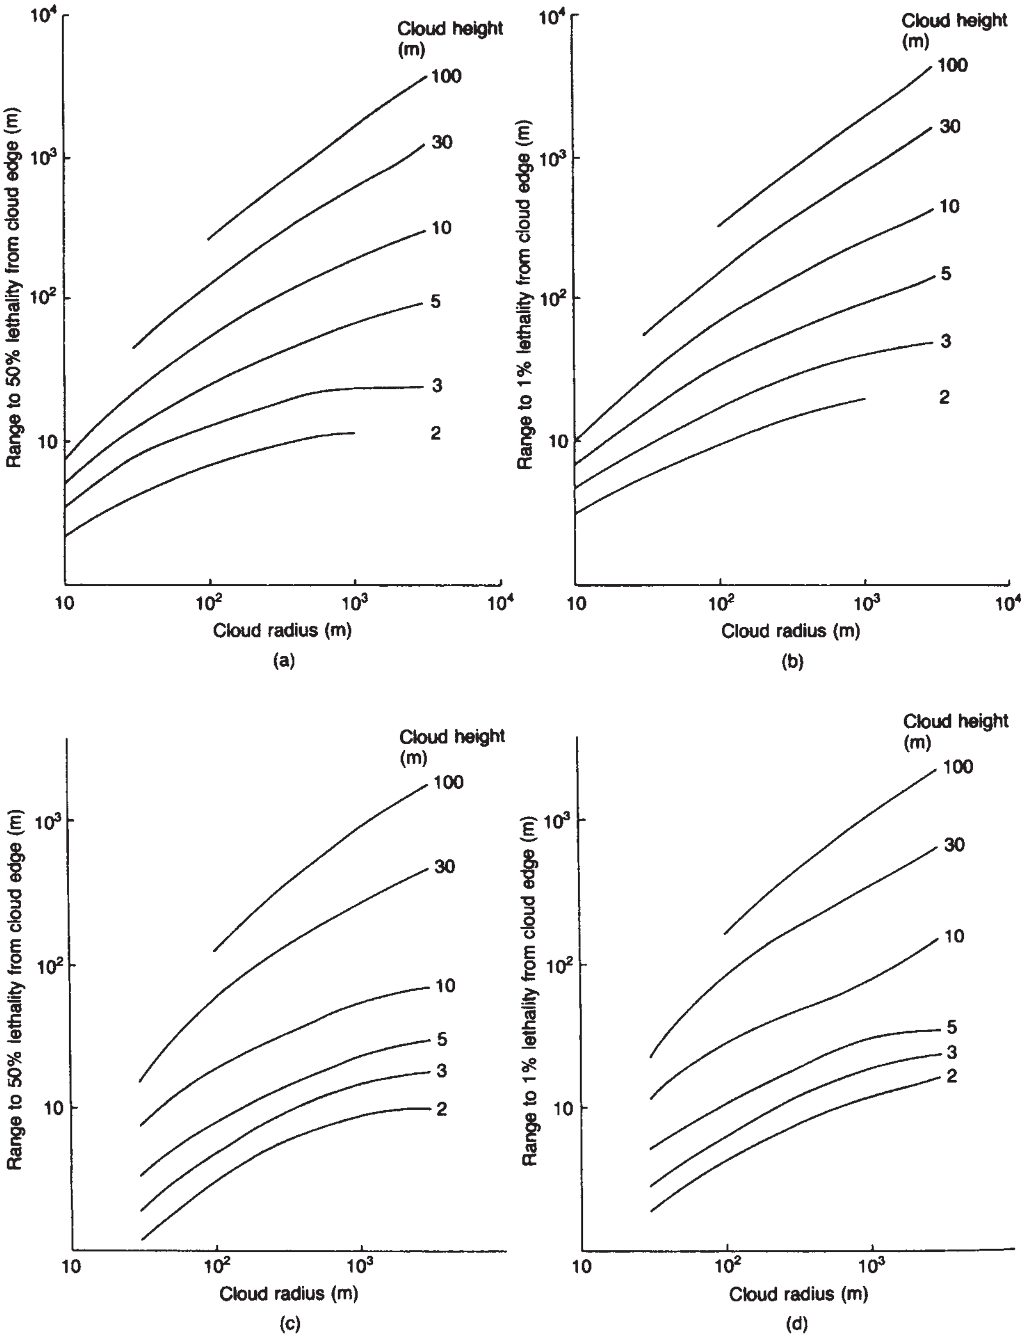

Figure 16.129 *Hazard ranges of flash fires (Considine and Grint, 1985): (a) vapour clouds with concentrations above the upper flammability limit, 50% lethality; (b) vapour clouds with concentrations above the upper flammability limits, 1% lethality; (c) vapour clouds with concentrations between the upper and lower flammability limits, 50% lethality; and (d) vapour clouds with concentrations between the upper and lower flammability limits, 1% lethality (Courtesy of Gastech)*

lethality (m). The side on relations are
